1 COMPUTER VISION **1**

- 1.1 Achieving Simple Vision Goals 1
- 1.2 High-Level and Low-Level Capabilities 2
- 1.3 A Range of Representations 6
- 1.4 The Role of Computers 9
- 1.5 Computer Vision Research and Applications 12

v

Part I
GENERALIZED IMAGES
13

2 IMAGE FORMATION 17

- 2.1 Images 17
- 2.2 Image Model 18
 - 2.2.1 Image Functions, 18
 - 2.2.2 Imaging Geometry, 19
 - 2.2.3 Reflectance, 22
 - 2.2.4 Spatial Properties, 24
 - 2.2.5 Color, 31
 - 2.2.6 Digital Images, 35
- 2.3 Imaging Devices for Computer Vision 42
 - 2.3.1 Photographic Imaging, 44
 - 2.3.2 Sensing Range, 52
 - 2.3.3 Reconstruction Imaging, 56

3 EARLY PROCESSING 63

- 3.1 Recovering Intrinsic Structure 63
- 3.2 Filtering the Image 65
 - 3.2.1 Template Matching, 65
 - 3.2.2 Histogram Transformations, 70
 - 3.2.3 Background Subtraction, 72
 - 3.2.4 Filtering and Reflectance Models, 73
- 3.3 Finding Local Edges 75
 - 3.3.1 Types of Edge Operators, 76
 - 3.3.2 Edge Thresholding Strategies, 80
 - 3.3.3 Three-Dimensional Edge Operators, 81
 - 3.3.4 How Good Are Edge Operators? 83
 - 3.3.5 Edge Relaxation, 85
- 3.4 Range Information from Geometry 88
 - 3.4.1 Stereo Vision and Triangulation, 88
 - 3.4.2 A Relaxation Algorithm for Stereo, 89
- 3.5 Surface Orientation from Reflectance Models 93
 - 3.5.1 Reflectivity Functions, 93
 - 3.5.2 Surface Gradient, 95
 - 3.5.3 Photometric Stereo, 98
 - 3.5.4 Shape from Shading by Relaxation, 99
- 3.6 Optical Flow 102
 - 3.6.1 The Fundamental Flow Constraint, 102
 - 3.6.2 Calculating Optical Flow by Relaxation, 103
- 3.7 Resolution Pyramids 106
 - 3.7.1 Gray-Level Consolidation, 106
 - 3.7.2 Pyramidal Structures in Correlation, 107
 - 3.7.3 Pyramidal Structures in Edge Detection, 109

PART II SEGMENTED IMAGES 115

4	BOUNDARY DETECTION	119
4.1	On Associating Edge Elements	119
4.2	Searching Near an Approximate Location	121
4.2.1	Adjusting A Priori Boundaries,	121
4.2.2	Non-Linear Correlation in Edge Space,	121
4.2.3	Divide-and-Conquer Boundary Detection,	122
4.3	The Hough Method for Curve Detection	123
4.3.1	Use of the Gradient,	124
4.3.2	Some Examples,	125
4.3.3	Trading Off Work in Parameter Space for Work in Image Space,	126
4.3.4	Generalizing the Hough Transform,	128
4.4	Edge Following as Graph Searching	131
4.4.1	Good Evaluation Functions,	133
4.4.2	Finding All the Boundaries,	133
4.4.3	Alternatives to the A Algorithm,	136
4.5	Edge Following as Dynamic Programming	137
4.5.1	Dynamic Programming,	137
4.5.2	Dynamic Programming for Images,	139
4.5.3	Lower Resolution Evaluation Functions,	141
4.5.4	Theoretical Questions about Dynamic Programming,	143
4.6	Contour Following	143
4.6.1	Extension to Gray-Level Images,	144
4.6.2	Generalization to Higher-Dimensional Image Data,	146
5	REGION GROWING	149
5.1	Regions	149
5.2	A Local Technique: Blob Coloring	151
5.3	Global Techniques: Region Growing via Thresholding	152
5.3.1	Thresholding in Multidimensional Space,	153
5.3.2	Hierarchical Refinement,	155
5.4	Splitting and Merging	155
5.4.1	State-Space Approach to Region Growing,	157
5.4.2	Low-Level Boundary Data Structures,	158
5.4.3	Graph-Oriented Region Structures,	159
5.5	Incorporation of Semantics	160
6	TEXTURE	166
6.1	What Is Texture?	166
6.2	Texture Primitives	169

6.3	Structural Models of Texel Placement	170
6.3.1	Grammatical Models,	172
6.3.2	Shape Grammars,	173
6.3.3	Tree Grammars,	175
6.3.4	Array Grammars,	178
6.4	Texture as a Pattern Recognition Problem	181
6.4.1	Texture Energy,	184
6.4.2	Spatial Gray-Level Dependence,	186
6.4.3	Region Texels,	188
6.5	The Texture Gradient	189

7 MOTION 195

7.1	Motion Understanding	195
7.1.1	Domain-Independent Understanding,	196
7.1.2	Domain-Dependent Understanding,	196
7.2	Understanding Optical Flow	199
7.2.1	Focus of Expansion,	199
7.2.2	Adjacency, Depth, and Collision,	201
7.2.3	Surface Orientation and Edge Detection,	202
7.2.4	Egomotion,	206
7.3	Understanding Image Sequences	207
7.3.1	Calculating Flow from Discrete Images,	207
7.3.2	Rigid Bodies from Motion,	210
7.3.3	Interpretation of Moving Light Displays—A Domain-Independent Approach,	214
7.3.4	Human Motion Understanding—A Model- Directed Approach,	217
7.3.5	Segmented Images,	220

Part III GEOMETRICAL STRUCTURES 227

8 REPRESENTATION OF TWO-DIMENSIONAL GEOMETRIC STRUCTURES 231

8.1	Two-Dimensional Geometric Structures	231
8.2	Boundary Representations	232
8.2.1	Polylines,	232
8.2.2	Chain Codes,	235
8.2.3	The Ψ -s Curve,	237
8.2.4	Fourier Descriptors,	238
8.2.5	Conic Sections,	239
8.2.6	B-Splines,	239
8.2.7	Strip Trees,	244

- 8.3 Region Representations 247
 - 8.3.1 Spatial Occupancy Array, 247
 - 8.3.2 y Axis, 248
 - 8.3.3 Quad Trees, 249
 - 8.3.4 Medial Axis Transform, 252
 - 8.3.5 Decomposing Complex Areas, 253
- 8.4 Simple Shape Properties 254
 - 8.4.1 Area, 254
 - 8.4.2 Eccentricity, 255
 - 8.4.3 Euler Number, 255
 - 8.4.4 Compactness, 256
 - 8.4.5 Slope Density Function, 256
 - 8.4.6 Signatures, 257
 - 8.4.7 Concavity Tree, 258
 - 8.4.8 Shape Numbers, 258

9 REPRESENTATION OF THREE-DIMENSIONAL STRUCTURES

264

- 9.1 Solids and Their Representation 264
- 9.2 Surface Representations 265
 - 9.2.1 Surfaces with Faces, 265
 - 9.2.2 Surfaces Based on Splines, 268
 - 9.2.3 Surfaces That Are Functions on the Sphere, 270
- 9.3 Generalized Cylinder Representations 274
 - 9.3.1 Generalized Cylinder Coordinate Systems and Properties, 275
 - 9.3.2 Extracting Generalized Cylinders, 278
 - 9.3.3 A Discrete Volumetric Version of the Skeleton, 279
- 9.4 Volumetric Representations 280
 - 9.4.1 Spatial Occupancy, 280
 - 9.4.2 Cell Decomposition, 281
 - 9.4.3 Constructive Solid Geometry, 282
 - 9.4.4 Algorithms for Solid Representations, 284
- 9.5 Understanding Line Drawings 291
 - 9.5.1 Matching Line Drawings to Three-Dimensional Primitives, 293
 - 9.5.2 Grouping Regions Into Bodies, 294
 - 9.5.3 Labeling Lines, 296
 - 9.5.4 Reasoning About Planes, 301

Part IV RELATIONAL STRUCTURES 313

10 KNOWLEDGE REPRESENTATION AND USE

317

- 10.1 Representations 317
 - 10.1.1 The Knowledge Base—Models and Processes, 318

10.1.2	Analogical and Propositional Representations,	319
10.1.3	Procedural Knowledge,	321
10.1.4	Computer Implementations,	322
10.2	Semantic Nets	323
10.2.1	Semantic Net Basics,	323
10.2.2	Semantic Nets for Inference,	327
10.3	Semantic Net Examples	334
10.3.1	Frame Implementations,	334
10.3.2	Location Networks,	335
10.4	Control Issues in Complex Vision Systems	340
10.4.1	Parallel and Serial Computation,	341
10.4.2	Hierarchical and Heterarchical Control,	341
10.4.3	Belief Maintenance and Goal Achievement,	346

11 MATCHING

352

11.1	Aspects of Matching	352
11.1.1	Interpretation: Construction, Matching, and Labeling	352
11.1.2	Matching Iconic, Geometric, and Relational Structures,	353
11.2	Graph-Theoretic Algorithms	355
11.2.1	The Algorithms,	357
11.2.2	Complexity,	359
11.3	Implementing Graph-Theoretic Algorithms	360
11.3.1	Matching Metrics,	360
11.3.2	Backtrack Search,	363
11.3.3	Association Graph Techniques,	365
11.4	Matching in Practice	369
11.4.1	Decision Trees,	370
11.4.2	Decision Tree and Subgraph Isomorphism,	375
11.4.3	Informal Feature Classification,	376
11.4.4	A Complex Matcher,	378

12 INFERENCE

383

12.1	First-Order Predicate Calculus	384
12.1.1	Clause-Form Syntax (Informal),	384
12.1.2	Nonclausal Syntax and Logic Semantics (Informal),	385
12.1.3	Converting Nonclausal Form to Clauses,	387
12.1.4	Theorem Proving,	388
12.1.5	Predicate Calculus and Semantic Networks,	390
12.1.6	Predicate Calculus and Knowledge Representation,	392
12.2	Computer Reasoning	395
12.3	Production Systems	396
12.3.1	Production System Details,	398
12.3.2	Pattern Matching,	399

- 12.3.3 An Example, 401
- 12.3.4 Production System Pros and Cons, 406
- 12.4 Scene Labeling and Constraint Relaxation 408
 - 12.4.1 Consistent and Optimal Labelings, 408
 - 12.4.2 Discrete Labeling Algorithms, 410
 - 12.4.3 A Linear Relaxation Operator and a Line-Labeling Example, 415
 - 12.4.4 A Nonlinear Operator, 419
 - 12.4.5 Relaxation as Linear Programming, 420
- 12.5 Active Knowledge 430
 - 12.5.1 Hypotheses, 431
 - 12.5.2 HOW-TO and SO-WHAT Processes, 431
 - 12.5.3 Control Primitives, 431
 - 12.5.4 Aspects of Active Knowledge, 433

