IEEE ACOUSTICS, SPEECH, AND SIGNAL PROCESSING SOCIETY

The Acoustics, Speech, and Signal Processing Society is an organization, within the framework of the IEEE, of members with principal professional interest in the technology of transmission, recording, reproduction, processing, and measurement of speech and other signals by digital electronic, electrical, acoustic, mechanical, and optical means, the components and systems to accomplish these and related aims, and the environmental, psychological, and physiological factors concerned therewith. All members of the IEEE are eligible for membership in the Society and will receive this TRANSACTIONS upon payment of the annual Society membership fee of \$7.00. For information on joining, write to the IEEE at the address below

Separating Multipaths by Global Optimization of a Multidimensional Matched Filter

BRADLEY M. BELL AND TERRY E. EWART

Abstract-A transmitted signal can arrive at a receiver via several refracted Fermat paths. If the paths are independent in the Fresnel sense, then the received signal can be modeled as the sum of amplitude scaled and time shifted copies of a predetermined replica plus white noise. We present an algorithm that uses the replica to determine the time shifts and amplitudes for each path. It is referred to as an ndimensional matched filter algorithm by analogy with the well-known matched filter algorithm. The cross correlation between the received signal and the replica oscillates near the center frequency of the transmitted signal. This causes the n-dimensional matched filter output to have many local maxima that are not globally optimal. The time shifts and amplitude scalings for the Fermat paths are determined by maximizing the output of the n-dimensional matched filter. The algorithm is more robust and efficient than others currently available. Simulated realizations of received signals were generated with multipath and noise characteristics similar to an ocean acoustic transmission case. These realizations were then separated into arrival times and corresponding amplitudes by the algorithm. The results of these tests and the general limitations of the algorithm are discussed.

I. INTRODUCTION

A sound pulse transmitted in the ocean almost always arrives at a receiver via several paths. Theoretically, separating the pulse energy in the individual paths can be impossible. Path separation is possible if their arrival these and other methods which purport to determine the arrival time and amplitude of each path. These estimates MATE data set in 20 days without operator intervention. are biased when the pulses from two or more paths overap in time. Nilsson [2] introduced a method that eliminates these biases. Ehrenberg et al. [3] and Ewart et al. [4] present a technique to evaluate Nilsson's method, demonstrate the improved accuracies in the arrival time

Regular-Pulse Excitation—A Novel Approach to Effective and Efficient Multipulse Coding of Speech

PETER KROON, STUDENT MEMBER, IEEE, ED F. DEPRETTERE, MEMBER, IEEE, AND ROB J. SLUYTER

Abstract—This paper describes an effective and efficient time do-varying linear predictive (LP) filter to model the shortmain speech encoding technique that has an appealing low complexity, time spectral envelope of the quasi-stationary speech sigposed coder uses linear predictive techniques to remove the short-time correlation in the speech signal. The remaining (residual) information is then modeled by a low bit rate reduced excitation sequence that, when applied to the time-varying model filter, produces a signal that is "close" to the reference speech signal. The procedure for finding the optimal constrained excitation signal incorporates the solution of a few strongly coupled sets of linear equations and is of moderate comnovel coding idea and the procedure for finding the excitation sequence. We then show that the coding procedure can be considered as an "optimized" baseband coder with spectral folding as high-frequency regeneration technique. The effect of various analysis parameters on the quality of the reconstructed speech is investigated using both objective and subjective tests. Further, modifications of the basic algorithm, and their impact on both the quality of the reconstructed speech signal and the complexity of the encoding algorithm, are discussed. Using the generalized baseband coder formulation, we demonstrate that under reasonable assumptions concerning the weighting filter, an attractive low-complexity/high-quality coder can be obtained.

I. INTRODUCTION

A N interesting application area for digital speech coding can be found in mobile telephony systems and computer networks. For these applications, toll quality speech at bit rates below 16 kbits/s is a prerequisite. Many of the conventional speech coding techniques [1] fail to obey this condition. However, a class of coders, the socalled delayed decision coders (DDC) [1, ch. 9], seems to be promising for these applications. Coders that belong to this class utilize an encoding delay to find the "best" quantized version of the input speech signal or a transformed version of it. Quite effective algorithms can be designed by combining predictive and DDC techniques to yield low bit rate waveform matching encoding schemes. A powerful and common approach is to use a slowly time-

citation signal for an LP speech coder that not only enpropose a method in which the prediction residual is modof this regularity, we refer to this coder as the regularpulse excitation (RPE) coder [5]. The values of the nonzero samples in this signal are optimally determined by a least-squares analysis-by-synthesis fitting procedure that

In Section II we describe in more detail the regular-

II. BASIC CODER STRUCTURE

The basic coder structure can be viewed as a residual modeling process, as depicted in Fig. 1. In this figure, the residual r(n) is obtained by filtering the speech signal s(n)

nal. The problem that remains is how to describe the resulting prediction residual that contains the necessary information to describe the fine structure of the underlying spectrum. In other words, what is the "best" low-capacity model for the speech prediction residual subjected to one or more judgment criteria. These may include objecplexity compared to competing coding systems such as adaptive transform coding and multipulse excitation coding. The paper describes the tions and listening scores, respectively), but coder complexity can also be taken into account. Although certain models have been shown to behave very satisfactorily [2]-[4], the question of optimality remains difficult to answer.

In this paper we address the problem of finding an exsures a comparable quality with existing approaches, but is also structurally powerful. By the latter we mean that a fast realization algorithm and a corresponding high throughput (VLSI) implementation can be obtained. We eled by a signal that resembles an upsampled sequence and has, therefore, a regular (in time) structure. Because can be expressed in terms of matrix arithmetic.

pulse excitation coding procedure and the algorithm for finding the excitation sequence. In Section III we show that the proposed encoding procedure can be interpreted in terms of optimized baseband coding. In Section IV, the influence of the various analysis parameters on the quality of the reconstructed speech is investigated. Further, to exploit the long-term correlation in the speech signal, the use of a pitch predictor is discussed. Modifications to the basic procedure, to attain a further reduction in complexity without noticeable quality loss, are described in Section V. Finally, in Section VI, we describe the effect of quantization on the quality of the reconstructed speech

In this figure, the locations of the pulses are marked by a vertical dash and the zero samples by dots. If k (k = 1, $2, \cdots, N$) denotes the *phase* of the upsampled version of the vector $b^{(k)}$, i.e., the position of the first nonzero sample in a particular segment, then we have to compute for every value of k the amplitudes $b^{(k)}(\cdot)$ that minimize the accumulated squared error. The vector that yields the minimum error is selected and transmitted. The decoding procedure is then straightforward, as is shown in Fig.

