[57] ABSTRACT

In a chem-mech polishing process for planarizing insulators such as silicon oxide and silicon nitride, a pool of slurry is utilized at a temperature between 85° F.-95° F. The slurry particulates (e.g. silica) have a hardness commensurate to the hardness of the insulator to be polished. Under these conditions, wafers can be polished at a high degree of uniformity more economically (by increasing pad lifetime), without introducing areas of locally incomplete polishing.

## WAFER FLOOD POLISHING

### BACKGROUND OF THE INVENTION

#### 1. Technical Field

The invention relates to a method of planarizing workpieces utilizing an abrasive slurry in conjunction with a polishing pad.

#### 2. Background Art

In the art of forming metallic interconnection layers on processed semiconductor substrates, it is known that various processing difficulties are presented if the primary passivation layer has an irregular topography. Such difficulties include unacceptable variations in metal layer thickness, which result in the possibility of undesired metal opens/shorts.

At first, this problem was dealt with by using a passivation material (such as phosphosilicate glass (PSG) or boro-phosphosilicate glass (BPSG)) that could be melted (or reflowed) to smooth out the upper surface. While this solution was perfectly acceptable for the device densities of the day, recent advances in integration have forced workers in the art to consider other alternatives. One such alternative is the so-called "planarizing etch-back" procedure, in which a layer of conventional photosensitive polymer (or "photoresist") is spin-applied on top of the passivation layer. The photoresist presents a planar upper surface. Then using an etch technique that is non-selective between the photoresist and the passivation layer, the layers are simultaneously etched such that the planar upper surface of the photoresist is transferred to the underlying passivation layer. Such etch processes include sputter etches and reactive ion etches (RIE) in  $CF_4$ - $O_2$  plasmas. For example, see U.S. Pat. No. 4,710,264 (issued 12/1/87 to Waschler et al and assigned to Telefonken GmbH). This alternative has not been widely accepted in the art because it is very difficult to accurately determine etch endpoint.

Another alternative presently under consideration is the so-called "chem-mech polish" (CMP) process. In this process, passivated substrates are rotated against a polishing pad in the presence of an abrasive slurry. Typically the slurry is pH-controlled such that the etch rate of the passivation layer can be controlled. In U.S. Patent Application Ser. No. 791,860, entitled "Chem-Mech Polishing Method for Producing Co-Planar Metal/Insulator Films On a Substrate," filed Oct. 28, 1985, by Beyer et al and assigned to the assignee of the present invention, different slurry chemistries are used to optimize insulator-to-metal (or visa-versa) etch rate ratios to achieve a planar surface. For example, using an abrasive pad at a pressure of 2-8 PSI, and a slurry of 0.06 micron alumina particles in deionized water, a 1:1 etch rate ratio of metal:insulator was achieved. The metal etch rate increased (and the oxide etch rate decreased) as different acids are used to lower the pH to 2.2. Alternatively, by increasing the pH to 11-11.5, the insulator removal rate increased relative to metal when using silica particulates at a concentration of 1-10 weight. In U.S. Patent Application Ser. No. 085,836 entitled "Via Filling and Planarizing Technique," filed Aug. 17, 1987, by Cote et al and assigned to the assignee of the present invention, an alumina/deionized water/hydrogen peroxide slurry was used utilizing a pressure of 10-12 PSI to provide a planarized tungsten-BPSG surface, such that filled vias and a planarized passivation layer were simultaneously formed. See also U.S. Pat.

No. 4,702,792 (issued 10/27/87 to Chow et al and assigned to IBM), in which a polymer film is chem-mech polished to define an image pattern.

In the above chem-mech polishing art, the amount of slurry is kept to a minimum. Typically, the slurry is applied by a dropper suspended above the center of the polish wheel. As the wheel spins, the slurry is spread over the polish pad. Examples of low slurry content polishing are shown in U.S. Pat. No. 3,841,031, entitled "Process for Polishing Thin Elements"; U.S. Pat. No. 3,342,652, entitled "Chemical Polishing of A Semiconductor Substrate"; U.S. Pat. No. 4,256,535, entitled "Method of Polishing a Semiconductor Wafer"; U.S. Pat. No. 4,373,991, entitled "Method and Apparatus for Polishing A Semiconductor Wafer"; and an article entitled "Spinning Etchant Polishes Flat, Fast" Electronics, Jan. 13, 1982, pp. 40-41.