13 GOAL ACHIEVEMENT

438

- 13.1 Symbolic Planning 439
 - 13.1.1 Representing the World, 439
 - 13.1.2 Representing Actions, 441
 - 13.1.3 Stacking Blocks, 442
 - 13.1.4 The Frame Problem, 444
- 13.2 Planning with Costs 445
 - 13.2.1 Planning, Scoring, and Their Interaction, 446
 - 13.2.2 Scoring Simple Plans, 446
 - 13.2.3 Scoring Enhanced Plans, 451
 - 13.2.4 Practical Simplifications, 452
 - 13.2.5 A Vision System Based on Planning, 453

APPENDICES

465

A1 SOME MATHEMATICAL TOOLS

465

- A1.1 Coordinate Systems 465
 - A1.1.1 Cartesian, 465
 - A1.1.2 Polar and Polar Space, 465
 - A1.1.3 Spherical and Cylindrical, 466
 - A1.1.4 Homogeneous Coordinates, 467
- A1.2 Trigonometry 468
 - A1.2.1 Plane Trigonometry, 468
 - A1.2.2 Spherical Trigonometry, 469
- A1.3 Vectors 469
- A1.4 Matrices 471
- A1.5 Lines 474
 - A1.5.1 Two Points, 474
 - A1.5.2 Point and Direction, 474
 - A1.5.3 Slope and Intercept, 474

A1.5.4	Ratios, 474	
A1.5.5	Normal and Distance from Origin (Line Equation), 475	
A1.5.6	Parametric, 476	
A1.6	Planes	476
A1.7	Geometric Transformations	477
A1.7.1	Rotation, 477	
A1.7.2	Scaling, 478	
A1.7.3	Skewing, 479	
A1.7.4	Translation, 479	
A1.7.5	Perspective, 479	
A1.7.6	Transforming Lines and Planes, 480	
A1.7.7	Summary, 480	
A1.8	Camera Calibration and Inverse Perspective	481
A1.8.1	Camera Calibration, 482	
A1.8.2	Inverse Perspective, 483	
A1.9	Least-Squared-Error Fitting	484
A1.9.1	Pseudo-Inverse Method, 485	
A1.9.2	Principal Axis Method, 486	
A1.9.3	Fitting Curves by the Pseudo-Inverse Method, 487	
A1.10	Conics	488
A1.11	Interpolation	489
A1.11.1	One-Dimensional, 489	
A1.11.2	Two-Dimensional, 490	
A1.12	The Fast Fourier Transform	490
A1.13	The Icosahedron	492
A1.14	Root Finding	493

A2 ADVANCED CONTROL MECHANISMS 497

A2.1	Standard Control Structures	497
A2.1.1	Recursion, 498	
A2.1.2	Co-Routing, 498	
A2.2	Inherently Sequential Mechanisms	499
A2.2.1	Automatic Backtracking, 499	
A2.2.2	Context Switching, 500	
A2.3	Sequential or Parallel Mechanisms	500
A2.3.1	Modules and Messages, 500	
A2.3.2	Priority Job Queue, 502	
A2.3.3	Pattern-Directed Invocation, 504	
A2.3.4	Blackboard Systems, 505

SUBJECT INDEX 513

Preface

The dream of intelligent automata goes back to antiquity; its first major articulation in the context of digital computers was by Turing around 1950. Since then, this dream has been pursued primarily by workers in the field of *artificial intelligence*, whose goal is to endow computers with information-processing capabilities comparable to those of biological organisms. From the outset, one of the goals of artificial intelligence has been to equip machines with the capability of dealing with sensory inputs.

Computer vision is the construction of explicit, meaningful descriptions of physical objects from images. Image understanding is very different from image processing, which studies image-to-image transformations, not explicit description building. Descriptions are a prerequisite for recognizing, manipulating, and thinking about objects.

We perceive a world of coherent three-dimensional objects with many invariant properties. Objectively, the incoming visual data do not exhibit corresponding coherence or invariance; they contain much irrelevant or even misleading variation. Somehow our visual system, from the retinal to cognitive levels, understands, or imposes order on, chaotic visual input. It does so by using *intrinsic information* that may reliably be extracted from the input, and also through assumptions and *knowledge* that are applied at various levels in visual processing.

The challenge of computer vision is one of *explicitness*. Exactly what information about scenes can be extracted from an image using only very basic assumptions about physics and optics? Explicitly, what computations must be performed? Then, at what stage must domain-dependent, prior knowledge about the world be incorporated into the understanding process? How are world models and knowledge represented and used? This book is about the representations and mechanisms that allow image information and prior knowledge to interact in image understanding.

Computer vision is a relatively new and fast-growing field. The first experiments were conducted in the late 1950s, and many of the essential concepts

have been developed during the last five years. With this rapid growth, crucial ideas have arisen in disparate areas such as artificial intelligence, psychology, computer graphics, and image processing. Our intent is to assemble a selection of this material in a form that will serve both as a senior/graduate-level academic text and as a useful reference to those building vision systems. This book has a strong artificial intelligence flavor, and we hope this will provoke thought. We believe that both the intrinsic image information and the internal model of the world are important in successful vision systems.

The book is organized into four parts, based on descriptions of objects at four different levels of abstraction.

1. Generalized images—images and image-like entities.
2. Segmented images—images organized into subimages that are likely to correspond to “interesting objects.”
3. Geometric structures—quantitative models of image and world structures.
4. Relational structures—complex symbolic descriptions of image and world structures.

The parts follow a progression of increasing abstractness. Although the four parts are most naturally studied in succession, they are not tightly interdependent. Part I is a prerequisite for Part II, but Parts III and IV can be read independently.

Parts of the book assume some mathematical and computing background (calculus, linear algebra, data structures, numerical methods). However, throughout the book mathematical rigor takes a backseat to concepts. Our intent is to transmit a set of ideas about a new field to the widest possible audience.

In one book it is impossible to do justice to the scope and depth of prior work in computer vision. Further, we realize that in a fast-developing field, the rapid influx of new ideas will continue. We hope that our readers will be challenged to think, criticize, read further, and quickly go beyond the confines of this volume.

D. H. Ballard
C. M. Brown

Acknowledgments

Jerry Feldman and Herb Voelcker (and through them the University of Rochester) provided many resources for this work. One of the most important was a capable and forgiving staff (secretarial, technical, and administrative). For massive text editing, valuable advice, and good humor we are especially grateful to Rose Peet. Peggy Meeker, Jill Orioli, and Beth Zimmerman all helped at various stages.

Several colleagues made suggestions on early drafts: thanks to James Allen, Norm Badler, Larry Davis, Takeo Kanade, John Kender, Daryl Lawton, Joseph O'Rourke, Ari Requicha, Ed Riseman, Azriel Rosenfeld, Mike Schneier, Ken Sloan, Steve Tanimoto, Marty Tenenbaum, and Steve Zucker.

Graduate students helped in many different ways: thanks especially to Michel Denber, Alan Frisch, Lydia Hrechanyk, Mark Kahrs, Keith Lantz, Joe Maleson, Lee Moore, Mark Peairs, Don Perlis, Rick Rashid, Dan Russell, Dan Sabbah, Bob Schudy, Peter Selfridge, Uri Shani, and Bob Tilove. Bernhard Stuth deserves special mention for much careful and critical reading.

Finally, thanks go to Jane Ballard, mostly for standing steadfast through the cycles of elation and depression and for numerous engineering-to-English translations.

As Pat Winston put it: "A willingness to help is not an implied endorsement." The aid of others was invaluable, but we alone are responsible for the opinions, technical details, and faults of this book.

Funding assistance was provided by the Sloan Foundation under Grant 78-4-15, by the National Institutes of Health under Grant HL21253, and by the Defense Advanced Research Projects Agency under Grant N00014-78-C-0164.

The authors wish to credit the following sources for figures and tables. For complete citations given here in abbreviated form (as "from . . ." or "after . . ."), refer to the appropriate chapter-end references.

Computer Vision

1

Computer Vision Issues

1.1 ACHIEVING SIMPLE VISION GOALS

Suppose that you are given an aerial photo such as that of Fig. 1.1a and asked to locate ships in it. You may never have seen a naval vessel in an aerial photograph before, but you will have no trouble predicting generally how ships will appear. You might reason that you will find no ships inland, and so turn your attention to ocean areas. You might be momentarily distracted by the glare on the water, but realizing that it comes from reflected sunlight, you perceive the ocean as continuous and flat. Ships on the open ocean stand out easily (if you have seen ships from the air, you know to look for their wakes). Near the shore the image is more confusing, but you know that ships close to shore are either moored or docked. If you have a map (Fig. 1.1b), it can help locate the docks (Fig. 1.1c); in a low-quality photograph it can help you identify the shoreline. Thus it might be a good investment of your time to establish the correspondence between the map and the image. A search parallel to the shore in the dock areas reveals several ships (Fig. 1.1d).

Again, suppose that you are presented with a set of computer-aided tomographic (CAT) scans showing “slices” of the human abdomen (Fig. 1.2a). These images are products of high technology, and give us views not normally available even with x-rays. Your job is to reconstruct from these cross sections the three-dimensional shape of the kidneys. This job may well seem harder than finding ships. You first need to know what to look for (Fig. 1.2b), where to find it in CAT scans, and how it looks in such scans. You need to be able to “stack up” the scans mentally and form an internal model of the shape of the kidney as revealed by its slices (Fig. 1.2c and 1.2d).

This book is about *computer vision*. These two example tasks are typical com-

1

puter vision tasks; both were solved by computers using the sorts of knowledge and techniques alluded to in the descriptive paragraphs. Computer vision is the enterprise of automating and integrating a wide range of processes and representations used for vision perception. It includes as parts many techniques that are useful by themselves, such as *image processing* (transforming, encoding, and transmitting images) and *statistical pattern classification* (statistical decision theory applied to general patterns, visual or otherwise). More importantly for us, it includes techniques for geometric modeling and cognitive processing.

1.2 HIGH-LEVEL AND LOW-LEVEL CAPABILITIES

The examples of Section 1.1 illustrate vision that uses *cognitive processes*, *geometric models*, *goals*, and *plans*. These *high-level* processes are very important; our examples only weakly illustrate their power and scope. There surely would be some overall purpose to finding ships; there might be collateral information that there were submarines, barges, or small craft in the harbor, and so forth. CAT scans would be used with several diagnostic goals in mind and an associated medical history available. Goals and knowledge are high-level capabilities that can guide visual activities, and a visual system should be able to take advantage of them.

(c)

(d)

Fig. 1.1 (cont.)

Even such elaborated tasks are very special ones and in their way easier to think about than the commonplace visual perceptions needed to pick up a baby, cross a busy street, or arrive at a party and quickly “see” who you know, your host’s taste in decor, and how long the festivities have been going on. All these tasks require judgment and large amounts of knowledge of objects in the world, how they look, and how they behave. Such high-level powers are so well integrated into “vision” as to be effectively inseparable.