Fig. 1. Block diagram of the regular-pulse excitation coder: (a) encoder (b) decoder

Fig. 2. Possible excitation patterns with L = 40 and N = 4.

through a pth-order time-varying filter A(z),

$$A(z) = 1 + \sum_{k=1}^{p} a_k z^{-k}, \tag{1}$$

which can be determined with the use of linear prediction (LP) techniques as described in, e.g., [6]. The difference between the LP-residual r(n) and a certain model residual v(n) (to be defined below) is fed through the shaping filter

$$\frac{1}{A(z/\gamma)} = \frac{1}{1 + \sum_{k=1}^{p} a_k \gamma^k z^{-k}}, \quad 0 \le \gamma \le 1.$$
 (2)

This filter, which serves as an error weighting function, plays the same role as the feedback filter in adaptive predictive coding with noise shaping (APC-NS) [7] and the weighting filter in multipulse excitation (MPE) coders [2]. The resulting weighted difference e(n) is squared and accumulated, and is used as a measure for determining the where effectiveness of the presumed model v(n) of the residual r(n).

The excitation sequence v(n) is determined for adjacent frames consisting of L samples each, and is constrained as follows. Within a frame, it is required to correspond to an upsampled version of a certain "optimal" vector b = $(b(1), \dots, b(Q))$ of length Q(Q < L). Thus, each segment of the excitation signal contains Q equidistant samples of nonzero amplitude, while the remaining samples are equal to zero. The spacing between nonzero samples is N = L/Q. For a particular coder, the parameters L and N are optimally chosen but are otherwise fixed quantities. The duration of a frame of size L is typically 5 ms. Each excitation frame can support N sets of Q equidistant nonzero samples, resulting in N candidate excitation sequences. Fig. 2 shows the possible excitation patterns for a frame containing 40 samples and a spacing of N = 4.

A. Encoding Algorithm

Denoting by M_k the Q by L position matrix with entries

$$m_{ij} = 1$$
 if $j = i*N + k - 1$

$$m_{ij} = 0$$
 otherwise
$$0 \le i \le Q - 1$$

$$0 \le j \le L - 1,$$
(3)

the segmental excitation row vector $v^{(k)}$, corresponding to the kth excitation pattern, can be written as

$$\boldsymbol{v}^{(k)} = \boldsymbol{b}^{(k)} \boldsymbol{M}_k. \tag{4}$$

Let H be an uppertriangular L by L matrix whose jth row $(j = 0, \dots, L - 1)$ contains the (truncated) response h(n) of the error weighting filter $1/A(z/\gamma)$ caused by a unit impulse $\delta(n-i)$. That is,

$$H = \begin{bmatrix} h(0) & h(1) & \cdots & h(L-1) \\ 0 & h(0) & & h(L-2) \\ 0 & 0 & & h(L-3) \\ \vdots & \vdots & & \vdots \\ 0 & 0 & 0 & h(0) \end{bmatrix} .$$
 (5)

If e_0 denotes the output of the weighting filter due to the memory hangover (i.e., the output as a result of the initial filter state) of previous intervals, then the signal e(n) produced by the input vector $b^{(k)}$ can be described as

$$e^{(k)} = e^{(0)} - b^{(k)}H_k, \quad k = 1, \dots, N,$$
 (6)

$$e^{(0)} = e_0 + rH, (7)$$

$$H_k = M_k H, \tag{8}$$

and the vector r represents the residual r(n) for the current frame. The objective is to minimize the squared error

$$E^{(k)} = e^{(k)}e^{(k)t}. (9)$$

where t denotes transpose. For a given phase the optimal amplitudes $b^{(k)}(\cdot)$ can be computed from (6) and (9), by requiring $e^{(k)}H_k^t$ to be equal to zero. Hence,

$$\boldsymbol{b}^{(k)} = \boldsymbol{e}^{(0)} \boldsymbol{H}_k^t [\boldsymbol{H}_k \boldsymbol{H}_k^t]^{-1}. \tag{10}$$

By substituting (10) in (6) and thereafter the resulting expression in (9), we obtain the following expression for

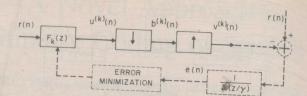

$$E^{(k)} = e^{(0)}[I - H'_k[H_k H'_k]^{-1}H_k] e^{(0)t}.$$
 (11)

The vector $\boldsymbol{b}^{(k)}$ that yields the minimum value of $E^{(k)}$ over all k is then selected. The resulting optimal excitation vector $v^{(k)}$ is entirely characterized by its phase k and the corresponding amplitude vector $\boldsymbol{b}^{(k)}$. The whole procedure comprises the solution of N sets of linear equations as given by (10). A fast algorithm to compute the N vectors $b^{(k)}$ simultaneously has been presented in [8] and [9]. We Fig. 3. Block diagram of a BBC coder (solid lines), and an RPE coder plexity can be obtained by exploiting the nature of the matrix product $H_k H_k^t$ in (10).

III. GENERALIZED BASEBAND CODING

It may be observed that the regular-pulse excitation sequence bears some resemblance to the excitation signal of excited baseband coder (BBC) using spectral folding as high-frequency regeneration technique [4], [10]. In this section we show that the RPE coder can be interpreted as and a generalized version of this baseband coder. For this purpose we use the block diagram of Fig. 3. The blocks drawn with solid lines represent the conceptual structure of a residual excited BBC coder with spectral folding. For this coder, the index k has no significance and is set to zero. In this scheme, the LP-residual signal r(n), ob- put $u^{(k)}(n)$ of the filter $F_k(z)$ tained by filtering the speech signal through the filter A(z), is band-limited by an (almost) ideal low-pass filter $F_0(z)$, downsampled to $b^{(0)}(n)$ and transmitted. At the receiver, this signal is upsampled to $v^{(0)}(n)$ to recover the original $u^{(k)} = f^{(k)}$ bandwidth, and is fed through the synthesis filter to retrieve the speech signal $\hat{s}(n)$. When the dashed blocks are included in Fig. 3, one provides a possibility to optimize the filter $F_k(z)$, i.e., to replace the ideal low-pass filter $F_0(z)$ by another filter, which is more tailored to "optimal" waveform matching, where the optimality criterion The vector $b^{(k)}$, which is the downsampled version of the original and the reconstructed signal.

