MICROSURGERY OF SCHLEMM'S CANAL AND THE HUMAN AQUEOUS OUTFLOW SYSTEM

MURRAY A. JOHNSTONE, M.D., AND W. MORTON GRANT, M.D. Boston, Massachusetts

One basis for some of the present approaches to microsurgery of Schlemm's canal is the finding by Grant¹⁻³ that approximately 75% of the resistance of the aqueous outflow system could be eliminated in perfused enucleated human eyes by providing an opening from the anterior chamber into Schlemm's canal by internal trabeculotomy with a cystotome, and that in open-angle. glaucomatous eyes, abnormal resistance could be eliminated in the same way. Much earlier, Barkan^{4,5} showed that open-angle glaucoma could be relieved in adults by an internal trabeculotomy with a goniotomy knife. The effect of the Barkan trabeculotomy procedure appears generally not to have been long lasting. The cystotome laboratory procedure has not been readily adaptable to clinical use, but recently Bietti and Quaranta⁶ have reported clinical successes by internal trabeculotomy with another type of cutting instrument.

Other procedures have been devised and applied clinically with the aim of reducing resistance to aqueous outflow by surgery on Schlemm's canal, in particular ab externo trabeculotomy procedures, but their effects have not been evaluated in the same experimental manner as those of internal cystotome trabeculotomy.

The present study was carried out to compare in postmortem enucleated human eyes the changes induced in the structure and function of the trabecular meshwork and Schlemm's canal aqueous outflow system by

DOCKE

internal cystotome trabeculotomy, by ablexterno probing of Schlemm's canal with nylon and metal probes, and by causing the probes to rupture from the canal into the anterior chamber as in current clinical practice.

PROCEDURES AND METHODS

Quantitative aqueous perfusion-We made measurements before and after experimental dissections as follows. We stored enucleated normal eyes obtained at autopsy at 4°C in a moist environment until 30 minutes prior to perfusion, which was started 4 to 48 hours post mortem. After removal from refrigeration, we placed the eyes in a silicone rubber mold that enveloped the posterior segment to the equator. We covered the anterior segment with absorbent paper saturated in perfusion fluid. An opening 5 mm in diameter was trephined in the center of the cornea to give access to the anterior chamber and the inner angle. Except in one special group of eyes, we regularly performed a radial iridotomy through the tre phine opening to prevent artificial deepening of the chamber. For quantitative aqueous perfusion, we used Bárány's' constant pressure technique, with a commercial, sterile filtered, phosphate-buffered balanced salt solution containing glucose. We infused the so lution into the anterior chamber through a stainless steel fitting (previously described). which sealed the opening in the cornea. We generally measured steady state flow while maintaining intraocular pressure at 15 mm Hg, but in certain instances at 5, 30, or 50 mm Hg. The measurements made before each experimental procedure required approx imately ten minutes of perfusion to attain what appeared to be a steady state, After manipulation or dissection, we carried out similar perfusion and monitored flow rate tor 120 minutes. If the same eye underwent a sec

Hicroscopic morphological methods—For stologic examination, tissues were perused with 4% glutaraldehyde, and small eridional sections containing the angle ructures were excised. We treated these th 1% osmium tetroxide, then they were hydrated in ethyl alcohol and embedded in pon. For light microscopy, we cut sections $| \mu$ and stained them with 1% toluidine

For scanning electron microscopy the tise was fixed for 24 to 48 hours in a solution ntaining equal parts of 10% neutral foralin and 4% glutaraldehyde in Sorensen ISM phosphate buffer (pH 7.2). It was en rinsed in distilled water for one hour, ozen in isopentane, and chilled in a bath of uid nitrogen. The frozen tissue was dehyated for three hours under high vacuum. e coated the freeze-dried tissue with 60% Id and 40%' palladium. Although this tise from stored enucleated eyes was not of quality generally prepared by anatomists rexamination of fine detail, we felt it was value in demonstrating the principal morologic features in control normal eyes and e gross alterations resulting from microssection procedures.

Dissections and surgical manipulations-Internal cystotome trabeculotomy was permed in 180 degrees of the circumference the same manner as by Grant^{1,2} and by lingsen and Grant.⁸ This was done rough the 5-mm corneal trephine opening der direct visualization with an operating Moscope at 25 to $40 \times$ magnification, emwing a cystotome with the point oriented fight angles to the shaft. We inserted the ont from within the anterior chamber wough the trabecular meshwork to Hilemm's canal, and passed it along in the anal circumferentially, with the blunt surface of the cystotome facing the external wall of Schlemm's canal. In this position it presented a triangular shape with its base facing the external wall of Schlemm's canal, and a sharp slanting edge engaging the trabecular meshwork. This was intended to cut the inner wall of the canal and the trabecular sheets from within the canal while limiting damage to the external wall of the canal. Usually the cystotome pushed a strip of meshwork ahead of itself in the manner of a plow.