Knowledge and goals are only part of the vision story. Vision requires many *low-level* capabilities we often take for granted; for example, our ability to extract *intrinsic images* of “lightness,” “color,” and “range.” We perceive black as black in a complex scene even when the lighting is such that some black patches are reflecting more light than some white patches. Similarly, perceived colors are not related simply to the wavelengths of reflected light; if they were, we would consciously see colors changing with illumination. Stereo fusion (stereopsis) is a low-level facility basic to short-range three-dimensional perception.

An important low-level capability is *object perception*: for our purposes it does not really matter if this talent is innate, (“hard-wired”), or if it is developmental or even learned (“compiled-in”). The fact remains that mature biological vision systems are specialized and tuned to deal with the relevant objects in their environ-

(a)

(c)

(b)

(d)

ments. Further specialization can often be learned, but it is built on basic immutable assumptions about the world which underlie the vision system.

A basic sort of object recognition capability is the “figure/ground” discrimination that separates objects from the “background.” Other basic organizational predispositions are revealed by the “Gestalt laws” of clustering, which demonstrate rules our vision systems use to form simple arrays of stimuli into more coherent spatial groups. A dramatic example of specialized object perception for

human beings is revealed in our “face recognition” capability, which seems to occupy a large volume of brain matter. Geometric visual illusions are more surprising symptoms of nonintuitive processing that is performed by our vision systems, either for some direct purpose or as a side effect of its specialized architecture. Some other illusions clearly reflect the intervention of high-level knowledge. For instance, the familiar “Necker cube reversal” is grounded in our three-dimensional models for cubes.

Low-level processing capabilities are elusive; they are unconscious, and they are not well connected to other systems that allow direct introspection. For instance, our visual memory for images is quite impressive, yet our quantitative verbal descriptions of images are relatively primitive. The biological visual “hardware” has been developed, honed, and specialized over a very long period. However, its organization and functionality is not well understood except at extreme levels of detail and generality—the behavior of small sets of cat or monkey cortical cells and the behavior of human beings in psychophysical experiments.

Computer vision is thus immediately faced with a very difficult problem; it must reinvent, with general digital hardware, the most basic and yet inaccessible talents of specialized, parallel, and partly analog biological visual systems. Figure 1.3 may give a feeling for the problem; it shows two visual renditions of a familiar subject. The inset is a normal image, the rest is a plot of the intensities (gray levels) in the image against the image coordinates. In other words, it displays information

Fig. 1.3 Two representations of an image. One is directly accessible to our low-level processes; the other is not.

with “height” instead of “light.” No information is lost, and the display is an image-like object, but we do not immediately see a face in it. The initial representation the computer has to work with is no better; it is typically just an array of numbers from which human beings could extract visual information only very painfully. Skipping the low-level processing we take for granted turns normally effortless perception into a very difficult puzzle.

Computer vision is vitally concerned with both low-level or “early processing” issues and with the high-level and “cognitive” use of knowledge. Where does vision leave off and reasoning and motivation begin? We do not know precisely, but we firmly believe (and hope to show) that powerful, cooperating, rich representations of the world are needed for any advanced vision system. Without them, no system can derive relevant and invariant information from input that is beset with ever-changing lighting and viewpoint, unimportant shape differences, noise, and other large but irrelevant variations. These representations can remove some computational load by predicting or assuming structure for the visual world.

Finally, if a system is to be successful in a variety of tasks, it needs some “meta-level” capabilities: it must be able to model and reason about its own goals and capabilities, and the success of its approaches. These complex and related models must be manipulated by cognitive-like techniques, even though introspectively the perceptual process does not always “feel” to us like cognition.

Computer Vision Systems

1.3 A RANGE OF REPRESENTATIONS

Visual perception is the relation of visual input to previously existing *models* of the world. There is a large representational gap between the image and the models (“ideas,” “concepts”) which explain, describe, or abstract the image information. To bridge that gap, computer vision systems usually have a (loosely ordered) *range of representations* connecting the input and the “output” (a final description, decision, or interpretation). Computer vision then involves the design of these intermediate representations and the implementation of algorithms to construct them and relate them to one another.

We broadly categorize the representations into four parts (Fig. 1.4) which correspond with the organization of this volume. Within each part there may be several layers of representation, or several cooperating representations. Although the sets of representations are loosely ordered from “early” and “low-level” *signals* to “late” and “*cognitive*” symbols, the actual flow of effort and information between them is not unidirectional. Of course, not all levels need to be used in each computer vision application; some may be skipped, or the processing may start partway up the hierarchy or end partway down it.

Generalized images (Part I) are *iconic* (image-like) and *analogical* representations of the input data. Images may initially arise from several technologies.

(a)

(b)

(c)

Fig. 1.4 Examples of the four categories of representation used in computer vision. (a) Iconic; (b) segmented; (c) geometric; (d) relational.

Domain-independent processing can produce other iconic representations more directly useful to later processing, such as arrays of *edge elements* (gray-level discontinuities). *Intrinsic images* can sometimes be produced at this level—they reveal physical properties of the imaged scene (such as surface orientations, range, or surface reflectance). Often *parallel processing* can produce generalized images. More generally, most “low-level” processes can be implemented with parallel computation.

Segmented images (Part II) are formed from the generalized image by gathering its elements into sets likely to be associated with meaningful *objects* in the scene. For instance, segmenting a scene of planar polyhedra (blocks) might result in a set of *edge segments* corresponding to polyhedral edges, or a set of two-

(d)

Fig. 1.4 (cont.)

dimensional *regions* in the image corresponding to polyhedral faces. In producing the segmented image, knowledge about the particular domain at issue begins to be important both to save computation and to overcome problems of *noise* and inadequate data. In the planar polyhedral example, it helps to know beforehand that the line segmentations must be straight. *Texture* and *motion* are known to be very important in segmentation, and are currently topics of active research; knowledge in these areas is developing very fast.

Geometric representations (Part III) are used to capture the all-important idea

of two-dimensional and three-dimensional *shape*. Quantifying shape is as important as it is difficult. These geometric representations must be powerful enough to support complex and general processing, such as “simulation” of the effects of lighting and motion. Geometric structures are as useful for encoding previously acquired knowledge as they are for re-representing current visual input. Computer vision requires some basic mathematics; Appendix 1 has a brief selection of useful techniques.

Relational models (Part IV) are complex assemblages of representations used to support sophisticated high-level processing. An important tool in *knowledge representation* is *semantic nets*, which can be used simply as an organizational convenience or as a formalism in their own right. High-level processing often uses prior knowledge and models acquired prior to a perceptual experience. The basic mode of processing turns from *constructing* representations to *matching* them. At high levels, *propositional* representations become more important. They are made up of assertions that are true or false with respect to a model, and are manipulated by rules of *inference*. Inference-like techniques can also be used for *planning*, which models situations and actions through time, and thus must reason about temporally varying and hypothetical worlds. The higher the level of representation, the more marked is the flow of *control* (direction of attention, allocation of effort) downward to lower levels, and the greater the tendency of algorithms to exhibit *serial processing*. These issues of control are basic to complex information processing in general and computer vision in particular; Appendix 2 outlines some specific control mechanisms.

Figure 1.5 illustrates the loose classification of the four categories into analogical and propositional representations. We consider generalized and segmented images as well as geometric structures to be analogical models. Analogical models capture directly the relevant characteristics of the represented objects, and are manipulated and interrogated by simulation-like processes. Relational models are generally a mix of analogical and propositional representations. We develop this distinction in more detail in Chapter 10.

1.4 THE ROLE OF COMPUTERS

The computer is a congenial tool for research into visual perception.

- Computers are versatile and forgiving experimental subjects. They are easily and ethically reconfigurable, not messy, and their workings can be scrutinized in the finest detail.
- Computers are demanding critics. Imprecision, vagueness, and oversights are not tolerated in the computer implementation of a theory.
- Computers offer new metaphors for perceptual psychology (also neurology, linguistics, and philosophy). Processes and entities from computer science provide powerful and influential conceptual tools for thinking about perception and cognition.
- Computers can give precise measurements of the amount of processing they

Fig. 1.5 The knowledge base of a complex computer vision system, showing four basic representational categories.

Table 1.1
EXAMPLES OF IMAGE ANALYSIS TASKS

<i>Domain</i>	<i>Objects</i>	<i>Modality</i>	<i>Tasks</i>	<i>Knowledge Sources</i>
Robotics	Three-dimensional outdoor scenes indoor scenes Mechanical parts	Light X-rays Light Structured light	Identify or describe objects in scene Industrial tasks	Models of objects Models of the reflection of light from objects
Aerial images	Terrain Buildings, etc.	Light Infrared Radar	Improved images Resource analyses Weather prediction Spying Missile guidance Tactical analysis	Maps Geometrical models of shapes Models of image formation

Chemistry	Molecules	Electron densities	Analysis of molecular compositions	Chemical models Structured models
Neuroanatomy	Neurons	Light Electronmicroscopy	Determination of spatial orientation	Neural connectivity
Physics	Particle tracks	Light	Find new particles Identify tracks	Atomic physics

do. A computer implementation places an upper limit on the amount of computation necessary for a task.

- Computers may be used either to mimic what we understand about human perceptual architecture and processes, or to strike out in different directions to try to achieve similar ends by different means.
- Computer models may be judged either by their efficacy for applications and on-the-job performance or by their internal organization, processes, and structures—the theory they embody.

1.5 COMPUTER VISION RESEARCH AND APPLICATIONS

“Pure” computer vision research often deals with relatively domain-independent considerations. The results are useful in a broad range of contexts. Almost always such work is demonstrated in one or more applications areas, and more often than not an initial application problem motivates consideration of the general problem. Applications of computer vision are exciting, and their number is growing as computer vision becomes better understood. Table 1.1 gives a partial list of “classical” and current applications areas.

Within the organization outlined above, this book presents many specific ideas and techniques with general applicability. It is meant to provide enough basic knowledge and tools to support attacks on both applications and research topics.

GENERALIZED IMAGES

I

The first step in the vision process is image formation. Images may arise from a variety of technologies. For example, most television-based systems convert reflected light intensity into an electronic signal which is then digitized; other systems use more exotic radiations, such as x-rays, laser light, ultrasound, and heat. The net result is usually an array of samples of some kind of energy.

The vision system may be entirely passive, taking as input a digitized image from a microwave or infrared sensor, satellite scanner, or a planetary probe, but more likely involves some kind of *active imaging*. Automated active imaging systems may control the direction and resolution of sensors, or regulate and direct their own light sources. The light source itself may have special properties and structure designed to reveal the nature of the three-dimensional world; an example is to use a plane of light that falls on the scene in a stripe whose structure is closely related to the structure of opaque objects. Range data for the scene may be provided by stereo (two images), but also by triangulation using light-stripe techniques or by "spotranging" using laser light. A single hardware device may deliver range and multispectral reflectivity ("color") information. The image-forming device may also perform various other operations. For example, it may automatically smooth or enhance the image or vary its resolution.