We shall now show that for this "optimized" BBC version, the output of the filter $F_k(z)$, after down- and upsampling, is exactly the excitation signal $v^{(k)}(n)$ as computed by the RPE algorithm. Thus, let there exist for each k, (k with

= 1, \cdots , N), an FIR filter $F_k(z)$ such that the weighted least-squares error $\Sigma_n e^2(n)$ over the interval L is minimal. Define $F_k(z)$ as

$$F_k(z) = \sum_{i=0}^{L-1} f_i^{(k)} z^{-i},$$
 (12)

$$f^{(k)} = [f^{(k)}(0) f^{(k)}(1) \cdots f^{(k)}(L-1)].$$
 (13)

Let $r_+(n)$ and $r_-(n)$ $(n = 0, \dots, L - 1)$ denote the residual samples of the current frame and those of the previous frame, respectively. Then we can write for the out-

$$\mathbf{u}^{(k)} = \mathbf{f}^{(k)} \begin{bmatrix} r_{+}(0) & r_{+}(1) & \cdots & r_{+}(L-1) \\ r_{-}(L-1) & r_{+}(0) & & r_{+}(L-2) \\ r_{-}(L-2) & r_{-}(L-1) & & r_{+}(L-3) \\ \vdots & & \vdots & & \vdots \\ r_{-}(1) & r_{-}(2) & & r_{+}(0) \end{bmatrix}$$

$$= \mathbf{f}^{(k)} \mathbf{R}.$$

 $u^{(k)}$ (with downsampling factor N), can be written as

$$b^{(k)} = f^{(k)} R M_k^t,$$

$$= f^{(k)} R_k$$
(15)

$$R_{k} = \begin{bmatrix} r_{+}(k-1) & r_{+}(N-1+k) & \cdots & r_{+}((Q-1)N-1+k) \\ r_{-}(L-2+k) & r_{+}(N-2+k) & r_{+}((Q-1)N-2+k) \\ r_{-}(L-3+k) & & & \vdots \\ \vdots & & & \vdots \\ r_{-}(k) & & & & \vdots \\ r_{-}((Q-1)N+k) \end{bmatrix},$$
(16)

where M_k is the position matrix as defined in (3), and where the definition $r_{-}(L + k) = r_{+}(k)$. The excitation vector $v^{(k)}$ can be expressed as the product

$$v^{(k)} = f^{(k)} \begin{bmatrix} 0 & \cdots & 0 & r_{+}(k-1) & 0 & \cdots & 0 & \cdots & r_{+}((Q-1)N-1+k) & 0 & \cdots & 0 \\ 0 & \cdots & 0 & r_{-}(L-2+k) & 0 & \cdots & 0 & \cdots & r_{+}((Q-1)N-2+k) & 0 & \cdots & 0 \\ \vdots & \vdots & & \ddots & \vdots & & \vdots & & \ddots \\ 0 & \cdots & 0 & r_{-}(k) & 0 & \cdots & 0 & & \vdots & & \ddots \\ k-1 & & N-k & & & N-k & & N-k \end{bmatrix}$$

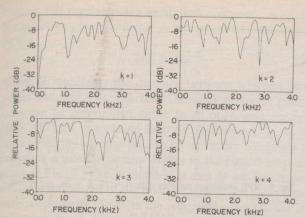

Fig. 4. Power spectra $|F_k(e^{j\theta})|^2$ for different values of k, obtained from a 5 ms speech segment.

Hence, with the matrix H and the initial error $e^{(0)}$ as defined in the previous section,

$$e^{(k)} = e^{(0)} - f^{(k)} R_k M_k H$$

$$= e^{(0)} - f^{(k)} R_k H_k.$$
(18)

Minimizing $e^{(k)}e^{(k)t}$, we obtain as solution

$$f^{(k)} = e^{(0)} (R_k H_k)^t [R_k H_k (R_k H_k)^t]^{-1}.$$
(19)

Substituting this result in (15), we obtain the vector $b^{(k)}$, which is equal to the pulse amplitude vector $b^{(k)}$ obtained via the procedure described in Section II (see the proof in the Appendix).

Fig. 4 gives an example of the spectra $|F_k(e^{j\theta})|^2$ obtained from real speech data. From this figure we see that the filters $F_k(z)$ are rather different from the one $(F_0(z))$ used in the classical baseband coder, and have a more allpass character.

Although the RPE algorithm and the optimal BBC algorithm are conceptually equivalent, the optimized BBC variant will in general not offer any computational advantage over the RPE approach. However, in Section V, it is demonstrated that under certain reasonable assumptions concerning the weighting filter, the BBC approach can provide an attractive alternative in practice.

IV. EVALUATION OF THE RPE ALGORITHM

Fig. 5 shows a typical example of the waveforms as produced by the RPE coder, using the analysis parameters listed in Table I. The corresponding short-time power spectra of the speech signal s(n) (solid line) and the reconstructed signal $\hat{s}(n)$ (dashed line) are shown in Fig. 6. To give an impression of the signal-to-noise ratio over a complete utterance, we show in Fig. 7 the segmental SNR (SNRSEG) computed every 10 ms for the utterance "a lathe is a big tool" spoken by both a female and a male speaker.

A. RPE Analysis Parameters

The RPE analysis parameters that could affect the final speech quality are listed below:

1) predictor parameters,

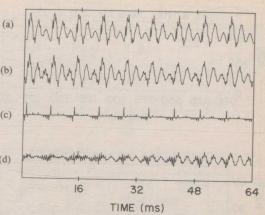

Fig. 5. (a) Speech signal s(n), (b) reconstructed speech signal $\hat{s}(n)$, (c) excitation signal v(n), and (d) difference signal $s(n) - \hat{s}(n)$ in the RPE coding procedure.

TABLE I DEFAULT PARAMETERS RPE ANALYSIS

Parameter	Value
sampling frequency	8 kHz
LP analysis procedure	autocorrelation
order (p)	12
update rate coefficients	10 ms
analysis frame size	25 ms Hamming window
pulse spacing N	4
frane size L	5 ms
weight factor y	0.80

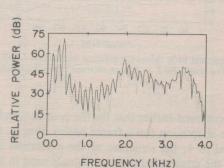

Fig. 6. Power spectra of the original speech segment (solid line) and the reconstructed speech segment (dashed line). The spectra were obtained with a Hamming window using the last 32 ms segment of the data displayed in Fig. 5.

