ACTH Stimulation Tests for the Diagnosis of Adrenal Insufficiency: Systematic Review and Meta-Analysis

Naykky Singh Ospina,* Alaa Al Nofal,* Irina Bancos, Asma Javed, Khalid Benkhadra, Ekta Kapoor, Aida N. Lteif, Neena Natt, and M. Hassan Murad

Evidence-Based Practice Research Program (N.S.O., A.A.N., K.B., M.H.M.), Mayo Clinic, Rochester, Minnesota; Knowledge and Evaluation Research Unit (N.S.O., K.B., M.H.M.), Mayo Clinic, Rochester, Minnesota; Division of Endocrinology, Diabetes, Metabolism, and Nutrition (N.S.O., N.N., I.B.), Mayo Clinic, Rochester, Minnesota; Division of Pediatric Endocrinology and Metabolism (A.A.N., A.J., A.N.L.), Mayo Clinic, Rochester, Minnesota; Division of General Internal Medicine (E.K.), Mayo Clinic, Rochester, Minnesota 55905

Context: The diagnosis of adrenal insufficiency is clinically challenging and often requires ACTH stimulation tests.

Objective: To determine the diagnostic accuracy of the high- (250 mcg) and low- (1 mcg) dose ACTH stimulation tests in the diagnosis of adrenal insufficiency.

Methods: We searched six databases through February 2014. Pairs of independent reviewers selected studies and appraised the risk of bias. Diagnostic association measures were pooled across studies using a bivariate model.

Data Synthesis: For secondary adrenal insufficiency, we included 30 studies enrolling 1209 adults and 228 children. High- and low-dose ACTH stimulation tests had similar diagnostic accuracy in adults and children using different peak serum cortisol cutoffs. In general, both tests had low sensitivity and high specificity resulting in reasonable likelihood ratios for a positive test (adults: high dose, 9.1; low dose, 5.9; children: high dose, 43.5; low dose, 7.7), but a fairly suboptimal likelihood ratio for a negative test (adults: high dose, 0.39; low dose, 0.19; children: high dose, 0.65; low dose, 0.34). For primary adrenal insufficiency, we included five studies enrolling 100 patients. Data were only available to estimate the sensitivity of high dose ACTH stimulation test (92%; 95% confidence interval, 81–97%).

Conclusion: Both high- and low-dose ACTH stimulation tests had similar diagnostic accuracy. Both tests are adequate to rule in, but not rule out, secondary adrenal insufficiency. Our confidence in these estimates is low to moderate because of the likely risk of bias, heterogeneity, and imprecision. *(J Clin Endocrinol Metab* 101: 427–434, 2016)

A drenal insufficiency is a life-threatening disorder characterized by failure of adrenal cortisol production either from adrenal disease (primary adrenal insufficiency, PAI) or deficiency of ACTH (secondary adrenal insufficiency, SAI) (1, 2). Prompt diagnosis is important because adequate hormonal replacement therapy is lifesaving (1, 3–5). Even with early diagnosis and institution of therapy, patients with the diagnosis of adrenal insufficiency have higher mortality (6, 7), decreased quality of life (8, 9), and increased risk of adrenal crisis (10, 11).

Adrenal insufficiency may present with nonspecific symptoms (eg, fatigue, weight loss, nausea, loss of appetite), resulting in a potential delay in diagnosis. In a crosssectional study of 216 patients with both primary and

^{*} N.S.O. and A.A.N. contributed equally to this study.

Abbreviations: CI, confidence interval; LR, likelihood ratio; OR, odds ratio; PAI, primary adrenal insufficiency; SAI, secondary adrenal insufficiency.

secondary adrenal insufficiency, 47% had symptoms for more than 1 year before diagnosis and 20% had symptoms for more than 5 years before diagnosis. The correct diagnosis was established during the initial medical encounter in only 15% of patients (12).

Once adrenal insufficiency is suspected, biochemical testing is required to confirm the diagnosis (1). The initial step in evaluation is the measurement of baseline morning serum cortisol and an ACTH stimulation test. The insulin hypoglycemia test (insulin tolerance test) is considered the gold standard for the diagnosis of SAI. This test may not be possible in all situations because it requires medical supervision and can be unsafe in patients with history of seizures, cardiac disease, or the elderly (1, 13). The singledose overnight metyrapone stimulation test is another confirmatory dynamic test that has been used in the past for the diagnosis of adrenal insufficiency. Through its inhibition of $11-\beta$ -hydroxylase, metyrapone results in decreased cortisol levels with subsequent feedback stimulation of ACTH and accumulation of the pre-enzyme block substrate 11-deoxycortisol. This test has a similar diagnostic performance to the insulin hypoglycemia test and is a potential alternative when there is a contraindication to the insulin hypoglycemia test (13, 14).