The *generalized image* is a set of related image-like entities for the scene. This set may include related images from several modalities, but may also include the results of significant processing that can extract *intrinsic images*. An intrinsic image is an "image," or array, of representations of an important physical quantity such as surface orientation, occluding contours, velocity, or range. Object color, which is a different entity from sensed red-green-blue wavelengths, is an intrinsic quality. These intrinsic physical qualities are extremely useful; they can be related to physical objects far more easily than the original input values, which reveal the physical parameters only indirectly. An intrinsic image is a major step toward scene understanding and usually represents significant and interesting computations.

The information necessary to compute an intrinsic image is contained in the input image itself, and is extracted by “inverting” the transformation wrought by the imaging process, the reflection of radiation from the scene, and other physical processes. An example is the fusion of two stereo images to yield an intrinsic range image. Many algorithms to recover intrinsic images can be realized with *parallel* implementations, mirroring computations that may take place in the lower neurological levels of biological image processing.

All of the computations listed above benefit from the idea of *resolution pyramids*. A pyramid is a generalized image data structure consisting of the same image at several successively increasing levels of resolution. As the resolution increases, more samples are required to represent the increased information and hence the successive levels are larger, making the entire structure look like a pyramid. Pyramids allow the introduction of many different coarse-to-fine image-resolution algorithms which are vastly more efficient than their single-level, high-resolution-only counterparts.

Image Formation

2

2.1 IMAGES

Image formation occurs when a *sensor* registers *radiation* that has interacted with *physical objects*. Section 2.2 deals with mathematical models of images and image formation. Section 2.3 describes several specific image formation technologies.

The mathematical model of imaging has several different components.

1. A *image function* is the fundamental abstraction of an image.
2. A *geometrical model* describes how three dimensions are projected into two.
3. A *radiometrical model* shows how the imaging geometry, light sources, and reflectance properties of objects affect the light measurement at the sensor.
4. A *spatial frequency model* describes how spatial variations of the image may be characterized in a transform domain.
5. A *color model* describes how different spectral measurements are related to image colors.
6. A *digitizing model* describes the process of obtaining discrete samples.

This material forms the basis of much image-processing work and is developed in much more detail elsewhere, e.g., [Rosenfeld and Kak 1976; Pratt 1978]. Our goals are not those of image processing, so we limit our discussion to a summary of the essentials.

The wide range of possible sources of samples and the resulting different implications for later processing motivate our overview of specific imaging techniques. Our goal is not to provide an exhaustive catalog, but rather to give an idea of the range of techniques available. Very different analysis techniques may be needed depending on how the image was formed. Two examples illustrate this

point. If the image is formed by reflected light intensity, as in a photograph, the image records both light from primary light sources and (more usually) the light reflected off physical surfaces. We show in Chapter 3 that in certain cases we can use these kinds of images together with knowledge about physics to derive the orientation of the surfaces. If, on the other hand, the image is a computed tomogram of the human body (discussed in Section 2.3.4), the image represents tissue density of internal organs. Here orientation calculations are irrelevant, but general segmentation techniques of Chapters 4 and 5 (the agglomeration of neighboring samples of similar density into units representing organs) are appropriate.

2.2 IMAGE MODEL

Sophisticated image models of a statistical flavor are useful in image processing [Jan 1981]. Here we are concerned with more geometrical considerations.

2.2.1 Image Functions

An *image function* is a mathematical representation of an image. Generally, an image function is a vector-valued function of a small number of arguments. A special case of the image function is the *digital (discrete) image function*, where the arguments to and value of the function are all integers. Different image functions may be used to represent the same image, depending on which of its characteristics are important. For instance, a camera produces an image on black-and-white film which is usually thought of as a real-valued function (whose value could be the density of the photographic negative) of two real-valued arguments, one for each of two spatial dimensions. However, at a very small scale (the order of the film grain) the negative basically has only two densities, “opaque” and “transparent.”

Most images are presented by functions of two *spatial* variables $f(\mathbf{x}) = f(x, y)$, where $f(x, y)$ is the brightness of the gray level of the image at a spatial coordinate (x, y) . A multispectral image \mathbf{f} is a vector-valued function with components $(f_1 \dots f_n)$. One special multispectral image is a color image in which, for example, the components measure the brightness values of each of three wavelengths, that is,

$$\mathbf{f}(\mathbf{x}) = \left\{ f_{\text{red}}(\mathbf{x}), f_{\text{blue}}(\mathbf{x}), f_{\text{green}}(\mathbf{x}) \right\}$$

Time-varying images $f(\mathbf{x}, t)$ have an added temporal argument. For special three-dimensional images, $\mathbf{x} = (x, y, z)$. Usually, both the domain and range of f are bounded.

An important part of the formation process is the conversion of the image representation from a continuous function to a discrete function; we need some way of describing the images as samples at discrete points. The mathematical tool we shall use is the *delta function*.

Formally, the delta function may be defined by

$$\delta(x) = \begin{cases} 0 & \text{when } x \neq 0 \\ \infty & \text{when } x = 0 \end{cases} \quad (2.1)$$

$$\int_{-\infty}^{\infty} \delta(x) dx = 1$$

If some care is exercised, the delta function may be interpreted as the limit of a set of functions:

$$\delta(x) = \lim_{n \rightarrow \infty} \delta_n(x)$$

where

$$\delta_n(x) = \begin{cases} n & \text{if } |x| < \frac{1}{2n} \\ 0 & \text{otherwise} \end{cases} \quad (2.2)$$

A useful property of the delta function is the *sifting property*:

$$\int_{-\infty}^{\infty} f(x) \delta(x-a) dx = f(a) \quad (2.3)$$

A continuous image may be multiplied by a two-dimensional “comb,” or array of delta functions, to extract a finite number of discrete *samples* (one for each delta function). This mathematical model of the sampling process will be useful later.

2.2.2 Imaging Geometry

Monocular Imaging

Point projection is the fundamental model for the transformation wrought by our eye, by cameras, or by numerous other imaging devices. To a first-order approximation, these devices act like a pinhole camera in that the image results from projecting scene points through a single point onto an *image plane* (see Fig. 2.1). In Fig. 2.1, the image plane is behind the point of projection, and the image is reversed. However, it is more intuitive to recompose the geometry so that the point of projection corresponds to a *viewpoint* behind the image plane, and the image occurs right side up (Fig. 2.2). The mathematics is the same, but now the viewpoint is $+f$ on the z axis, with $z = 0$ plane being the image plane upon which the image is projected. (f is sometimes called the *focal length* in this context. The use of f in this section should not be confused with the use of f for image function.) As the imaged object approaches the viewpoint, its projection gets bigger (try moving your hand toward your eye). To specify how its imaged size changes, one needs only the geometry of similar triangles. In Fig. 2.2b y' , the projected height of the object, is related to its real height y , its position z , and the focal length f by

$$\frac{y}{f-z} = \frac{y'}{f} \quad (2.4)$$

Fig. 2.1 A geometric camera model.

The case for x' is treated similarly:

$$\frac{x}{f-z} = \frac{x'}{f} \quad (2.5)$$

The projected image has $z = 0$ everywhere. However, projecting away the z component is best considered a separate transformation; the projective transform is usually thought to distort the z component just as it does the x and y . *Perspective distortion* thus maps (x, y, z) to

$$(x', y', z') = \left(\frac{fx}{f-z}, \frac{fy}{f-z}, \frac{fz}{f-z} \right) \quad (2.6)$$

The perspective transformation yields *orthographic projection* as a special case when the viewpoint is the *point at infinity* in the z direction. Then all objects are projected onto the viewing plane with no distortion of their x and y coordinates.

The perspective distortion yields a three-dimensional object that has been “pushed out of shape”; it is more shrunken the farther it is from the viewpoint. The z component is not available directly from a two-dimensional image, being identically equal to zero. In our model, however, the distorted z component has information about the distance of imaged points from the viewpoint. When this distorted object is projected orthographically onto the image plane, the result is a perspective picture. Thus, to achieve the effect of railroad tracks appearing to come together in the distance, the perspective distortion transforms the tracks so that they *do* come together (at a point at infinity)! The simple orthographic projection that projects away the z component unsurprisingly preserves this distortion. Several properties of the perspective transform are of interest and are investigated further in Appendix 1.

Binocular Imaging

Basic binocular imaging geometry is shown in Fig. 2.3a. For simplicity, we

Fig. 2.2 (a) Camera model equivalent to that of Fig. 2.1; (b) definition of terms.

use a system with two viewpoints. In this model the eyes do not *converge*; they are aimed in parallel at the point at infinity in the $-z$ direction. The depth information about a point is then encoded only by its different positions (*disparity*) in the two image planes.

With the stereo arrangement of Fig. 2.3,

$$x' = \frac{(x - d)f}{f - z}$$

$$x'' = \frac{(x + d)f}{f - z}$$

where (x', y') and (x'', y'') are the retinal coordinates for the world point imaged

Fig. 2.3 A nonconvergent binocular imaging system.

through each eye. The *baseline* of the binocular system is $2d$. Thus

$$(f - z)x' = (x - d)f \quad (2.7)$$

$$(f - z)x'' = (x + d)f \quad (2.8)$$

Subtracting (2.7) from (2.8) gives

$$(f - z)(x'' - x') = 2df$$

or

$$z = f - \frac{2df}{x'' - x'} \quad (2.9)$$

Thus if points can be matched to determine the disparity $(x'' - x')$ and the baseline and focal length are known, the z coordinate is simple to calculate.

If the system can converge its directions of view to a finite distance, convergence angle may also be used to compute depth. The hardest part of extracting depth information from stereo is the *matching* of points for disparity calculations. “Light striping” is a way to maintain geometric simplicity and also simplify matching (Section 2.3.3).

2.2.3 Reflectance

Terminology

A basic aspect of the imaging process is the physics of the reflectance of objects, which determines how their “brightness” in an image depends on their inherent characteristics and the geometry of the imaging situation. A clear presentation of the mathematics of reflectance is given in [Horn and Sjoberg 1978; Horn 1977]. Light *energy flux* Φ is measured in watts; “brightness” is measured with respect to area and solid angle. The *radiant intensity* I of a source is the exitant flux per unit solid angle:

$$I = \frac{d\Phi}{d\omega} \quad \text{watts/steradian} \quad (2.10)$$

Here $d\omega$ is an incremental solid angle. The solid angle of a small area dA measured perpendicular to a radius r is given by

$$d\omega = \frac{dA}{r^2} \quad (2.11)$$

in units of steradians. (The total solid angle of a sphere is 4π .)