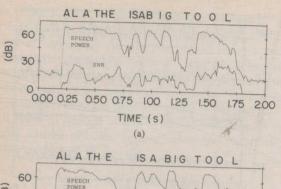

2) pulse spacing N,

3) frame size L, and

4) error weighting filter.

To evaluate the coder behavior, we used a set of default parameter values (see Table I), while the parameter under investigation was varied.

The effects of the predictor parameters in APC-like schemes have been extensively studied in the literature (e.g., [1]), and will not be discussed in detail in this paper. We found that good results were obtained with the autocorrelation method using a Hamming window on 25 ms frames. The predictor coefficients were updated every 20 ms and the predictor order p was chosen to be equal to 12.

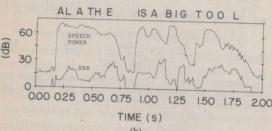

Fig. 7. Segmental SNR for successive time frames for a female speaker (a) and a male speaker (b). The upper curve represents the speech power

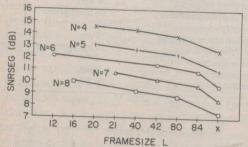

Fig. 8. Segmental SNR values for different frame sizes L and pulse space ings N. The results for L = X were obtained with a fixed value for k and

We mentioned earlier that for the case in which there is no phase adaptation (on a frame basis), that is, k is fixed and equal to 1, the structure of the excitation signal resembles the upsampled residual signals used in BBC coders with spectral folding. This observation can give us a rough estimate of the maximum spacing (N) between the pulses, to ensure a good synthetic speech quality. Assuming a maximum fundamental frequency of 500 Hz, we have to use a sampling rate of minimally 1000 Hz. Hence, for an 8 kHz sampling rate, the pulse spacing should be less than or equal to 8.

To investigate the effect of different frame sizes L and pulse spacings N, we computed the segmental SNR values of the reconstructed speech signals for various values of these parameters. Fig. 8 shows the averaged segmental SNR values for two female and two male speakers1 for different values of N and L. As far as possible, we have chosen the same frame size for different values of N. From this figure, we see that the SNR increases with the number of pulses and decreases with increasing frame size. How-

Fig. 9. RPE excitation patterns with D = 12, L = 24, and N = 3.

TABLE II SNR VALUES FOR DIFFERENT VALUES OF L AND D

L:D	SNRSEG	SNR
20:20	14.58 dB	11 00 17
40:20	14.75 dB	11.80 dE
40:40	14.28 dB	11.90 dF
80:40		11.17 dE
80:80	14.58 dB	11.29 dE
00.00	13.80 dB	10.44 dB

ever, there is no real tradeoff between the values of L and N. Informal listening tests confirmed the ranking as introduced by the SNR measurements. For values of N greater than 5, some of the utterances (especially those by female speakers) sounded distorted. From our experiments, we found that N = 4 and L = 5 ms will give the best results considering the bit rate constraints.

The pulse amplitudes $b^{(k)}(\cdot)$ and phase k are computed every L samples, which means that the phase adaptation rate is equal to 1/L. To investigate the effect of this "disturbance," without changing the size of L, we considered phase adaptation every D samples, where the value of Dis less than or equal to L, and L/D must be an integer ratio. Within a frame of size L, the possible number of excitation sequences is then given by

$$B = N^d, \quad d = L/D. \tag{20}$$

Hence, a value of D smaller than L results in a more complex procedure for the computation of the optimum excitation. Fig. 9 shows the possible excitation patterns for L= 24, D = 12, and N = 3. Table II lists the resulting averaged SNR values for different frame sizes L and ratios L/D = 1 and 2. From this table we see a small improvement in SNR for values of D less than L, at the expense of a much higher complexity.

B. Application of a Pitch Predictor

An examination of the regular-pulse excitation (see, for example, Fig. 5) reveals the periodic structure of the excitation for voiced sounds. Obviously, the RPE algorithm aligns the excitation "grid" to the major pitch pulses, thereby introducing the possibility that the remaining pulses within the grid are not optimally located. If we model the major pitch pulses with a pitch predictor/synthesizer, the remaining excitation sequence can be modeled by the regular-pulse excitation sequence. A simple but effective pitch predictor is the so-called one-tap pre-

$$1 - P(z) = \beta z^{-M}, \tag{21}$$

where M represents the distance between adjacent pitch pulses and β is a gain factor. The pitch predictor parameters can be determined either in an open-loop configuration [11], or in a closed-loop configuration [12]. In the latter case, the parameters can be optimally computed by including a pitch generator 1/P(z) in the closed-loop diagram of Fig. 1. The parameters β and M are determined such that the output of the pitch generator due to its initial state is optimally close (in the weighted sense) to the initial error signal $e^{(0)}(n)$. Once β and M have been deter- Fig. 10. (a) Speech signal s(n), (b) reconstructed speech signal $\hat{s}(n)$, (c) mined, the remaining regular-pulse excitation signal is computed as described in Section II, except that this signal is now to be fed through both the pitch generator and the weighting filter. The advantage of determining the pitch parameters within the analysis loop is that the pitch generator is then optimally contributing to the minimization of the weighted error. To be more specific, let $y_M(n)$ be the response of the pitch generator to an input v(n), which is zero for $n \geq 0$,

$$y_M(n) = v(n) + \beta y_M(n - M).$$
 (22)

Let $z_M(n)$ represent the response of the weighting filter to the input signal $y_M(n)$, defined in (22), and let $e^{(0)}(n)$ represent the initial error as defined in (7). The error to be minimized will then be

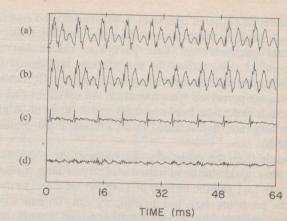

$$E(M, \beta) = \sum_{n} (e^{(0)}(n) - \beta z_{M}(n))^{2}.$$
 (23)

The approach is to compute β for all possible values of Mwithin a specified range, and then select the pair (M, β) for which $E(M, \beta)$ is minimal.

The range of M should be chosen to accommodate to the variation in pitch frequency in the speech signal. However, in simulations with a one-tap predictor using different ranges of M, we found that a range of M between 16 and 80 (i.e., a fundamental frequency between 100 and 470 Hz) is satisfactory. The effect of pitch prediction is demonstrated in Fig. 10, by using the same speech segment as used in Fig. 5. The short-time power spectra of the speech signal s(n) (solid line) and of the error signal $s(n) - \hat{s}(n)$ (dashed line) for $\gamma = 0.80$, without and with pitch filter, are shown in Figs. 11 and 12, respectively. The effect of pitch prediction on the averaged segmental SNR values is shown in Fig. 13. These figures show that the effect of pitch prediction is to decrease the absolute level of noise power and to flatten its spectrum, and thereby improving the performance in terms of SNR. This effect was most noticeable for high-pitched (average pitch ≥250 Hz) speakers.