Use of low slurry content polishing leads to several difficulties. One difficulty is shortened polish pad "lifetime." Pad lifetime relates to the total number of wafers that can be polished by a given pad. As the pad wears out, both the removal rate of the polished material and the uniformity of removal across the wafer substantially degrade. Pad lifetime is determined by the hardness of the pad, the polish conditions, and the break-in/conditioning procedures. Typically, in order to provide sufficient wetting of a polishing pad used in conjunction with a small amount of slurry, the pad must undergo a destructive break-in procedure (e.g., high-pressure scraping using a blade), as well as periodic conditioning (lower pressure scraping). Such procedures substantially reduce pad lifetime, such that the overall process is more expensive due to the frequency of pad replacement.

Another difficulty is the lack of removal rate uniformity across a given wafer. Using low slurry content processes, the inventors tried to optimize uniformity by changing the slurry content as well as varying the hardness of the pad. None of these changes appreciably enhanced uniformity.

Yet another difficulty is the occurrence of "bumps." Bumps are areas along the substrate having locally incomplete polishing. Typically they occur over areas that cover steep topologies. For example, when polishing an oxide passivation layer on top of a gate electrode, if the electrode provides a steep "step" (i.e., if it has a height more than approximately 0.5 microns), bumps will tend to form on the portion of the oxide above the edges of the electrode. In low slurry content applications, bumps cannot be eliminated without adversely affecting some other parameter (e.g., rate uniformity, pad life) that needs to be optimized.

Accordingly, there is a need in the art for a planarization process in which both pad lifetime and polish rate uniformity can be maximized while simultaneously minimizing the occurrence of bumps.

### SUMMARY OF THE INVENTION

It is thus an object of the invention to provide a chem-mech planarization process that maximizes both pad lifetime and planarization uniformity.

It is another object of the invention to optimize the above parameters while simultaneously minimizing the occurrence of bumps.

It is yet another object of the invention to provide a chem-mech polishing process wherein the need to selectively introduce different slurries is eliminated.

The above and other objects have been met by arranging a retaining wall about the polishing table, and introducing a pool of slurry that completely immerses the polish pad. Moreover, the slurry temperature is raised above room temperature.

By utilizing a polishing process under the above conditions, polish uniformity is in the range of 97%. At the same time, pad lifetime is appreciably extended (up to 10X) because a less vigorous break-in procedure may now be used. Finally, these enhancements do not come at the expense of increased occurrence of bumps; rather, bumps are eliminated.

#### BRIEF DESCRIPTION OF THE DRAWING

The above and other aspects of the invention will be described in more detail below. In the description to follow, reference will be made to the accompanying Drawing, in which:

FIG. 1 is a top view of the polishing apparatus of the invention; and

FIG. 2 is a cross-sectional view of the polishing apparatus of the invention.

#### DESCRIPTION OF THE BEST MODE FOR CARRYING OUT THE INVENTION

With reference to FIGS. 1 and 2, the invention is carried out on a rotating polish wheel 10 having a circular polishing pad 12 mounted thereon. The polishing wheel 10 rotates in a direction indicated by arrow 14. There are a number of commercial polish wheels upon which the invention can be carried out. The inventors have practiced the invention on a polish tool Model No. 6CU sold by the Strasbaugh Co. of Huntington Beach, CA.

Disposed about the periphery of polish wheel 10 is a retaining wall (or dam) 16. The purpose of the dam 16 is to increase the amount of slurry 30 provided to the polish pad 12, to the point where a slurry "pool" 30 is formed which is sufficient to completely cover the pad 12 even when it is spinning during the polishing process. See Namba et al, "Ultrafine Finishing of Ceramics and Metals by Float Polishing." Laser Induced Damage in Optical Materials" Conference Proceedings 1980, pgs. 171-179. See also U.S. Pat. No. 2,922,264. In the present invention, the dam is two inches high, such that a slurry pool approximately  $\frac{1}{4}$  inch deep is formed covering the polish pad 12.

The wafers 28 to be planarized are held against the spinning polish wheel 10 by a quill assembly 20. The quill assembly includes a moveable support arm 22 for bringing the wafer 28 into contact with the polish pad 12, and a wafer support 24 that spins in a direction indicated by arrow 26. Note that the wafer support 26 is rotated by a belt assembly (not shown) disposed within support arm 22. The support 24 has an elastomeric pad (not shown) disposed within it for receiving the wafer 28. Thus, the wafers 28 are polished by the action of the spinning support 24, the spinning pad 12, and the slurry pool 30 disposed therebetween.