The *irradiance* is flux incident on a surface element dA :

$$E = \frac{d\Phi}{dA} \quad \text{watts/meter}^2 \quad (2.12)$$

and the flux exitant from the surface is defined in terms of the *radiance* L , which is the flux emitted per unit foreshortened surface area per unit solid angle:

$$L = \frac{d^2\Phi}{dA \cos\theta d\omega} \quad \text{watts/(meter}^2 \text{ steradian)} \quad (2.13)$$

where θ is the angle between the surface normal and the direction of emission.

Image irradiance f is the “brightness” of the image at a point, and is proportional to scene radiance. A “gray-level” is a quantized measurement of image irradiance. Image irradiance depends on the reflective properties of the imaged surfaces as well as on the illumination characteristics. How a surface reflects light depends on its micro-structure and physical properties. Surfaces may be *matte* (dull, flat), *specular* (mirrorlike), or have more complicated reflectivity characteristics (Section 3.5.1). The *reflectance* r of a surface is given quite generally by its Bidirectional Reflectance Distribution Function (BRDF) [Nicodemus et al. 1977]. The BRDF is the ratio of reflected radiance in the direction towards the viewer to the irradiance in the direction towards a small area of the source.

Effects of Geometry on an Imaging System

Let us now analyze a simple image-forming system shown in Fig. 2.4 with the objective of showing how the gray levels are related to the radiance of imaged objects. Following [Horn and Sjöberg 1978], assume that the imaging device is properly focused; rays originating in the infinitesimal area dA_o on the object’s surface are projected into some area dA_p in the image plane and no rays from other portions of the object’s surface reach this area of the image. The system is assumed to be an ideal one, obeying the laws of simple geometrical optics.

The energy flux/unit area that impinges on the sensor is defined to be E_p . To show how E_p is related to the scene radiance L , first consider the flux arriving at the lens from a small surface area dA_o . From (2.13) this is given as

$$d\Phi = dA_o \int L \cos\theta d\omega \quad (2.14)$$

This flux is assumed to arrive at an area dA_p in the imaging plane. Hence the irradiance is given by [using Eq. (2.12)]

$$E_p = \frac{d\Phi}{dA_p} \quad (2.15)$$

Now relate dA_o to dA_p by equating the respective solid angles as seen from the lens; that is [making use of Eq. (2.12)],

Fig. 2.4 Geometry of an image forming system.

$$dA_o \frac{\cos \theta}{f_o^2} = dA_p \frac{\cos \alpha}{f_p^2} \quad (2.16)$$

Substituting Eqs. (2.16) and (2.14) into (2.15) gives

$$E = \cos \alpha \left(\frac{f_o}{f_p} \right)^2 \int L d\omega \quad (2.17)$$

The integral is over the solid angle seen by the lens. In most instances we can assume that L is constant over this angle and hence can be removed from the integral. Finally, approximate $d\omega$ by the area of the lens foreshortened by $\cos \alpha$, that is, $(\pi/4) D^2 \cos \alpha$ divided by the distance $f_o/\cos \alpha$ squared:

$$d\omega = \frac{\pi}{4} D^2 \frac{\cos^3 \alpha}{f_o^2} \quad (2.18)$$

so that finally

$$E = \frac{1}{4} \left(\frac{D}{f_p} \right)^2 \cos^4 \alpha \pi L \quad (2.19)$$

The interesting results here are that (1) the image irradiance is proportional to the scene radiance L , and (2) the factor of proportionality includes the fourth power of the off-axis angle α . Ideally, an imaging device should be calibrated so that the variation in sensitivity as a function of α is removed.

2.2.4 Spatial Properties

The Fourier Transform

An image is a spatially varying function. One way to analyze spatial variations is the decomposition of an image function into a set of orthogonal functions, one such set being the Fourier (sinusoidal) functions. The Fourier transform may be used to transform the intensity image into the domain of *spatial frequency*. For no-

tational convenience and intuition, we shall generally use as an example the continuous one-dimensional Fourier transform. The results can readily be extended to the discrete case and also to higher dimensions [Rosenfeld and Kak 1976]. In two dimensions we shall denote transform domain coordinates by (u, v) . The one-dimensional Fourier transform, denoted \mathcal{F} , is defined by

$$\mathcal{F}[f(x)] = F(u)$$

where

$$F(u) = \int_{-\infty}^{+\infty} f(x) \exp(-j2\pi ux) dx \quad (2.20)$$

where $j = \sqrt{-1}$. Intuitively, Fourier analysis expresses a function as a sum of sine waves of different frequency and phase. The Fourier transform has an *inverse* $^{-1}[F(u)] = f(x)$. This inverse is given by

$$f(x) = \int_{-\infty}^{\infty} F(u) \exp(j2\pi ux) du \quad (2.21)$$

The transform has many useful properties, some of which are summarized in Table 2.1. Common one-dimensional Fourier transform pairs are shown in Table 2.2.

The transform $F(u)$ is simply another representation of the image function. Its meaning can be understood by interpreting Eq. (2.21) for a specific value of x , say x_0 :

$$f(x_0) = \int F(u) \exp(j2\pi ux_0) du \quad (2.22)$$

This equation states that a particular point in the image can be represented by a weighted sum of complex exponentials (sinusoidal patterns) at different spatial frequencies u . $F(u)$ is thus a *weighting function* for the different frequencies. Low-spatial frequencies account for the “slowly” varying gray levels in an image, such as the variation of intensity over a continuous surface. High-frequency components are associated with “quickly varying” information, such as edges. Figure 2.5 shows the Fourier transform of an image of rectangles, together with the effects of removing low- and high-frequency components.

The Fourier transform is defined above to be a continuous transform. Although it may be performed instantly by optics, a discrete version of it, the “fast Fourier transform,” is almost universally used in image processing and computer vision. This is because of the relative versatility of manipulating the transform in the digital domain as compared to the optical domain. Image-processing texts, e.g., [Pratt 1978; Gonzalez and Wintz 1977] discuss the FFT in some detail; we content ourselves with an algorithm for it (Appendix 1).

The Convolution Theorem

Convolution is a very important image-processing operation, and is a basic operation of linear systems theory. The convolution of two functions f and g is a function h of a displacement y defined as

$$h(y) = f * g = \int_{-\infty}^{\infty} f(x) g(y - x) dx \quad (2.23)$$

Table 2.1

Table 2.2 (cont.)

Intuitively, one function is “swept past” (in one dimension) or “rubbed over” (in two dimensions) the other. The value of the convolution at any displacement is the integral of the product of the (relatively displaced) function values. One common phenomenon that is well expressed by a convolution is the formation of an image by an optical system. The system (say a camera) has a “point-spread function,” which is the image of a single point. (In linear systems theory, this is the “impulse response,” or response to a delta-function input.) The ideal point-spread function is, of course, a point. A typical point-spread function is a two-dimensional Gaussian spatial distribution of intensities, but may include such phenomena as diffraction rings. In any event, if the camera is modeled as a linear system (ignor-

Fig. 2.5 (on facing page) (a) An image, $f(x, y)$. (b) A rotated version of (a), filtered to enhance high spatial frequencies. (c) Similar to (b), but filtered to enhance low spatial frequencies. (d), (e), and (f) show the logarithm of the power spectrum of (a), (b), and (c). The power spectrum is the log square modulus of the Fourier transform $F(u, v)$. Considered in polar coordinates (ρ, θ) , points of small ρ correspond to low spatial frequencies (“slowly-varying” intensities), large ρ to high spatial frequencies contributed by “fast” variations such as step edges. The power at (ρ, θ) is determined by the amount of intensity variation at the frequency ρ occurring at the angle θ .

(a)

(b)

(c)

(d)

(e)

(f)

ing the added complexity that the point-spread function usually varies over the field of view), the image is the convolution of the point-spread function and the input signal. The point-spread function is rubbed over the perfect input image, thus blurring it.

Convolution is also a good model for the application of many other linear operators, such as line-detecting templates. It can be used in another guise (called correlation) to perform matching operations (Chapter 3) which detect instances of subimages or features in an image.

In the spatial domain, the obvious implementation of the convolution operation involves a shift–multiply–integrate operation which is hard to do efficiently. However, multiplication and convolution are “transform pairs,” so that the calculation of the convolution in one domain (say the spatial) is simplified by first Fourier transforming to the other (the frequency) domain, performing a multiplication, and then transforming back.

The convolution of f and g in the spatial domain is equivalent to the pointwise product of F and G in the frequency domain,

$$\mathcal{F}(f * g) = FG \quad (2.24)$$

We shall show this in a manner similar to [Duda and Hart 1973]. First we prove the *shift theorem*. If the Fourier transform of $f(x)$ is $F(u)$, defined as

$$F(u) = \int_x f(x) \exp[-j2\pi(ux)] dx \quad (2.25)$$

then

$$\mathcal{F}[f(x - a)] = \int_x f(x - a) \exp[-j2\pi(ux)] dx \quad (2.26)$$

changing variables so that $x' = x - a$ and $dx = dx'$

$$= \int_{x'} f(x') \exp\{-j2\pi[u(x' + a)]\} dx' \quad (2.27)$$

Now $\exp[-j2\pi u(x' + a)] = \exp(-j2\pi ua) \exp(-j2\pi ux')$, where the first term is a constant. This means that

$$\mathcal{F}[f(x - a)] = \exp(-j2\pi ua) F(u) \quad (\text{shift theorem})$$

Now we are ready to show that $\mathcal{F}[f(x) * g(x)] = F(u)G(u)$.

$$\mathcal{F}(f * g) = \int_y \left\{ \int_x f(x) g(y - x) \right\} \exp(-j2\pi uy) dx dy \quad (2.28)$$

$$= \int_x f(x) \left\{ \int_y g(y - x) \exp(-j2\pi uy) dy \right\} dx \quad (2.29)$$

Recognizing that the terms in braces represent $\mathcal{F}[g(y - x)]$ and applying the shift theorem, we obtain

$$\mathcal{F}(f * g) = \int_x f(x) \exp(-j2\pi ux) G(u) dx \quad (2.30)$$

$$= F(u)G(u) \quad (2.31)$$

2.2.5 Color

Not all images are monochromatic; in fact, applications using multispectral images are becoming increasingly common (Section 2.3.2). Further, human beings intuitively feel that color is an important part of their visual experience, and is useful or even necessary for powerful visual processing in the real world. Color vision provides a host of research issues, both for psychology and computer vision. We briefly discuss two aspects of color vision: color spaces and color perception. Several models of the human visual system not only include color but have proven useful in applications [Granrath 1981].

Color Spaces

Color spaces are a way of organizing the colors perceived by human beings. It happens that weighted combinations of stimuli at three principal wavelengths are sufficient to define almost all the colors we perceive. These wavelengths form a natural basis or coordinate system from which the color measurement process can be described. Color perception is not related in a simple way to color measurement, however.