C. Error Weighting Filter

Although the effect of noise shaping can be heard, the real mechanism behind this effect is not clear. We will not pursue the question whether the proposed noise-shap-

excitation signal (i.e., output of the pitch generator), (d) difference signal $s(n) - \hat{s}(n)$ in the RPE coding procedure with pitch prediction.

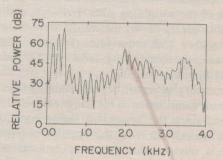

Fig. 11. Power spectra of the speech signal (solid line) and the difference signal $s(n) - \hat{s}(n)$ (dashed line) for $\gamma = 0.80$. The spectra were obtained from the last 32 ms segment of Fig. 5.

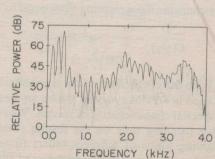

Fig. 12. Power spectra of the speech signal (solid line) and the difference signal $s(n) - \hat{s}(n)$ (dashed line) for $\gamma = 0.80$, and pitch prediction. The spectra were obtained from the last 32 ms segment of Fig. 10.

ing filter of (2) is an effective choice or not, and concen- A. Modification of $H_k H_k^t$ to a Toeplitz Matrix trate instead on the effect of the suggested filter and its control parameter γ . This parameter determines the amount of noise power in the formant regions of the speech spectrum. Noise shaping reduces the SNR, but improves the perceived speech quality. An optimal value for γ was found to be between 0.80 and 0.90 at an 8 kHz sampling rate, and resulted in an average 2 dB decrease be the impulse response of the weighting filter $1/A(z/\gamma)$,

Aside from the value of γ , the order of the noise-shaping filter could also be of importance. By default, the coefof the predictor A(z), but instead, we can compute a qthorder predictor (q < p) and use the resulting q coefficients to define the weighting filter. While reducing the order, we nevertheless must take care that the noise remains properly weighted. We examined the effect of decreasing the order of the weighting filter $1/A(z/\gamma)$, and observed that for low orders (2-4), the results were close to those $H = \begin{bmatrix} 0 & 0 & \cdots & h(L-3) & h(L-2) \end{bmatrix}$ obtained with a 16th-order filter. However, the computational savings obtained by reducing the order of the weighting filter are marginal.

The time-varying nature of the weighting filter provides a significant contribution to the complexity of the analysis procedure, since the system of linear equations to be Notice that the matrix HH' is also a Toeplitz matrix. solved is entirely built on the impulse response of this Moreover, when substituting H from (26) into (8), we filter. It is obvious that the computational complexity shall have that the matrices $H_k H_k^t$ are independent of the would be considerably lower in case a weighting filter phase index k and are equal to a single Toeplitz matrix. could be chosen such that the matrix to be inverted no It should also be remarked that the matrix of (26) is an L

$$\frac{1}{C(z/\gamma)} = \frac{1}{1 + \sum_{k=1}^{9} c_k \gamma^k z^{-k}},$$
 (24)

fixed weighting filters of different orders (q = 1 to 3). spoken by both a male and a female speaker. The value of γ was set to 0.80 and we used for $\{c_k\}$ the coefficients tabulated in [13]. It was surprising to find that B. Modification of $H_k H_k'$ to a Band Matrix the effects of the weighting filters $1/A(z/\gamma)$ and $1/C(z/\gamma)$ In the previous subsection, a computationally attractive were judged to be almost equivalent. This remarkable rescheme was obtained by forcing the matrix operator H to sult can be exploited to dramatically reduce the complex- be of the form of (26). Recall, however, that this structure

V. COMPLEXITY REDUCTION OF THE RPE CODER

the solution of N sets of linear equations, where N repsingle Toeplitz matrix, whether data dependent or not, is resents the spacing between successive pulses within a strongly diagonal dominant. Hence, when minimizing frame in the excitation model. However, the matrices $E^{(k)}$ in (11), where now H is built on $1/C(z/\gamma)$, or equiv- $H_kH_k^t$, which have to be inverted, can be solved very efalently, when maximizing ficiently as was described in [8] and [9]. We shall not pursue the details of this procedure here, but we shall instead look for modifications of the algorithm to reduce the we can conveniently replace the (Toeplitz) matrix $H_k H_k^l$ complexity without affecting the coder performance.

To begin with, we can reconfigure the algorithm to force the matrix product $H_k H_k^t$ in (10) to become a single Toeplitz matrix which is independent of the phase k. Thus,

$$h(n) = \gamma^n g(n), \quad n = 0, 1, 2, \cdots,$$
 (25)

where g(n) is the impulse response of the all-pole filter 1/A(z). For values of $|\gamma|$ less than one, h(n) converges faster to zero than g(n) and, as a result, the L by 2L matrix ficients $\{a_k\}$ and the order p of $1/A(z/\gamma)$ are equal to those built on h(n) can be very well approximated by the uppertriangular Toeplitz matrix H in (26).

$$H = \begin{bmatrix} \overline{h}(0) & h(1) & \cdots & h(L-1) & 0 & \cdots & 0 \\ 0 & h(0) & \cdots & h(L-2) & h(L-1) & 0 \\ 0 & 0 & \cdots & h(L-3) & h(L-2) & \vdots & 0 \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ 0 & 0 & \cdots & h(0) & \cdots & h(L-1) & 0 \end{bmatrix}$$

longer depends on short-time data. It turns out that this is by 2L matrix instead of an L by L. Thus, when substitutpossible by choosing the weighting filter equal to $1/C(z/\gamma)$, ing H of (26) in (7) and (8), the vectors e_0 , $e^{(0)}$, and $e^{(k)}$ in (6) and (7) will now be of length 2L, while the vectors (24) $v^{(k)}$ and r in (4) and (7) remain of dimension L. The RPE encoding procedure that is based on the mapping H in (26), and for which g(n) in (25) is the impulse response where $\{c_k\}$ are the coefficients of the fixed low-order pre- of the transfer function 1/A(z), will be referred to as dictors as used in DPCM systems, which are based on the RPM1. Fig. 14(a) shows the segmental SNR values per averaged spectral characteristics of speech. We carried out 10 ms for this method (dashed line) and the original comparative listening tests on the results obtained with method (solid line) for the utterance "a lathe is a big tool"

ity of the proposed coder, as we will show in the next is almost naturally emerging when the mapping originally defined via (5) is taken to be of dimension L by 2L instead of L by L. This is the more so when h(n) in (26) is the impulse response of the fixed filter $1/C(z/\gamma)$ of (24). But The analysis procedure of the RPE coder necessitates an even more interesting observation is that the resulting

which means that no matrix inversion is needed to find the optimum phase k. Table III lists the SNR and SNRSEG values for the different methods, obtained by averaging the results of the same four utterances used in previous state must be properly taken into account.