The insulin-induced hypoglycemia test and the singledose overnight metyrapone tests are expensive, cumbersome, and have potential significant side effects compared to the ACTH stimulation tests. These latter tests assess the serum cortisol response to acute ACTH stimulation with either a 250- μ g dose (high or standard dose) or 1- μ g dose (low dose) (1, 13).

The objective of this systematic review and meta-analysis was to compare the diagnostic accuracy of the highand low-dose ACTH stimulation tests in patients with either primary or secondary adrenal insufficiency.

Materials and Methods

Eligibility criteria

DOCKE.

Inclusion criteria for eligible studies were predefined in a study protocol. We included observational and randomized studies that assessed the diagnostic accuracy of high- and lowdose ACTH stimulation tests for the diagnosis of PAI or SAI when compared to a gold standard. In cases of PAI the gold standard included clinical features, serum cortisol, serum ACTH levels, and follow-up. In SAI, both the insulin tolerance test and metyrapone test were considered gold standards. Exclusion criteria included case series (uncontrolled studies), review studies, and studies that evaluated patients with critical illness; patients with expected secondary adrenal insufficiency because of exogenous steroid use (eg, patients with autoimmune diseases treated with steroids, patients with asthma) or steroid therapy not discontinued before adrenal insufficiency testing (with no restriction regarding time of discontinuation).

Search strategy

We conducted a comprehensive search of several databases without language restriction from each database's earliest inception to February 28, 2014. The databases included Ovid Medline In-Process & Other Non-Indexed Citations, Ovid MEDLINE, Ovid EMBASE, Ovid Cochrane Central Register of Controlled Trials, Ovid Cochrane Database of Systematic Reviews, and Scopus. The search strategy was designed and conducted by an experienced librarian with input from the study's principal investigator (M.H.M.). Controlled vocabulary supplemented with keywords was used to search for adrenal insufficiency. The details of the search are available in the supplemental material. Cross-referencing with previously published systematic reviews and contacting content experts were also performed to supplement the electronic search.

Working independently and in duplicate, the reviewers screened the available abstracts (N.SO., A.A., I.B., A.J., K.B., E.K.). Articles in full text were then retrieved and were reviewed independently and in duplicate for eligibility. Disagreements between reviewers were resolved by consensus.

Data extraction for systematic review

Working independently and in duplicate, data from the included studies were extracted using a standardized data extraction sheet, including baseline information about included studies and the number of patients with true-positive, true-negative, false-positive, and false-negative results. In cases where the required data were not present in the published manuscript, authors were contacted for additional information (four authors were contacted with response obtained from one author).

Quality of the studies

Critical appraisal of the included studies was performed independently and in duplicate following the Quality Assessment of Diagnostic Accuracy Studies instrument. This includes the assessment of the risk of bias and applicability in the following domains: patient selection, index test, reference standard, and flow and timing. This tool includes signaling questions to help reviewers assess the risk of bias. One domain of the tool evaluates patient selection and the methods used for enrolling patients (eg, consecutive or random sample) and the appropriateness of exclusion criteria. Another domain evaluates the index test and whether it was interpreted without knowledge of the standard reference. A domain about the reference standard evaluates whether the interpretation of the reference standard was performed without knowing the results of the index text. Finally, the domain of flow and timing focuses on knowing when the reference standard was performed and in how many patients (15, 16). Cases in which the reviewers' assessment of the risk of bias differed were resolved by consensus.

Statistical analysis

Diagnostic estimates from included studies were pooled by fitting a two-level mixed logistic regression model with independent binomial distributions for the true positives and true negatives. These distributions were conditional on the sensitivity and specificity in each study. We also used a bivariate normal model for the logit transforms of sensitivity and specificity between studies (17, 18). The analysis was done using STATA, version 13 (StataCorp, College Station, TX). Heterogeneity between the studies was assessed using the I² statistic. We report

sensitivity, specificity, likelihood ratios, and diagnostic odds ratios (ORs), with 95% confidence intervals (CIs).

Results

DOCKE

Search results

The results of the systematic search are shown in Figure 1. The systematic search identified 1284 potentially rele-

vant references of which 35 studies were included (30 in SAI, five in PAI).

Risk of bias

Using the Quality Assessment of Diagnostic Accuracy Studies-2 instrument, all included studied had moderate risk of bias as shown in Supplemental Figure 1. This conclusion is mainly driven by unclear or inappropriate patient selection and referral bias leading to high prevalence.