Color is a perceptual phenomenon related to human response to different wavelengths in the visible *electromagnetic spectrum* [400 (blue) to 700 nanometers (red); a nanometer (nm) is 10^{-9} meter]. The sensation of color arises from the sensitivities of three types of neurochemical sensors in the retina to the visible spectrum. The relative response of these sensors is shown in Fig. 2.6. Note that each sensor responds to a range of wavelengths. The illumination source has its own spectral composition $f(\lambda)$ which is modified by the reflecting surface. Let $r(\lambda)$ be this reflectance function. Then the measurement R produced by the “red” sensor is given by

$$R = \int f(\lambda)r(\lambda)h_R(\lambda) d\lambda \quad (2.32)$$

So the sensor output is actually the integral of three different wavelength-dependent components: the source f , the surface reflectance r , and the sensor h_R .

Surprisingly, only weighted combinations of three delta-function approximations to the different $f(\lambda)h(\lambda)$, that is, $\delta(\lambda_R)$, $\delta(\lambda_G)$, and $\delta(\lambda_B)$, are necessary to

Fig. 2.6 Spectral response of human color sensors.

produce the sensation of nearly all the colors. This result is displayed on a *chromaticity diagram*. Such a diagram is obtained by first normalizing the three sensor measurements:

$$\begin{aligned} r &= \frac{R}{R + G + B} \\ g &= \frac{G}{R + G + B} \\ b &= \frac{B}{R + G + B} \end{aligned} \quad (2.33)$$

and then plotting perceived color as a function of any two (usually red and green). Chromaticity explicitly ignores intensity or brightness; it is a section through the three-dimensional color space (Fig. 2.7). The choice of $(\lambda_R, \lambda_G, \lambda_B) = (410, 530, 650) \text{ nm}$ maximizes the realizable colors, but some colors still cannot be realized since they would require negative values for some of $r, g,$ and b .

Another more intuitive way of visualizing the possible colors from the *RGB* space is to view these measurements as Euclidean coordinates. Here any color can be visualized as a point in the unit cube. Other coordinate systems are useful for different applications; computer graphics has proved a strong stimulus for investigation of different color space bases.

Color Perception

Color perception is complex, but the essential step is a transformation of three input intensity measurements into another basis. The coordinates of the new

(a)

(b)

Fig. 2.7 (a) An artist's conception of the chromaticity diagram—see color insert; (b) a more useful depiction. Spectral colors range along the curved boundary; the straight boundary is the line of purples.

basis are more directly related to human color judgments.

Although the *RGB* basis is good for the acquisition or display of color information, it is not a particularly good basis to explain the perception of colors. Human vision systems can make good judgments about the relative surface reflectance $r(\lambda)$ despite different illuminating wavelengths; this reflectance seems to be what we mean by surface color.

Another important feature of the color basis is revealed by an ability to perceive in “black and white,” effectively deriving intensity information from the color measurements. From an evolutionary point of view, we might expect that color perception in animals would be compatible with preexisting noncolor perceptual mechanisms.

These two needs—the need to make good color judgments and the need to retain and use intensity information—imply that we use a transformed, non-*RGB* basis for color space. Of the different bases in use for color vision, all are variations on this theme: Intensity forms one dimension and color is a two-dimensional subspace. The differences arise in how the color subspace is described. We categorize such bases into two groups.

1. *Intensity/Saturation/Hue (IHS)*. In this basis, we compute intensity as

$$\text{intensity:} = R + G + B \quad (2.34)$$

The saturation measures the lack of whiteness in the color. Colors such as “fire engine” red and “grass” green are saturated; pastels (e.g., pinks and pale blues) are desaturated. Saturation can be computed from *RGB* coordinates by the formula [Tenenbaum and Weyl 1975]

$$\text{saturation:} = 1 - \frac{3 \min(R, G, B)}{\text{intensity}} \quad (2.35)$$

Hue is roughly proportional to the average wavelength of the color. It can be defined using *RGB* by the following program fragment:

$$\text{hue:} = \cos^{-1} \left\{ \frac{\{1/2[(R - G) + (R - B)]\}}{\sqrt{(R - G)^2 + (R - B)(G - B)^{1/2}}} \right\} \quad (2.36)$$

If $B > G$ then hue: = $2\pi - \text{hue}$

The *IHS* basis transforms the *RGB* basis in the following way. Thinking of the color cube, the diagonal from the origin to (1, 1, 1) becomes the intensity axis. Saturation is the distance of a point from that axis and hue is the angle with regard to the point about that axis from some reference (Fig. 2.8).

This basis is essentially that used by artists [Munsell 1939], who term saturation *chroma*. Also, this basis has been used in graphics [Smith 1978; Joblove and Greenberg 1978].

One problem with the *IHS* basis, particularly as defined by (2.34) through (2.36), is that it contains essential singularities where it is impossible to define the color in a consistent manner [Kender 1976]. For example, hue has an essential singularity for all values of (R, G, B) , where $R = G = B$. This means that special care must be taken in algorithms that use hue.

2. *Opponent processes*. The opponent process basis uses Cartesian rather than

Fig. 2.8 An IHS Color Space. (a) Cross section at one intensity; (b) cross section at one hue—see color inserts.

cylindrical coordinates for the color subspace, and was first proposed by Hering [Teevan and Birney 1961]. The simplest form of basis is a linear transformation from R, G, B coordinates. The new coordinates are termed “ $R - G$ ”, “ $B - Y$ ”, and “ $W - Bk$ ”:

$$\begin{bmatrix} R - G \\ B - Y \\ W - Bk \end{bmatrix} = \begin{bmatrix} 1 & -2 & 1 \\ -1 & -1 & 2 \\ 1 & 1 & 1 \end{bmatrix} \begin{bmatrix} R \\ G \\ B \end{bmatrix}$$

The advocates of this representation, such as [Hurvich and Jameson 1957], theorize that this basis has neurological correlates and is in fact the way human beings represent (“name”) colors. For example, in this basis it makes sense to talk about a “reddish blue” but not a “reddish green.” Practical opponent process models usually have more complex weights in the transform matrix to account for psychophysical data. Some startling experiments [Land 1977] show our ability to make correct color judgments even when the illumination consists of only two principal wavelengths. The opponent process, at the level at which we have developed it, does not demonstrate how such judgments are made, but does show how stimulus at only two wavelengths will project into the color subspace. Readers interested in the details of the theory should consult the references.

Commercial television transmission needs an intensity, or “ $W - Bk$ ” component for black-and-white television sets while still spanning the color space. The National Television Systems Committee (NTSC) uses a “YIQ” basis extracted from RGB via

$$\begin{bmatrix} I \\ Q \\ Y \end{bmatrix} = \begin{bmatrix} 0.60 & -0.28 & -0.32 \\ 0.21 & -0.52 & 0.31 \\ 0.30 & 0.59 & 0.11 \end{bmatrix} \begin{bmatrix} R \\ G \\ B \end{bmatrix}$$

This basis is a weighted form of

$$(I, Q, Y) = (\text{“R-cyan,” “magenta-green,” “W-Bk”})$$

2.2.6 Digital Images

The *digital images* with which computer vision deals are represented by m -vector discrete-valued image functions $f(\mathbf{x})$, usually of one, two, three, or four dimensions.

Usually $m = 1$, and both the domain and range of $f(\mathbf{x})$ are discrete. The domain of f is finite, usually a rectangle, and the range of f is positive and bounded: $0 \leq f(\mathbf{x}) \leq M$ for some integer M . For all practical purposes, the image is a continuous function which is represented by measurements or *samples* at regularly spaced intervals. At the time the image is sampled, the intensity is usually *quantized* into a number of different *gray levels*. For a discrete image, $f(\mathbf{x})$ is an integer gray level, and $\mathbf{x} = (x, y)$ is a pair of *integer* coordinates representing a sample point in a two-dimensional image plane. Sampling involves two important choices: (1) the *sampling interval*, which determines in a basic way whether all the information in the image is represented, and (2) the *tessellation* or spatial pattern of sample points, which affects important notions of connectivity and distance. In our presentation, we first show qualitatively the effects of sampling and gray-level quantization. Second, we discuss the simplest kinds of tessellations of the plane. Finally, and most important, we describe the sampling theorem, which specifies how close the image samples must be to represent the image unambiguously.

The choice of integers to represent the gray levels and coordinates is dictated by limitations in sensing. Also, of course, there are hardware limitations in representing images arising from their sheer size. Table 2.3 shows the storage required for an image in 8-bit bytes as a function of m , the number of bits per sample, and N , the linear dimension of a square image.

For reasons of economy (and others discussed in Chapter 3) we often use images of considerably less spatial resolution than that required to preserve fidelity to the human viewer. Figure 2.9 provides a qualitative idea of image degradation with decreasing spatial resolution.

As shown in Table 2.3, another way to save space besides using less spatial resolution is to use fewer bits per gray level sample. Figure 2.10 shows an image represented with different numbers of bits per sample. One striking effect is the “contouring” introduced with small numbers of gray levels. This is, in general, a problem for computer vision algorithms, which cannot easily discount the false contours. The choice of spatial and gray-level resolution for any particular computer vision task is an important one which depends on many factors. It is typical in

Fig. 2.9 Using different numbers of samples. (a) $N = 16$; (b) $N = 32$; (c) $N = 64$; (d) $N = 128$; (e) $N = 256$; (f) $N = 512$.

8	1,024	4,096	16,384	65,536	262,144

computer vision to have to balance the desire for increased resolution (both gray scale and spatial) against its cost. Better data can often make algorithms easier to write, but a small amount of data can make processing more efficient. Of course, the image domain, choice of algorithms, and image characteristics all heavily influence the choice of resolutions.

Tessellations and Distance Metrics

Although the spatial samples for $f(\mathbf{x})$ can be represented as points, it is more satisfying to the intuition and a closer approximation to the acquisition process to think of these samples as finite-sized cells of constant gray-level partitioning the image. These cells are termed *pixels*, an acronym for *picture elements*. The pattern into which the plane is divided is called its *tessellation*. The most common regular tessellations of the plane are shown in Fig. 2.11.

Although rectangular tessellations are almost universally used in computer vision, they have a structural problem known as the “connectivity paradox.” Given a pixel in a rectangular tessellation, how should we define the pixels to which it is connected? Two common ways are *four-connectivity* and *eight-connectivity*, shown in Fig. 2.12.

However, each of these schemes has complications. Consider Fig. 2.12c, consisting of a black object with a hole on a white background. If we use four-connectedness, the figure consists of four disconnected pieces, yet the hole is separated from the “outside” background. Alternatively, if we use eight-connectedness, the figure is one connected piece, yet the hole is now connected to the outside. This paradox poses complications for many geometric algorithms. Triangular and hexagonal tessellations do not suffer from connectivity difficulties (if we use three-connectedness for triangles); however, *distance* can be more difficult to compute on these arrays than for rectangular arrays.

The distance between two pixels in an image is an important measure that is fundamental to many algorithms. In general, a distance d is a *metric*. That is,

Fig. 2.10 Using different numbers of bits per sample. (a) $m = 1$; (b) $m = 2$; (c) $m = 4$; (d) $m = 8$.