examples. Method RPM2 refers to the procedure described in this subsection, where the optimal phase index k is determined from (28), after which the excitation string $b^{(k)}$ is computed according to (10). From this table, we see that the modifications introduced resulted in a slight decrease in SNR. But from informal listening tests, the modified methods were judged to be almost equivalent to the original RPE method. Fig. 14(b) shows the segmental SNR values per 10 ms for RPM2 (dashed lines) and the original method (solid line) for the utterance "a lathe is a big tool" spoken by both a male and a female speaker.

C. Avoiding Matrix Inversion

The discussions in the previous two subsections have led to the conclusion that the complexity of the RPE coder, although moderate by itself, can be substantially reduced without any significant degradation of the speech quality. We shall show in this subsection that it is even possible to obtain an extremely simple encoding algorithm that turns out to yield an applicable practical version of the (conceptual) optimal baseband coder which was described in Section III and was shown there to be equivalent to the RPE coder. Thus, let h(n) in (26) be the impulse response of the time-invariant filter $1/C(z/\gamma)$ as defined in (24). Next, use in (8) the matrix H as defined in (26) and discard the zeroth-order approximation e_0 in (7). Then (6) and (10) become

$$e^{(k)} = rH - b^{(k)}H_k, \tag{29}$$

$$\boldsymbol{b}^{(k)}[\boldsymbol{H}_k \boldsymbol{H}_k^t] = r \boldsymbol{H} \boldsymbol{H}^t \boldsymbol{M}_k^t, \tag{30}$$

respectively. Now denoting

$$S = HH', \tag{31}$$

and recalling that

$$H_k H_k^t \approx r_0 I, \qquad (32)$$

$$r_0 = \sum_{i=0}^{L-1} h^2(i)$$

as a coder constant, it is easy to show that

$$b^{(k)} = \frac{1}{r_0} rSM_k^t. (33)$$

Interpreting M_k^t as a downsampling operator, (33) says that $b^{(k)}$ resembles² a downsampled output of a smoother S whose input is a scaled version of the residual r [see Fig. 15(a)]. The excitation selection in the diagram of Fig. 15(a) is based on the minimization of the approximation error given by (11). Under the above-mentioned constraints, this equation becomes

$$E^{(k)} = rHH^{t}r^{t} - r_{0}b^{(k)}b^{(k)t}.$$
 (34)

²This statement must be carefully interpreted. In fact, (33) is a block smoother, and hence, the boundary conditions of the smoother's internal

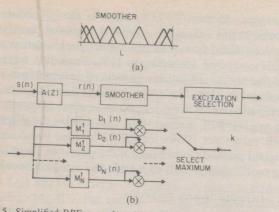

Fig. 15. Simplified RPE procedure (a) and excitation selection (b). The smoother is represented by a triangle shape.

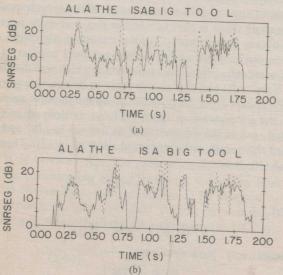

Fig. 16. Segmental SNR for RPF1 procedure (solid line) and RPF2 procedure (dashed line) for a female (a) and a male (b) speaker.

Hence,

$$\min \{E^{(k)}\} = \max \{b^{(k)}b^{(k)'}\}. \tag{35}$$

The whole procedure is now extremely simple. The residual signal r is "smoothed" with the smoother S = HH'. The resulting output vector is downsampled by applying M_k^t , and the $b^{(k)}$ for which $b^{(k)}b^{(k)t}$ is maximum is selected [see Fig. 15(b)]. Notice that since **H** is built on $1/C(z/\gamma)$, the smoother S will be of low order (typically 3rd order), since h(n) is a rapidly decaying sequence. For comparispeaker. From this figure, it is clear that for a fixed weighting filter procedure RPF2 provides a quality com-

VI. QUANTIZATION

To quantize the pulses (i.e., entries of $b^{(k)}$), we used an 8-level adaptive quantizer whose input range was adjusted to the largest pulse amplitude within the current frame of size L. The quantization bins can be determined by a Lloyd-Max procedure (nonuniform), but we found that a uniform quantizer also performs quite well. The quantizer normalization factor is logarithmically encoded with 6 bits and is transmitted every L samples (typically 5 ms). The normalized pulses are encoded using 3 bits per pulse. To minimize quantization errors, the quantizer has to be incorporated in the minimization procedure. This can be done in two ways. In the first case (RPQ1), only the optimal excitation vector is quantized; and in the second case (RPQ2), every candidate $b^{(k)}$ is quantized and the quantized vector that produces a minimum error is selected. From segmental SNR measurements, we found that RPQ2 yields a higher SNR, and in listening tests the quality of the reconstructed speech of RPQ2 was judged to be somewhat better than that of RPQ1.

The 12 reflection coefficients were transformed to inverse sine coefficients and encoded with 44 bits/set. The bit-allocation and quantizer characteristics were determined by the minimum deviation method [14]. Using 3 bits/pulse and a pulse spacing of N = 4, the excitation signal can be encoded with 7 kbits/s. The predictor coefficients can be encoded with 2.2 kbits/s resulting in a total bit rate of 9.2 kbits/s. The quality of the reconstructed speech was judged to be good but definitely not transparent. In informal listening tests, it was determined that the RPE approach has fewer artifacts than the baseband coder as proposed in [4], and that the performance is comparable to that of the MPE schemes. A pitch predictor will enhance the coder performance but goes at the cost of an additional 1000 bits/s (4 bits for β and 6 bits for M).