When utilizing large slurry amounts, the inventors have found that both greater uniformity and prolonged pad life results. Specifically, under these conditions polish uniformity across the surface of a wafer can be as high as 97%. At the same time, polish pad lifetime is increased because a less vigorous break-in procedure can be used. Specifically, break-in can now be performed by polishing a number of blank wafers having

an exposed coarse film thereon for a relatively short amount of time (e.g. five minutes). The amount of wafers is a function of polish pad hardness (the harder the pad, the less break-in is needed). For a very hard polish pad (e.g., the IC-40 pad sold by Rodel Corp. of Scottsdale, AZ), no break-in is necessary in this process.

In carrying out experiments utilizing the polish apparatus discussed above, the inventors found that the temperature of the slurry plays a significant role in polish uniformity. Specifically, by raising the slurry temperature from room temperature to 85-95° F., the uniformity of the planarization etch was greatly improved, by up to a factor of two in some experiments. These findings were not anticipated, particularly in polishing layers such as oxides where the process is predominantly mechanical in nature. Moreover, after this phenomena was uncovered, the inventors expected that it would hold (and even increase) as a function of increased temperature. However, the inventors found that at temperatures above approximately 95-100° F., uniformity substantially degrades. The inventors postulate that at these higher temperatures, non-uniformity increases because it is very difficult to maintain constant slurry concentration due to evaporation. In other words, above approximately 100° F., increases in polish uniformity are negated by slurry non-uniformity.

The inventors have found that the percentage of particulates in the slurry, plays a role in the overall process. Specifically, the inventors found that when utilizing a pool of silica slurry, the polishing rate of the substrates increases (and the occurrence of bumps decreases) linearly with increasing solids percentage up to 10%. Above 10%, both polish rate and polish rate uniformity stay essentially constant, and bumps are at a minimum. Experiments indicate that above approximately 15 weight percent solids, polish rate uniformity degrades. When polishing in the presence of a small amount of slurry, both polish rate and polish rate non-uniformity increase with increasing solids percent. In other words, there is no appreciable operating "window" within which both polish rate and polish rate uniformity can be maximized by percent solids.

The size of particulates also plays a role in the overall process. The inventors thought bumps were caused by small non-uniformities in the particulate concentration within the slurry. They tried to eliminate bumps by using a slurry having small (0.006 micron average size) particulates, on the assumption that smaller particulates would enhance the effective particulate concentration. Bumps continue to occur. When the size of the particulates was increased to 0.02 microns, bumps were eliminated. These results were achieved at removal rates between approximately 500 and 1500 angstroms per minute. Above approximately 2000 angstroms per minute, bumps could not be eliminated. Note that this removal rate limit is for blanket layers; in practice, when planarizing passivation layers overlying steep topographies, localized removal rates of up to 6000 angstroms per minute have been achieved without bumps.

Moreover, by utilizing a pool of slurry, large particulates can be used for all polish applications, including those in which slurries having fine particulates are ordinarily used. In the invention, the slurry has been diluted in water to 12% (by weight) SiO<sub>2</sub> particulates (average diameter of 0.02 microns) suspended in water. The slurry is sold under the trade name "Cab-0-Sperse SCI" by Cabot Corp. Normally, a slurry having much smaller

particulates would be used in situations in which only a small amount of material is to be polished away, and/or the underlying surface is particularly sensitive to scratching (e.g., in polishing a thin silicon dioxide layer atop a polish-stop layer formed on a silicon substrate, we wish to avoid dislocations in the silicon crystallography that can result from scratching the silicon surface). The inventors found that by utilizing a pool of slurry at an elevated temperature, the mechanism by which particulate size contributes to scratching is eliminated. Thus, under these conditions scratching becomes a sole function of pad hardness (the harder the pad, the more scratches). In low slurry applications, softer pads could not be used because bumps would occur; this problem could only be alleviated by utilizing the destructive pad break-in/conditioning procedures previously discussed. Here, one can use a softer pad without producing bumps and without utilizing such pad break-in/conditioning procedures. Thus, the same coarse slurry can now be used in conventional fine slurry applications, reducing expense by eliminating the need to change slurries as a function of coarse/fine application.