- (1) $d(\mathbf{x}, \mathbf{y}) = 0$ iff $\mathbf{x} = \mathbf{y}$
- (2) $d(\mathbf{x}, \mathbf{y}) = d(\mathbf{y}, \mathbf{x})$
- (3) $d(\mathbf{x}, \mathbf{y}) + d(\mathbf{y}, \mathbf{z}) \geq d(\mathbf{x}, \mathbf{z})$

For square arrays with unit spacing between pixels, we can use any of the following common distance metrics (Fig. 2.13) for two pixels $\mathbf{x} = (x_1, y_1)$ and $\mathbf{y} = (x_2, y_2)$.

Euclidean:

$$d_e(\mathbf{x}, \mathbf{y}) = \sqrt{(x_1 - x_2)^2 + (y_1 - y_2)^2} \quad (2.37)$$

City block:

$$d_{cb}(\mathbf{x}, \mathbf{y}) = |x_1 - x_2| + |y_1 - y_2| \quad (2.38)$$

Fig. 2.11 Different tessellations of the image plane. (a) Rectangular; (b) triangular; (c) hexagonal.

Chessboard:

$$d_{ch}(\mathbf{x}, \mathbf{y}) = \max\{|x_1 - x_2|, |y_1 - y_2|\} \quad (2.39)$$

Other definitions are possible, and all such measures extend to multiple dimensions. The tessellation of higher-dimensional space into pixels usually is confined to (n -dimensional) cubical pixels.

The Sampling Theorem

Consider the one-dimensional “image” shown in Fig. 2.14. To digitize this image one must sample the image function. These samples will usually be separated at regular intervals as shown. How far apart should these samples be to allow reconstruction (to a given accuracy) of the underlying continuous image from its samples? This question is answered by the Shannon sampling theorem. An excellent rigorous presentation of the sampling theorem may be found in [Rosenfeld and Kak 1976]. Here we shall present a shorter graphical interpretation using the results of Table 2.2. For simplicity we consider the image to be periodic in order to avoid small edge effects introduced by the finite image domain. A more rigorous

Fig. 2.12 Connectivity paradox for rectangular tessellations. (a) A central pixel and its 4-connected neighbors; (b) a pixel and its 8-connected neighbors; (c) a figure with ambiguous connectivity.

Fig. 2.13 Equidistant contours for different metrics.

Fig. 2.14 One-dimensional image and its samples.

treatment, which considers these effects, is given in [Andrews and Hunt 1977].

Suppose that the image is sampled with a “comb” function of spacing x_0 (see Table 2.2). Then the sampled image can be modeled by

$$f_s(x) = f(x) \sum_n \delta(x - nx_0) \quad (2.40)$$

where the image function modulates the comb function. Equivalently, this can be written as

$$f_s(x) = \sum_n f(nx_0) \delta(x - nx_0) \quad (2.41)$$

The right-hand side of Eq. (2.40) is the product of two functions, so that property

(6) in Table 2.1 is appropriate. The Fourier transform of $f_s(x)$ is equal to the convolution of the transforms of each of the two functions. Using this result yields

$$F_s(u) = F(u) * \frac{1}{x_0} \sum_n \delta(u - \frac{n}{x_0}) \quad (2.42)$$

But from Eq. (2.3),

$$F(u) * \delta(u - \frac{n}{x_0}) = F(u - \frac{n}{x_0}) \quad (2.43)$$

so that

$$F_s(u) = \frac{1}{x_0} \sum_n F(u - \frac{n}{x_0}) \quad (2.44)$$

Therefore, sampling the image function $f(x)$ at intervals of x_0 is equivalent in the frequency domain to replicating the transform of f at intervals of $\frac{1}{x_0}$. This limits the recovery of $f(x)$ from its sampled representation, $f_s(x)$. There are two basic situations to consider. If the transform of $f(x)$ is *bandlimited* such that $F(u) = 0$ for $|u| > 1/(2x_0)$, then there is no overlap between successive replications of $F(u)$ in the frequency domain. This is shown for the case of Fig. 2.15a, where we have arbitrarily used a triangular-shaped image transform to illustrate the effects of sampling. Incidentally, note that for this transform $F(u) = F(-u)$ and that it has no imaginary part; from Table 2.2, the one-dimensional image must also be real and even. Now if $F(u)$ is not bandlimited, i.e., there are $u > \frac{1}{2x_0}$ for which $F(u) \neq 0$, then components of different replications of $F(u)$ will interact to produce the composite function $F_s(u)$, as shown in Fig. 2.15b. In the first case $f(x)$ can be recovered from $F_s(u)$ by multiplying $F_s(u)$ by a suitable $G(u)$:

$$G(u) = \begin{cases} 1 & |u| < \frac{1}{2x_0} \\ 0 & \text{otherwise} \end{cases} \quad (2.45)$$

Then

$$f(x) = \mathcal{F}^{-1}[F_s(u)G(u)] \quad (2.46)$$

However, in the second case, $F_s(u)G(u)$ is very different from the original $F(u)$. This is shown in Fig. 2.15c. Sampling a $F(u)$ that is not bandlimited allows information at high spatial frequencies to interfere with that at low frequencies, a phenomenon known as *aliasing*.

Thus the sampling theorem has this very important result: As long as the image contains no spatial frequencies greater than one-half the sampling frequency, the underlying continuous image is unambiguously represented by its samples. However, lest one be tempted to insist on images that have been so sampled, note that it may be useful to sample at lower frequencies than would be required for total reconstruction. Such sampling is usually preceded by some form of blurring of

Fig. 2.15 (a) $F(u)$ bandlimited so that $F(u) = 0$ for $|u| > 1/2x_0$. (b) $F(u)$ not band-limited as in (a). (c) reconstructed transform.

the image, or can be incorporated with such blurring (by integrating the image intensity over a finite area for each sample). Image blurring can bury irrelevant details, reduce certain forms of noise, and also reduce the effects of aliasing.

2.3 IMAGING DEVICES FOR COMPUTER VISION

There is a vast array of methods for obtaining a digital image in a computer. In this section we have in mind only “traditional” images produced by various forms of radiation impinging on a sensor after having been affected by physical objects.

Many sensors are best modeled as an *analog* device whose response must be *digitized* for computer representation. The types of imaging devices possible are limited only by the technical ingenuity of their developers; attempting a definitive

Fig. 2.16 Imaging devices (boxes), information structures (rectangles), and processes (circles).

taxonomy is probably unwise. Figure 2.16 is a flowchart of devices, information structures, and processes addressed in this and succeeding sections.

When the image already exists in some form, or physical considerations limit choice of imaging technology, the choice of digitizing technology may still be open. Most images are carried on a permanent medium, such as film, or at least are available in (essentially) analog form to a digitizing device. Generally, the relevant technical characteristics of imaging or digitizing devices should be foremost in mind when a technique is being selected. Such considerations as the signal-to-noise ratio of the device, its resolution, the speed at which it works, and its expense are important issues.

2.3.1 Photographic Imaging

The camera is the most familiar producer of optical images on a permanent medium. We shall not address here the multitudes of still- and movie-camera options; rather, we briefly treat the characteristics of the photographic film and of the digitizing devices that convert the image to machine-readable form. More on these topics is well presented in the References.

Photographic (black-and-white) film consists of an emulsion of silver halide crystals on a film base. (Several other layers are identifiable, but are not essential to an understanding of the relevant properties of film.) Upon exposure to light, the silver halide crystals form *development centers*, which are small grains of metallic silver. The photographic development process extends the formation of metallic silver to the entire silver halide crystal, which thus becomes a binary (“light” or “no light”) detector. Subsequent processing removes undeveloped silver halide. The resulting film *negative* is dark where many crystals were developed and light where few were. The resolution of the film is determined by the *grain size*, which depends on the original halide crystals and on development techniques. Generally, the *faster* the film (the less light needed to expose it), the coarser the grain. Film exists that is sensitive to infrared radiation; x-ray film typically has two emulsion layers, giving it more gray-level range than that of normal film.

A repetition of the negative-forming process is used to obtain a photographic *print*. The negative is projected onto photographic paper, which responds roughly in the same way as the negative. Most photographic print paper cannot capture in one print the range of densities that can be present in a negative. Positive films do exist that do not require printing; the most common example is color slide film.

The response of film to light is not completely linear. The photographic *density* obtained by a negative is defined as the logarithm (base 10) of the ratio of incident light to transmitted light.

$$D = \log_{10} \left(\frac{I}{I_t} \right)$$

The *exposure* of a negative dictates (approximately) its response. Exposure is defined as the energy per unit area that exposed the film (in its sensitive spectral range). Thus exposure is the product of the *intensity* and the time of exposure. This mathematical model of the behavior of the photographic exposure process is correct for a wide operating range of the film, but *reciprocity failure* effects in the film keep one from being able always to trade light level for exposure time. At very low light levels, longer exposure times are needed than are predicted by the product rule.

The response of film to light is usually plotted in an “H&D curve” (named for Hurter and Driffield), which plots density versus exposure. The H&D curve of film displays many of its important characteristics. Figure 2.17 exhibits a typical H&D curve for a black and white film.

The *toe* of the curve is the lower region of low slope. It expresses reciprocity failure and the fact that the film has a certain bias, or *fog* response, which dominates its behavior at the lowest exposure levels. As one would expect, there is an upper limit to the density of the film, attained when a maximum number of silver

Fig. 2.17 Typical H & D curve.

halide crystals are rendered developable. Increasing exposure beyond this maximum level has little effect, accounting for the *shoulder* in the H&D curve, or its flattened upper end.

In between the toe and shoulder, there is typically a linear operating region of the curve. High-contrast films are those with high slope (traditionally called *gamma*); they respond dramatically to small changes in exposure. A high-contrast film may have a gamma between about 1.5 and 10. Films with gammas of approximately 10 are used in graphics arts to copy line drawings. General-purpose films have gammas of about 0.5 to 1.0.

The resolution of a general film is about 40 lines/mm, which means that a 1400×1400 image may be digitized from a 35mm slide. At any greater sampling frequency, the individual film grains will occupy more than a pixel, and the resolution will thus be grain-limited.

Image Digitizers (Scanners)

Accuracy and speed are the main considerations in converting an image on film into digital form. Accuracy has two aspects: spatial resolution, loosely the level of image spatial detail to which the digitizer can respond, and gray-level resolution, defined generally as the range of densities or reflectances to which the digitizer responds and how finely it divides the range. Speed is also important because usually many data are involved; images of 1 million samples are commonplace.

Digitizers broadly take two forms: mechanical and "flying spot." In a mechanical digitizer, the film and a sensing assembly are mechanically transported past one another while readings are made. In a flying-spot digitizer, the film and sensor are static. What moves is the "flying spot," which is a point of light on the face of a cathode-ray tube, or a laser beam directed by mirrors. In all digitizers a very narrow beam of light is directed through the film or onto the print at a known coordinate point. The light transmittance or reflectance is measured, transformed from analog to digital form, and made available to the computer through interfacing electronics. The location on the medium where density is being measured may also be transmitted with each reading, but it is usually determined by relative offset from positions transmitted less frequently. For example, a "new scan line" impulse is transmitted for TV output; the position along the current scan line yields an x position, and the number of scan lines yields a y position.

