ABSTRACT OF THE DISCLOSURE

Semiconductor devices of the type having a thin active region of the semiconductor material on a support body are made by depositing the active region on a silicon substrate with a thin barrier layer of highly doped P type silicon being provided between the active region and the substrate. The support body is applied to the active region and the substrate is removed by etching in a solution of potassium hydroxide and 1-propanol. The etching solution removes the substrate but stops at the barrier layer leaving a smooth, flat surface. The barrier layer can be either used as part of the semiconductor device being made or easily removed with a suitable etchant.

BACKGROUND OF THE INVENTION

This is a continuation-in-part of our patent application Ser. No. 293,804, filed Oct. 2, 1972, now abandoned, entitled "Method of Making Semiconductor Devices Having Thin Active Regions of the Semiconductor Material."

The present invention relates to a method of making semiconductor devices having thin active regions of the semiconductor material. More particularly, the present invention relates to a method of selectively etching away a semiconductor substrate to leave a thin region of semiconductor material on a support.

High frequency semiconductor devices and integrated circuits require high quality, ultra-thin, uniformly thick bodies of a semiconductor material on a metallic or electrically insulating support. A problem in making such devices is to achieve the ultra-thin, less than about 10 microns, bodies of the semiconductor material. To handle a large wafer of the semiconductor material which is this thin is very difficult since such a thin wafer is very brittle and subject to be easily broken. To overcome this problem, it has been the practice to use a relatively thick wafer, in the order of .075 mm. in thickness, which can be more easily handled. The thick wafer is mounted on a support and is then thinned down to the desired thickness either by mechanical or chemical polishing techniques.

Thinning the wafer by mechanical polishing has the disadvantage that as the wafer becomes thinner it becomes more subject to being broken under the application of the mechanical polishing process. Also, the mechanical polishing processes have a tendency to create defects in the surface of the wafer which can adversely affect the electrical characteristics of the device being formed. Thinning the wafer by heretofore known chemical polishing processes has the disadvantage that such chemical polishing processes have a tendency to provide the wafer with a curved surface rather than a flat surface, particularly when the wafer must be thinned a large amount. Thus, the thinned wafer would be of non-uni-

2

Another process which has been developed to achieve a thin body of a semiconductor material on a support is an electrolytic etching process. For this process a barrier layer of a high resistance semiconductor material is applied to the surface of a substrate of a low resistance semiconductor material, the thin body of the semiconductor material is applied to the barrier layer and the support is applied to the body. The substrate is then removed by electrolytically etching away the substrate. The etching of the substrate will stop when the barrier layer is reached so as to leave the thin body on the support. However, this process also has certain disadvantages. To achieve the electrolytic etching, the device must be connected in a suitable electric circuit. To so etch a plurality of the devices at one time for mass production requires a separate circuit for each device so that the apparatus becomes cumbersome. Also, to ensure that all of the substrate is etched away, it is necessary to either properly position the device at an angle in the electrolytic etching solution and/or repeatedly dip the device deeper and deeper in the solution. Thus, special handling of the device is required during the etching operation which makes mass production more difficult.

SUMMARY OF THE INVENTION

A semiconductor device is made by forming on a surface of a substrate of single crystalline silicon a thin barrier layer of single crystalline, P type conductivity silicon with the free carrier concentration being greater than 5×10^{19} cm.$^{-3}$. On the silicon layer is formed a region of single crystalline silicon which is of a conductivity type or types required by the semiconductor device being formed, and the substrate is removed by etching with a solution of potassium hydroxide and 1-propanol.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. 1 is a flow chart of the method of the present invention.

FIG. 2 is a sectional view showing one form of a semiconductor device being made by the method of the present invention.

FIG. 3 is a sectional view showing another form of a semiconductor device being made by the method of the present invention.

FIG. 4 is a schematic view of an apparatus used to carry out one operation of the method of the present invention.

DETAILED DESCRIPTION

Referring initially to FIG. 2, there is shown one form of a semiconductor device generally designated as **10**, being made by the method of the present invention. The device shown comprises a flat substrate **12** of single crystalline silicon of either P type or N type conductivity. The substrate **12** can be relatively thick, in the order of 75 microns, so as to be rigid. If the substrate **12** is of boron doped P type, it should have a carrier concentration of no greater than 5×10^{19} cm.$^{-3}$. If the substrate **12** is of N type it can contain any desired dopant concentration. The substrate **12** also has its surfaces oriented on a <100> crystellographic plane. On a surface of the substrate **12** is a barrier layer **14** of P type conductivity single crystalline silicon. The barrier layer **14** is doped with boron and has a carrier concentration of greater than 5×10^{19} cm.$^{-3}$ and preferably at least 1×10^{20} cm.$^{-3}$. Also, the barrier layer **14** is preferably very thin, in the order of five microns.