VII. CONCLUSION

In this paper, a novel coding concept has been proposed that uses linear prediction to remove the short-time correlation in the speech signal. The remaining residual signal is then modeled by a regular (in time) excitation sequence, that resembles an upsampled sequence. This model excitation signal is determined in such a way that the perceptual error between the original and the reconstructed signal is minimized. The computational effort is son, the averaged SNRSEG values obtained with this procedure have been included in Table III. In this table, the error weighting filter and an appropriate vector size (min-RPE coder using a fixed weighting filter is referred to as imization segment length). The coder can produce high-RPF1, while the procedure outlined above is referred to quality speech at bit rates around 9600 bits/s by using a as RPF2. In Fig. 16, the same comparison is made of the pulse spacing equal to 4 and quantizing each pulse with 3 segmental SNR as a function of time for the utterance "a bits. The use of pitch prediction improves the speech lathe is a big tool" spoken by both a male and a female quality but, in general, the RPE coder performs adequately without a pitch predictor. Other applications for the proposed coder can be found in the area of wide-band parable to that of procedure RPF1. The advantage of the speech coding (7 kHz bandwidth) as encountered in teleand video-conferencing applications [15].

APPENDIX

The excitation vector $b^{(k)}$, obtained with the optimized BBC (Section III), coincides with the vector $b^{(k)}$ produced [14] A. H. Gray and J. D. Markel, "Implementation and comparison of by the RPE algorithm (Section II).

Proof: Equation (19) can be written as

$$f^{(k)}\mathbf{R}_{k}[\mathbf{H}_{k}\mathbf{H}_{k}^{t}]\mathbf{R}_{k}^{t}=e^{(0)}\mathbf{H}_{k}^{t}\mathbf{R}_{k}^{t}.$$

Multiplying both sides to the right by R_k gives

$$f^{(k)}R_k[H_kH_k^t]R_k^tR_k = e^{(0)}H_k^tR_k^tR_k.$$

Now assuming that $R_k^t R_k$ is nonsingular (which will almost always be the case for speech signals), we can as

$$f^{(k)}R_k[H_kH_k^t] = e^{(0)}H_k^t.$$

Substituting $b^{(k)}$ for $f^{(k)}R_k$, see (15), in this equation, we

Peter Kroon (S'82-M'86) was born in Vlaardingen, The Netherlands, on September 7, 1957. He received the B.S., M.S., and Ph.D. degrees in electrical engineering from Delft University of Technology, Delft, The Netherlands, in 1978, 1981, and 1985, respectively.

His Ph.D. work focused on time-domain techniques for toll quality speech coding at rates below 16 kbits/s. From 1982 to 1983 he was a Research Assistant at the Network Theory Group, Delft University of Technology. During the years

1984 and 1985 he was sponsored by Philips Research Labs to work on coders suitable for mobile radio applications. He is currently with the Acoustics Research Department, AT&T Bell Laboratories, Murray Hill, NJ. His research interests include speech coding, signal processing, and the development of software for signal processing.

Ed F. Deprettere (M'83) was born in Roeselare, Belgium, on August 10, 1944. He received the M.S. degree from the Gent State University, Gent, Belgium, in 1968, and the Ph.D. degree from Delft University of Technology, Delft, The Netherlands, in 1981.

In 1970 he became a Research Assistant and Lecturer at DUT, where he is now Associate Professor in the Department of Electrical Engineering. His current research interests are in VLSI and signal processing, particularly speech and image processing, filter design and modeling, systolic signal processors, and ma-

trix equation solvers.

Rob J. Sluyter was born in Nijmegen, The Netherlands, on July 12, 1946. In 1968 he graduated in electronic engineering from the Eindhoven Instituut voor Hoger Beroepsonderwijs.

He joined Philips Research Laboratories, Eindhoven, The Netherlands, in 1962. Until 1978 he was a Research Assistant involved in data transmission and low bit rate speech coding. In 1978 he became a Staff Researcher engaged in speech analysis, synthesis, digital coding of speech, and digital signal processing. Since 1982

he has been engaged in research on medium bit rate coding of speech for mobile radio applications as a member of the Digital Signal Processing Group. His current interests are in digital signal processing for television

1986 Index IEEE Transactions on Acoustics, Speech, and Signal Processing Vol. ASSP-34

This index covers all items—papers, correspondence, reviews, etc.—that appeared in this periodical during 1986, and items from prior years that were commented upon or corrected in 1986. The index is divided into an Author Index and a Subject Index, both arranged alphabetically

The Author Index contains the primary entry for each item; this entry is listed under the name of the first author and includes coauthor names, title, location of the item, and notice of corrections and comments if any. Crossreferences are given from each coauthor name to the name of the corresponding first author. The location of the item is specified by the journal name (abbreviated), year, month, and inclusive pages.

The Subject Index contains several entries for each item, each consisting of a subject heading, modifying phrase(s), first author's name—followed by + if the paper has coauthors—and enough information to locate the item. For coauthors, title, comments, and corrections if any, etc., it is necessary to refer to the primary entry in the Author Index. Subject cross-references are provided as required by the subject matter. Also provided whenever appropriate are listings under generic headings such as Bibliographies (for any paper with at least 50 references, as well as papers that are exclusively bibliographies), Book reviews, and Special issues.

AUTHOR INDEX

Abatzoglou, Theagenis J. A fast local maximum likelihood estimator for time delay estimation (Corresp.); T-ASSP Apr 86 375-378

Agarwal, Ramesh C., see Bhattacharya, M., T-ASSP Dec 86 1485-1492

Ahmed, M. S., and K. K. Tahboub. Recursive Wiener filtering for image restoration (Corresp.); T-ASSP Aug 86 990-992

Ahmed, N., and A. Webster. On an adaptive noise cancellation application for radar (Corresp.); T-ASSP Dec 86 1654-1655

Ahmed, Nasir, see Hush, Don R., T-ASSP Dec 86 1380-1390

Alengrin, G., M. Barlaud, and J. Menez. Unbiased parameter estimation of nonstationary signals in noise (Corresp.); T-ASSP Oct 86 1319-1322 Antoniou, Andreas, see Balla, Prabhakara C., T-ASSP Feb 86 60–68 Antoniou, Andreas, see Diniz, Paulo S. R., T-ASSP Aug 86 807–815