Figure 1. Study selection.

Otherwise, the studies had low risk of bias in the domains of index test, reference standard, and flow and timing.

Secondary adrenal insufficiency

We identified 30 studies (19–48) assessing the diagnostic performance of the ACTH stimulation test in patients with suspected SAI. Supplemental Tables 1 and 2 summarize the characteristics of these studies that enrolled adults and children, respectively. These studies enrolled a total of 1437 patients with a prevalence of SAI of 36% (35% in adults and 38% in children). Most studies administered ACTH IV.

We included studies that defined whether the test was positive or negative based on predefined cutoffs that the serum cortisol level had to exceed at any time after ACTH administration, "peak cortisol level." Other studies used a specific time (30 or 60 minutes) to assess for this predefined serum cortisol value to determine whether the test was positive or negative. The distribution of the included studies in terms of test used and cutoff is as follows:

- The overall analysis for the accuracy of high-dose ACTH stimulation test in adults included 29 datasets (19, 21–23, 25–29, 31, 33–40, 42, 44–46, 48). Six studies were included in the analysis of high-dose ACTH in adults using 500 nmol/L at 30 minutes as a cutoff (22, 25, 28, 34, 39, 44), 14 studies used a 500 nmol/L peak serum cortisol value as a cutoff (19, 21, 23, 26, 29, 33, 36–38, 40, 42, 45, 46, 48), and eight a serum cortisol cutoff of 550 nmol/L (21, 23, 31, 33, 35, 38, 45, 48).
- The overall analysis for the accuracy of the low-dose ACTH stimulation test in adults included 19 datasets (19, 20, 23–25, 29, 35, 37, 38, 40, 43, 45, 46, 48). Eleven studies used a 500-nmol/L peak serum cortisol value for the low-dose ACTH stimulation test in adults (19, 20, 23, 29, 37, 38, 40, 43, 45, 46, 48); six used a peak serum cortisol level of 550 nmol/L as the cutoff value (23, 35, 38, 43, 45, 48).
- The overall analysis of the low-dose ACTH stimulation test in children included five datasets (30, 32, 41, 47). Three studies evaluated the low-dose ACTH stimulation test in children with a peak cortisol of 500 nmol/L (32, 41, 47) and two a peak cortisol level of 550 nmol/ liter as the cutoff (30, 41). The overall analysis of the high-dose ACTH stimulation test in children included four datasets (30, 41, 47). Two studies evaluated the high-dose ACTH in children using a peak of 500 nmol/ liter (41, 47) and two studies with a peak cortisol of 550 nmol/liter (30, 41).

DOCKE

Diagnostic performance in SAI

The diagnostic performance for the high- and low-dose ACTH stimulation test in adults and children according to three different test cutoffs are summarized in Table 1 and 2. Summary receiving operator characteristics curves are in Figures 2 and 3 for low and high dose, respectively. Studies were excluded if patients on long-acting steroid were included or, because of the lack of a predefined gold standard, reported equivocal results for the gold standard or used a gold standard that was not compatible with the inclusion criteria (14, 49–60).

In general, both tests had low and high specificity resulting in reasonable likelihood ratios for a positive test (adults: high dose, 9.1; low dose, 5.9; children: high dose, 43.5; low dose, 7.7), but a fairly suboptimal likelihood ratio (LR) for a negative test (adults: high dose, 0.39; low dose, 0.19; children: high dose, 0.65; low dose, 0.34). Both high- and low-dose tests had moderate accuracy overall (diagnostic ORs ranging from 23 to 67) primarily because of the low sensitivity. However, there was no statistically significant difference between accuracy of the high- and the low-dose tests when comparing diagnostic ORs. The analysis was associated with significant heterogeneity, which is common in diagnostic meta-analysis. A summary

of the meta-analysis results is shown in Tables 1 and 2. The receiver operator characteristic (61) curve for the highand low-dose ACTH stimulation test in adults are found in Figures 2 and 3, respectively.

Primary adrenal insufficiency

We identified five studies (62–66) investigating the diagnostic performance of the high-dose ACTH stimulation test for the diagnosis of PAI. The characteristics of these studies are summarized in Supplemental Table 3.

Diagnostic performance in PAI

Data were insufficient to estimate specificity, likelihood, and diagnostic ORs. Only the sensitivity (the rate of a positive test among patients with confirmed PAI) was estimable and was 92% (95% CI, 81–97%).

Discussion

This systematic review and meta-analysis aimed at identifying the diagnostic accuracy of ACTH stimulation test