On the barrier layer **14** is a region **16** of a single crystalline silicon which forms the active portion of the semi-

DOCKET ALARM Find authenticated court documents without watermarks at docketalarm.com.

required for the particular semiconductor devices being made. For example, to form diodes, the region **16** would be superimposed contiguous layers of opposite conductivity type having a PN junction therebetween. To form a type of a transferred electron effect device, the region **16** may be a layer of P type conductivity sandwiched between two layers of N+ type conductivity. To form integrated circuits, the region **16** may be of either conductivity type into which will be formed active regions of the various components of the circuit to be formed. To make high frequency semiconductor devices, the region **16** is preferably relatively thin, in the order of about 10 microns. On the region **16** is a support body **18** of an electrical insulating or semi-insulating material, such as glass, quartz or a high resistance semiconductor material.

As indicated in the flow chart of FIG. 1, the device **10** shown in FIG. 2 can be formed by first depositing on the surface of the substrate **12** an epitaxial layer of the highly boron doped silicon to form the barrier layer **14**. The barrier layer **14** may be deposited by any well known epitaxial deposition technique. For example, the substrate **12** can be placed in a chamber through which is provided a flow of a gas containing silicon and boron, such as a mixture of silane and diborane. The chamber is heated to a temperature, approximately 1000° C., at which the gas reacts to form silicon and boron which deposit on the substrate as the barrier layer **14**. The silicon region **16** can then be epitaxially deposited on the barrier layer **14** in a manner similar to that for depositing the barrier layer. However, the number and composition of the epitaxial layers which form the region **16** depend on the semiconductor device being formed. To form a diode, two layers of opposite conductivity type may be deposited in sequence, or a single layer of one conductivity type may be epitaxially deposited on the barrier layer **12** and a conductivity modifier of the opposite conductivity type diffused into the single layer. To form a device in which only the concentration of the conductivity modifier varies, a single layer of the desired conductivity may be deposited with the ratio of the conductivity modifier containing gas in the deposition gas being varied during the deposition process. The support body **18** is then applied to the silicon region **16**. If the support body **18** is glass or quartz it can be fusion bonded directly to the silicon region. A semi-insulating semiconductor material support body can be epitaxially deposited on the bottom region **16** in the manner described above.

The substrate **12** is then completely removed. This is achieved by chemically etching the substrate **12** in a heated, concentrated solution of potassium hydroxide covered with a layer of 1-propanol. FIG. 4 shows an apparatus which can be used to carry out the etching away of the substrate **12**. The apparatus comprises a container **20** seated on a stirrer hot plate **22**. The concentrated potassium hydroxide **24** is within the container **20** and is covered by a layer **26** of the 1-propanol. A magnetic stirrer **28** is within the potassium hydroxide solution, and a water jacket **30** fits over the top of the container **20**. The devices **10** are placed in the potassium hydroxide solution **24** which is stirred by the stirrer **26** and heated to a temperature of about 85° C. A plurality of the devices **10** can be supported in the potassium hydroxide solution in a suitable holder, not shown. Each of the devices **10** may be coated with a suitable resist material around its periphery and over the surface of the support body **18** so that only the surface of the substrate **12** is exposed to the potassium hydroxide.

In the etching of the substrate **12**, it is known that the heated potassium hydroxide 1-propanol solution etches <100> oriented silicon at a relatively fast rate, approximately 1 micron per minute. However, we have discovered that when the concentration of the P type conductivity modifier, boron, in the silicon is made greater than 5×10^{19} cm.$^{-3}$ and preferably greater than 1×10^{20} cm.$^{-3}$

milliliters of water, 90 grams of potassium hydroxide and 200 milliliters of 1-propanol results in the following etch rates:

Conductivity type	Doping concentration (cm.$^{-3}$)	Etch rate (microns/min.)
P+ (boron)	Approximately 1×10^{20}	0.0106
P− (boron)	1×10^{16}–1×10^{17}	1.1
N− (phosphorus)	Approximately 10^{24}	1.27
N+ (antimony)	2–5×10^{19}	1.31

Thus, it can be seen that the etch rate for the highly doped boron (P+) silicon is over 100 times slower than for either the lower doped boron (P−) or the N type silicon. Also, it has been found that the potassium hydroxide 1-propanol etching solution has the advantages over other potassium hydroxide alcohol etching solutions of a faster etch rate for the lower doped boron silicon and the N type silicon and a slower etch rate for the highly doped boron silicon so as to have a greater etch rate differential. For example, using an etching solution of 300 milliliters of water, 90 grams of potassium hydroxide and 200 milliliters of iso-propyl alcohol results in the following etch rates:

Conductivity type	Doping concentration (cm.$^{-3}$)	Etch rate (microns/min.)
P+ (boron)	Approximately 1×10^{20}	0.017
P− (boron)	1×10^{16}–1×10^{17}	0.44
N+ (antimony)	2–5×10^{19}	0.58

By comparing the above two tables it can be seen that the potassium hydroxide 1-propanol etch solution etches the lower boron doped silicon and the N type silicon about twice as fast as the potassium hydroxide iso-propyl alcohol etching solution but etches the highly boron doped silicon only about one-half as fast.