2. We performed ab externo trabeculotomy and other ab externo surgical manipulations on excised human eyes in a manner similar to that employed by Dannheim and Harms in patients. A 4 \times 4-mm lamellar scleral flap hinged at the cornea was dissected to include approximately two thirds of the thickness of the sclera. With this flap reflected, we localized Schlemm's canal under the operating microscope, guided by the anatomic landmarks of gray corneoscleral transition zone and by use of a transilluminator to demonstrate the position of the scleral spur. The transilluminator was most helpful when applied to the outer surface of the globe just anterior to the limbus, diametrically opposite the site of dissection. This caused the structures anterior to the insertion of the ciliary body into the sclera to appear brightly illuminated, while those posterior were dark. A bright distinct line of demarcation, which was characteristically seen in the posterior part of the gray transition zone, provided a particularly reliable guide to localization of Schlemm's canal. We then made an opening in the outer wall of the canal to permit insertion of probes circumferentially in the canal. The ab externo dissections involved either three or six hours of the superior circumference, with no attempt at selection of quadrants. During the whole procedure, we maintained the intraocular pressure in the eyes at 15 mm Hg through connection with a reservoir of perfusion fluid. After we completed the experimental manipulations, we sutured the scleral flap

chamber.

tightly back in place with six 8-0 silk sutures. Testing with fluorescein added to the perfusion fluid established that we obtained a reliably leak-free closure in this way. The following experimental manipulations were performed.

2A. Ab externo, we made a nylon suture of 0.13-mm diameter slide circumferentially in the canal for 15 mm, and in some eyes the suture was pulled taut to rupture the trabecular meshwork in the manner described by Redmond Smith.^{9,10}

2B. We performed ab externo probe trabeculotomy with a curved hairpin probe (0.275-mm diameter) of the type described by Dannheim and Harms,11 inserting it circumferentially within Schlemm's canal and then rotating it to rupture through trabecular meshwork into the anterior chamber. We attempted to swing the probe in a plane that would cause disruption nearer to scleral spur than Schwalbe's line. In certain instances after this type of trabeculotomy had been completed, we performed an additional dissection in which we removed persisting flaps of trabecular meshwork with jeweler's forceps under direct view with the operating microscope through the corneal trephine opening.

2C. We performed ab externo diathermy probe trabeculotomy with a special probe devised by Ellingsen. This was made from hard stainless steel wire, 0.175-mm diameter, conforming to the basic curved hairpin design of Dannheim and Harms, but insulated with a 0.05-mm coating of TFE Teflon. We stripped the insulating Teflon coating from along that side of the probe that was to come into contact with the trabecular meshwork side of Schlemm's canal. The external wire handle was left bare. With the probe in the canal, a diathermy electrode was touched to the handle to carry cutting diathermy current through the probe to the bared portion facing the trabecular meshwork. We applied two to three bursts of diathermy of 0.5- to 1second duration so the probe could be rotated into Schlemm's canal with no mechanical resistance.

reveal undisturbed structures within Schlemm's canal and along the external wall, but this required careful cutting, because some of the tissues within the canal were firmly adherent to the trabecular meshwork. Scanning electron micorscopy of the opened canal in normal eyes revealed thick structures consisting of nonfibrillar homogeneous tissue extending at a slightly oblique angle along the canal, joining a ridge of tissue along the external wall, as shown in Figure 2. These structures seemed to represent septa previously firmly adherent to trabecu-

lar meshwork. The prominent ridges along the posterior portion of the external wall, which were joined by septa, ran in a circumferential fashion at a slightly oblique angle. An infolding was present along the posterior border of the ridges forming a narrow zone of discontinuity. Several deep clefts, apparently representing collector channel entrances, were visible at intervals along this line of discontinuity.

RESULTS OF EXPERIMENTAL PROCEDURES

1. Trabeculotomy performed internally with a cystotome in half the circumference caused a marked increase in outflow in each of five eyes, as recorded in Table 2. During 120 minutes of perfusion after trabeculotomy, the rate of flow generally remained high, with only a slight tendency to decrease toward pretrabeculotomy values, as shown in Figure 1 where mean values for the group are plotted.

As observed through the operating microscope, the cystotome generally passed along near the scleral spur, tending to push trabecular tissue ahead of it, but usually leaving the anterior portion of the trabecular meshwork in place. The residual material was rather ragged and what was exposed of the external wall of the canal had an irregular pattern.

From light microscopy of histologic sections (Fig. 3) it was evident that in addition to disruption of the trabecular meshwork the cystotome trabeculotomy caused damage to endothelium of the external wall of Schlemm's canal, disruption of septa, and splitting along the posterior wall of the canal. Scanning electron microscopy (Fig. 4) showed that a strip of trabecular meshwork was pulled from its attachments and moved ahead of the cystotome, leaving structures within the canal in a configuration suggesting that prior to disruption they had been drawn away from the external wall.

Ab externo procedures on Schlemm's canal gave the following results.

2A. Ab externo insertion of a nylon su ture circumferentially in Schlemm's canal was accomplished without difficulty, and although the suture had a diameter of only 0.13 mm compared with the 0.275 mm of the steel trabeculotomy probe, it stretched and distorted the walls of the canal. Light microscopy of sections after insertion of the suture showed damage to the trabecular mesh work, to the endothelium of both the internal and external walls, compression of scleral la mellae along the external wall, and splitting