Balla, Prabhakara C., Andreas Antoniou, and Salvatore D. Morgera. Higher radix aperiodic-convolution algorithms; *T-ASSP Feb 86* Bapeswara Rao, V. V., and K. Sankara Rao. A new algorithm for real-time median filtering (Corresp.); T-ASSP Dec 86 1674–1675
Bar-Shalom, Yaakov, see Ng, Lawrence C., T-ASSP Aug 86 669–678
Barabell, Arthur J., see Kaveh, Mostafa, T-ASSP Apr 86 331–341.
Barlaud, M., see Alengrin, G., T-ASSP Oct 86 1319–1322

A

Acoustic communication; cf. Underwater acoustic communication Acoustic signal detection

phase-angle estimation from cross-spectral matrix. Vezzosi, Georges, T-ASSP Jun 86 405-422

Acoustic tracking; cf. Sonar tracking Acoustic transducers; cf. Microphones

Adaptive arrays adaptive array algorithms for recursive solution of matrix problems arising in optimal beamforming and direction-finding. Schreiber, Robert, T-ASSP Oct 86 1038–1045

broadband beamforming; generalized sidelobe canceler. Buckley, Kevin M., T-ASSP Oct 86 1322-1323

rophone-array system for noise reduction. Kaneda, Yutaka, +, T-ASSP Dec 86 1391–1400

Adaptive coding subband coding with adaptive predictionn for 56 kb/s audio. Richardson, Edward B., +, T-ASSP Aug 86 691-696

Adaptive equalizers

gradient algorithm with simplified arithmetic for channel equalization. Xue, Ping, +, T-ASSP Dec 86 1603-1611 Adaptive estimation

IIR structure for sinusoidal enhancement, frequency estimation, and detection. Hush, Don R., +, T-ASSP Dec 86 1380–1390

+ Check author entry for coauthors

speech signals; estimation of time-varying ARMA parameters.

Miyanaga, Yoshikazu, + , T-ASSP Jun 86 423-433

Adaptive estimation; cf. Adaptive Kalman filtering

Adaptive filters

adaptive comb filtering for harmonic signal enhancement. Nehorai,
Arye, +, T-ASSP Oct 86 1124-1138

adaptive Gaussian filtering in routine ECG/VCG analysis. Talmon, Jan L., +, T-ASSP Jun 86 527–534

block processing fast-transversal-filter adaptive algorithm. Cioffi, John M., T-ASSP Feb 86 77-90

block realization of multirate adaptive digital filters. Lee, Jae Chon, +, T-ASSP Feb 86 105-117

complex adaptive algorithm for IIR filtering. Shynk, John J., T-ASSP Oct 86 1342-1344

IIR structure for sinusoidal enhancement, frequency estimation, and detection. Hush, Don R., +, T-ASSP Dec 86 1380–1390 nonlinear digital filters using distributed arithmetic. Sicuranza, Giovanni

L., + , T-ASSP Jun 86 518-526 nonlinear quantization effects in frequency-domain complex scalar LMS adaptive algorithm. Sherwood, Douglas T., +, T-ASSP Feb 86 140-151

normalized frequency-domain LMS adaptive algorithm. Bershad, Neil J., +, T-ASSP Jun 86 452-461
normalized least-mean-square adaptive filter algorithm with Gaussian inputs; analysis. Bershad, Neil J., T-ASSP Aug 86 793-806
optimum data nonlinearity in LMS adaptation. Bershad, Neil J., T-ASSP
Ebb 86 60-76 Feb 86 69-76

parameter drift in LMS adaptive filters. Sethares, William A., +, T-ASSP Aug 86 868-879

recursive center-frequency adaptive filters for enhancement of bypass

signals. Raja Kumar, Ratnam V., +, T-ASSP Jun 86 633-637 reply to comments on Comparison of the convergence of two algorithms for adaptive FIR digital filters' by T. A. C. M. Claasen and W. F. G. Mecklenbräucker. Claasen, T. A. C. M., +, T-ASSP Feb 86

Meckienbraucker. Claasen, T. A. C. M., + , T-ASSF Feb 80 202–203 (Original paper, Jun 81 670–678) rotational search methods for adaptive Pisarenko harmonic retrieval. Fuhrmann, Daniel R., + , T-ASSP Dec 86 1550–1565 self-orthogonalizing block adaptive filter (SOBAF) that yields FIR filter

self-orthogonalizing block adaptive filter (SOBAF) that yields FIR filter structures. Panda, Ganapati, +, T-ASSP Dec 86 1573–1582 stochastic operator norms for two-parameter adaptive lattice filters. Sohie, Guy R. L., +, T-ASSP Oct 86 1162–1165 tracking properties and steady-state performance of RLS adaptive filter algorithms. Eleftheriou, Evangelos, +, T-ASSP Oct 86 1097–1110

algorithms. transform-domain LMS adaptive digital filters; performance Lee, Jae Chon, +, T-ASSP Jun 86 499-510

variable-step adaptive filter algorithm; application to FIR and IIR filters. Harris, Richard W., +, T-ASSP Apr 86 309–316 zero-tracking adaptive filters. Orfanidis, Sophocles J., +, T-ASSP Dec

Adaptive Kalman filtering

robust adaptive Kalman filtering for systems with unknown step inputs and non-Gaussian measurement errors. Kirlin, R. Lynn, +, T-ASSP Apr 86 252-263

Adaptive signal detection detecting transient signals of unknown waveform in white Gaussian noise. Porat, Boaz, +, T-ASSP Dec 86 1410-1418

Adaptive signal processing

adaptive interpolation of discrete-time signals that can be modeled as autoregressive processes. Janssen, A. J. E. M., +, T-ASSP Apr 86 317-330

adaptive noise cancellation applied to case where acoustic barrier exists between primary and reference microphones. *Harrison, William* A., + , T-ASSP Feb 86 21-27

book review; Adaptive Signal Processing (Widrow, B., and Stearns, S. D.; 1985). Morgan, Dennis R., T-ASSP Aug 86 1017-1018 recursive estimation algorithm using selective updating for spectral analysis and adaptive signal processing. Huang, Y. F., T-ASSP Oct

86 1331-1334 Adaptive signal processing; cf. Adaptive arrays; Adaptive equalizers; Adaptive filters

Addition optimization of one-bit full adders embedded in regular structures. Iwano, Kazuo, + , T-ASSP Oct 86 1289-1300

Aircraft; cf. Helicopters All-pass circuits

first-order two-dimensional all-pass digital filter realization. Sudhakara Reddy, M., +, T-ASSP Aug 86 1011–1013

Angular position measurement; cf. Direction-finding

unconstrained partitioned realization for derivative-constrained broadband antenna array processors. Er, Meng Hwa, +, T-ASSP