Further, in utilizing a pool of slurry, the spin speed of both the table 10 and the quill 20 is reduced from 120 RPM to 15-30 RPM. Under these conditions, endpoint detection is facilitated. For example, when polishing oxide on a silicon wafer, it has been observed that silicon is much less susceptible to polishing. This means that when the silicon surface rubs against the polish wheel, it produces a far greater amount of drag than does the oxide. The inventors have taken advantage of this phenomenon to provide an accurate endpoint detection method. When multiple wafers are being polished, a monitor (or dummy) wafer is included. The dummy wafer is a silicon substrate having the same amount of oxide on it as the amount of oxide on the product wafers to be removed by polishing. Once the oxide is removed from the dummy wafer, the exposed silicon surface provides a large amount of drag. This maximum drag can be detected with a quill motor current detector. The motor controller is set to allow the quill to slow down at maximum drag. The controller senses that the motor rotation speed is too low and the motor current increases sharply, producing a current "spike." Thus, process endpoint is signaled by current spikes in the motor that turns the quill.

The above technique is applied to lower quill spin speeds, because at higher speeds the increased drag is less pronounced due to the increased angular momentum of the wafer.

The invention will now be discussed with reference to Example 1 below:

#### EXAMPLE 1

Purpose: To planarize a step height of approximately 8000Å of undoped oxide passivating a processed silicon substrate.

slurry: Cab-0-Sperse SC1, diluted in water to 12 weight percent

quill spin speed: 17 RPM

quill pressure: 9 PSI

polish pad: Rodel Suba 500

polish wheel spin speed: 17 RPM

slurry temperature: 90° F.

number of wafers: 9, plus endpoint detection wafer

Results: After 7 minutes, oxide is completely planarized on the silicon surface, without bumps or scratching.

Thus, in the invention, a pool of slurry is used in which the temperature is raised above room temperature, such that both polish rate uniformity and pad lifetime are maximized without promoting bumps. These advantages of the invention can be realized whenever insulators such as silicon oxide or silicon nitride are to be polished. Moreover, the advantages of the invention are not limited to the best mode embodiment described above; for example, other particulates having hardnesses commensurate with the hardness of the insulator to be polished can be used.

We claim:

1. In a process of chem-mech polishing an insulator layer arranged on a semiconductor wafer, wherein the wafer is brought into contact with a rotating polish wheel having a polishing pad disposed thereon, the improvement comprising:

providing sufficient slurry to form a pool defined by a dam disposed about the outer periphery of the polish wheel, wherein said polishing pad is immersed in said pool during polishing, and wherein said slurry comprises a liquid suspension of solid particulates having a hardness commensurate to the hardness of the insulator layer; and

elevating the temperature of said slurry to at least approximately 85° F.

2. The process as recited in claim 1, wherein said slurry is at a temperature between approximately 85° F.-95° F.

3. The process as recited in claim 1, wherein said solid particulates have an average size of at least 0.02 microns.

4. The process is recited in claim 1, wherein said solid particulates constitute approximately 10%-15% by weight of said slurry.

5. The process as recited in claim 4, wherein said particulates are comprised of SiO<sub>2</sub>.

6. The process as recited in claim 1, wherein said polish wheel rotates at a speed no greater than approximately 30 RPM.

7. The process as recited in claim 6, wherein said polish wheel rotates at a speed between approximately 15 RPM-20 RPM.

8. The process as recited in claim 6, wherein a plurality of semiconductor wafers are simultaneously polished by being brought into contact with the same polish wheel.

9. The process as recited in claim 8, wherein at least one of said wafers is a dummy wafer comprising a silicon substrate with a discrete layer thereon having a thickness commensurate to the amount of material to be removed from the remaining wafers.

10. The process as recited in claim 9, further comprising:

monitoring said dummy wafer during polishing to indicate when the polishing process is completed.

11. In a process of chem-mech polishing an insulator layer arranged on a semiconductor wafer, wherein the wafer is brought into contact with a rotating polish wheel having a polishing pad disposed thereon, the improvement comprising:

providing sufficient slurry to form a pool defined by a dam disposed about the outer periphery of the polish wheel, wherein said polishing pad is immersed in said pool during polishing, and wherein said slurry comprises a suspension of silica particulates having an average size greater than 0.006