Thus, by having the barrier layer **14** between the substrate **12** and the active region **16**, the substrate **12** will be etched away relatively fast but the etching will substantially stop when all of the substrate **12** is removed and the barrier layer **14** is reached. Also, when the substrate **12** is completely removed, the barrier layer **14** is left with a smooth, flat surface. In addition, while the substrate **12** is being etched away gas bubbles are formed in the potassium hydroxide solution and these bubbles stop when the substrate **12** is completely removed. Thus, there is provided a visible indication as to when the substrate **12** is completely removed and the devices **10** can be removed from the etchant. In this etching system the 1-propanol layer **26** serves the dual purpose of keeping the temperature of and the 1-propanol concentration in the potassium hydroxide solution **24** constant.

After the substrate **12** is removed, the device **10** comprises the support body **18** having the active silicon region **16** on a surface thereof and the barrier layer **14** over the active region **16**. Since the barrier layer **14** contains a high concentration of the conductivity modifier and is therefore of very low resistance, it can be used as a low resistance contact for the active region **16** if the semiconductor devices being made so permits. For example, if diodes were being made and the active region **16** had the P type layer adjacent the barrier layer **14**, the barrier layer could serve as a low resistance contact to the P type layer. However, if the barrier layer **14** is not desired, it can be easily removed by etching in a nitric and hydrofluoric acid mixture. Since the barrier layer **14** is very thin it can be etched away quickly leaving the active region **16** with a flat, smooth surface. The device **10** can then be processed to complete the semiconductor device being made. For example, metal contacts can be applied, to form an integrated circuit the active region **16** may be provided with areas of different conductivity types by diffusion or ion implantation to form the desired circuit, and the device may be diced into individual semiconductor devices.

tion is generally designated as **100.** The semiconductor device **100,** like the semiconductor device **10** shown in FIG. 2, comprises a substrate **112** of single crystalline silicon, a thin barrier layer **114** of a highly doped P type conductivity single crystalline silicon on a surface of the substrate **112,** an active region **116** of single crystalline silicon on the barrier layer **114,** and a support body **118** on the active region **116.** However, the support body **118** is of an electrically conductive metal, such as copper, which is bonded to a thin metal film **120** coated on the surface of the active region **116.** The metal support body **118** can serve as a heat sink and/or as an electrode for the semiconductor devices being made. The device **100** is made in the same manner as previously described with regard to the device **10** shown in FIG. 2. However, after the active region **116** is deposited on the barrier layer **114,** the metal film **120** is coated on the surface of the active region **116** by any well known technique, such as by vacuum evaporation. The metal support body **118** is then applied to the metal film **120.** This can be achieved either by bonding a metal body to the metal film, such as by thermocompression bonding or by soldering, or the metal body can be electroplated onto the metal film. The substrate **112** is then removed by the chemical etching process previously described.

Thus, there is provided by the present invention a method of making a semiconductor device which has a thin active region of single crystalline silicon on a support body. By forming the active region of the device as an epitaxial layer on a substrate, thin active regions of uniform thickness and good quality semiconductor material can be obtained without danger of breaking the thin region. By providing the thin highly doped P type barrier layer between the active region and the substrate, the substrate can be easily removed by a chemical etching procedure which completely removes the substrate without adversely affecting the active region and leaves a smooth flat surface. Also, the etching procedure is suitable for mass production since it can be carried out on a plurality of the devices simultaneously and provides a visual indication of when the etching of the substrate is completed. In addition, since the barrier layer is of low resistance it can be utilized as a contact for certain types of semiconductor devices which can be formed by the method of the present invention. However, where the barrier layer cannot be so used, it can be easily and quickly removed.

We claim:

1. A method of making a semiconductor device comprising the steps of:

(a) forming on a surface of a substrate of single crystalline silicon a thin barrier layer of single crystalline P type conductivity silicon with the free carrier concentration being greater than 5×10^{19} cm.$^{-3}$,

(b) forming on said barrier layer a region of single crystalline silicon, said region being of a conductivity type or types required by the semiconductor device being formed, and

(c) removing said substrate by etching with a solution of potassium hydroxide and 1-propanol.

2. The method in accordance with claim **1** in which the substrate is either P type conductivity with a free carrier concentration of not greater than 5×10^{19} cm.$^{-3}$ or N type conductivity.

3. The method in accordance with claim **2** including providing a support body on the region prior to removing the substrate.

4. The method in accordance with claim **3** in which the support body is of an electrical insulating material and is bonded to the surface of the region.

5. The method in accordance with claim **3** in which the support body is of an electrically conductive metal.

6. The method in accordance with claim **5** in which a metal film is coated on the surface of the region and the support body is provided on the metal film.

7. The method in accordance with claim **6** in which the metal body is bonded to the metal film.

8. The method in accordance with claim **6** in which the metal body is plated onto the metal film.

9. The method in accordance with claim **1** in which after the substrate is etched away the barrier layer is removed.