The mechanical scanners are mostly of two types, *flat-bed* and *drum*. In a flat-bed digitizer, the film is laid flat on a surface over which the light source and the sensor (usually a very accurate photoelectric cell) are transported in a raster fashion. In a drum digitizer, the film is fastened to a circular drum which revolves as the sensor and light source are transported down the drum parallel to its axis of rotation.

Color mechanical digitizers also exist; they work by using colored filters, effectively extracting in three scans three "color overlays" which when superimposed would yield the original color image. Extracting some "composite" color signal with one reading presents technical problems and would be difficult to do as accurately.

Satellite Imagery

LANDSAT and ERTS (Earth Resources Technology Satellites) have similar scanners which produce images of 2340×3380 7-bit pixels in four spectral bands, covering an area of 100×100 nautical miles. The scanner is mechanical, scanning six horizontal scan lines at a time; the rotation of the earth accounts for the advancement of the scan in the vertical direction.

A set of four images is shown in Fig. 2.18. The four spectral bands are numbered 4, 5, 6, and 7. Band 4 [0.5 to $0.6 \mu\text{m}$ (green)] accentuates sediment-laden water and shallow water, band 5 [0.6 to $0.7 \mu\text{m}$ (red)] emphasizes cultural features such as roads and cities, band 6 [0.7 to $0.8 \mu\text{m}$ (near infrared)] emphasizes vegetation and accentuates the contrast between land and water, band 7 [0.8 to $1.1 \mu\text{m}$ (near infrared)] is like band 6 except that it is better at penetrating atmospheric haze.

The LANDSAT images are available at nominal cost from the U.S. government (The EROS Data Center, Sioux Falls, South Dakota 57198). They are furnished on tape, and cover the entire surface of the earth (often the buyer has a choice of the amount of cloud cover). These images form a huge data base of multispectral imagery, useful for land-use and geological studies; they furnish something of an image analysis challenge, since one satellite can produce some 6 billion bits of image data per day.

Television Imaging

Television cameras are appealing devices for computer vision applications for several reasons. For one thing, the image is immediate; the camera can show events as they happen. For another, the image is already in electrical, if not digital form. "Television camera" is basically a nontechnical term, because many different technologies produce video signals conforming to the standards set by the FCC and NTSC. Cameras exist with a wide variety of technical specifications.

Usually, TV cameras have associated electronics which scan an entire "picture" at a time. This operation is closely related to broadcast and receiver standards, and is more oriented to human viewing than to computer vision. An entire image (of some 525 scan lines in the United States) is called a *frame*, and consists of two *fields*, each made up of alternate scan lines from the frame. These fields are generated and transmitted sequentially by the camera electronics. The transmitted image is thus *interlaced*, with all odd-numbered scan lines being "painted" on the

Fig. 2.18 The straits of Juan de Fuca as seen by the LANDSAT multispectral scanner. (a) Band 4; (b) band 5; (c) band 6; (d) band 7.

screen alternating with all even-numbered scan lines. In the United States, each field takes $\frac{1}{60}$ sec to scan, so a whole frame is scanned every $\frac{1}{30}$ sec. The interlacing is largely to prevent flickering of the image, which would become noticeable if the frame were painted from top to bottom only once in $\frac{1}{30}$ sec. These automatic scanning electronics may be replaced or overridden in many cameras, allowing “random access” to the image. In some technologies, such as the image dissector, the longer the signal is collected from any location, the better the signal-to-noise performance.

There are a number of different systems used to generate television images. We discuss five main methods below.

Image orthicon tube. This is one of the two main methods in use today (in addition to the vidicon). It offers very stable performance at all incident light levels

and is widely used in commercial television. It is a storage-type tube, since it depends on the neutralization of positive charges by a scanning electron beam.

The image orthicon (Fig. 2.19) is divided into an imaging and readout section. In the imaging section, light from the scene is focused onto a semitransparent photocathode. This photocathode operates the same way as the cathode in a phototube. It emits electrons which are magnetically focused by a coil and are accelerated toward a positively charged target. The target is a thin glass disk with a fine-wire-mesh screen facing the photocathode. When electrons strike it, secondary emission from the glass takes place. As electrons are emitted from the photocathode side of the disk, positive charges build up on the scanning side. These charges correspond to the pattern of light intensity in the scene being viewed.

In the readout section, the back of the target is scanned by a low velocity electron beam from an electron gun at the rear of the tube. Electrons in this beam are absorbed by the target in varying amounts, depending on the charge on the target. The image is represented by the amplitude-modulated intensity of the returned beam.

Vidicon tube. The vidicon is smaller, lighter, and more rugged than the image orthicon, making it ideal for portable use. Here the target (the inner surface of the face plate) is coated with a transparent conducting film which forms a video signal electrode (Fig. 2.20). A thin photosensitive layer is deposited on the film, consisting of a large number of tiny resistive globules whose resistance decreases on illumination. This layer is scanned in raster fashion by a low velocity electron beam from the electron gun at the rear of the tube. The beam deposits electrons on the layer, thus reducing its surface potential. The two surfaces of the target essentially form a capacitor, and the scanning action of the beam produces a capacitive current at the video signal electrode which represents the video signal.

The plumbicon is essentially a vidicon with a lead oxide photosensitive layer. It offers the following advantages over the vidicon: higher sensitivity, lower dark current, and negligible persistence or lag.

Fig. 2.19 The image orthicon.

Fig. 2.20 The vidicon.

Iconoscope tube. The iconoscope is now largely of historical interest. In it, an electron beam scans a target consisting of a thin mica sheet or mosaic coated with a photosensitive layer. In contrast to the vidicon and orthicon, the electron beam and the light both strike the same side of the target surface. The back of the mosaic is covered with a conductive film connected to an output load. The arrangement is equivalent to a matrix of small capacitors which discharge through a common lead.

Image dissector tube. The image dissector tube operates on instantaneous scanning rather than by neutralizing positive charges. Light from the scene is focused on a cathode coated with a photosensitive layer (Fig. 2.21). The cathode emits electrons in proportion to the amount of light striking it. These electrons are accelerated toward a target by the anode. The target is an electron multiplier covered by a small aperture which allows only a small part of the "electron image" emitted by the cathode to reach the target. The electron image is focused by a focusing coil that produces an axial magnetic field. The deflection coils then scan the electron image past the target aperture, where the electron multiplier produces a varying voltage representing the video signal. The image is thus "dissected" as it is scanned past the target, in an electronic version of a flat-bed digitizing process.

Charge transfer devices. A more recent development in image formation is that of solid-state image sensors, known as charge transfer devices (CTDs). There are two main classes of CTDs: charge-coupled devices (CCDs) and charge-injection devices (CIDs).

CCDs resemble MOSFETs (metal-oxide semiconductor field-effect transistor) in that they contain a "source" region and a "drain" region coupled by a depletion-region channel (Fig. 2.22). For imaging purposes, they can be considered as a monolithic array of closely spaced MOS capacitors forming a shift register (Fig. 2.23). Charges in the depletion region are transferred to the output by applying a series of clocking pulses to a row of electrodes between the source and the drain.

Photons incident on the semiconductor generate a series of charges on the CCD array. They are transferred to an output register either directly one line at a time (line transfer) or via a temporary storage area (frame transfer). The storage

Fig. 2.21 Image dissector.

area is needed in frame transfer because the CCD array is scanned more rapidly than the output can be directly accommodated.

Charge injection devices (CIDs) resemble CCDs except that during sensing the charge is confined to the image site where it was generated (Fig. 2.24). The charges are read using an *X-Y* addressing technique similar to that used in computer memories. Basically, the stored charge is “injected” into the substrate and the resulting displacement current is detected to create the video signal.

CTD technology offers a number of advantages over conventional-tube-type cameras: light weight, small size, low power consumption, resistance to burn-in, low blooming, low dark current, high sensitivity, wide spectral and dynamic range, and lack of persistence. CIDs have the further advantages over CCDs of tolerance to processing defects, simple mechanization, avoidance of charge transfer losses, and minimized blooming. CTD cameras are now available commercially.

Analog-to-Digital Conversion

With current technology, the representation of an image as an analog electrical waveform is usually an unavoidable precursor to further processing. Thus the operation of deriving a digital representation of an analog voltage is basic to computer vision input devices.

Fig. 2.22 Charge coupled device.

Fig. 2.23 A CCD array (line transfer).

The function of an analog-to-digital (A/D) converter is to take as input a voltage such as a video signal and to produce as output a representation of the voltage in digital memory, suitable for reading by an interface to a digital computer. The quality of an A/D converter is measured by its temporal resolution (the speed at which it can perform conversions) and the accuracy of its digital output. Analog-

Fig. 2.24 A CID array.

to-digital converters are being produced as integrated circuit chips, but high-quality models are still expensive. The output precision is usually in the 8- to 12-bit range.

It is quite possible to digitize an entire frame of a TV camera (i.e., approximately 525 scan lines by 300 or so samples along a scan line) in a single frame time (1/30 sec in the United States). Several commercial systems can provide such fast digitization into a "frame buffer" memory, along with raster graphics display capabilities from the same frame buffer, and "video rate processing" of the digital data. The latter term refers to any of various low-level operations (such as averaging, convolution with small templates, image subtraction) which may be performed as fast as the images are acquired.

One inexpensive alternative to digitizing entire TV frames at once is to use an interface that acquires the TV signal for a particular point when the scan passes the requested location. With efficient programming, this point-by-point digitization can acquire an entire frame in a few seconds.

2.3.2 Sensing Range

The third dimension may be derived from binocular images by triangulation, as we saw earlier, or inferred from single monocular visual input by a variety of "depth cues," such as size and occlusion. Specialized technology exists to acquire "depth images" directly and reliably. Here we outline two such techniques: "light striping," which is based on triangulation, and "spot ranging," which is based on different principles.

Light Striping

Light striping is a particularly simple case of the use of *structured light* [Will and Pennington 1971]. The basic idea is to use geometric information in the illumination to help extract geometric information from the scene. The spatial frequencies and angles of bars of light falling on a scene may be clustered to find faces; randomly structured light may allow blank, featureless surfaces to be matched in stereo views; and so forth.

Many researchers [Poppstone et al. 1975; Agin 1972; Sugihara 1977] have used striping to derive three dimensions. In light striping, a single plane of light is projected onto a scene, which causes a stripe of light to appear on the scene (Fig. 2.25). Only the part of the scene illuminated by the plane is sensed by the vision system. This restricts the "image" to be an essentially one-dimensional entity, and simplifies matching corresponding points. The plane itself has a known position (equation in world coordinates), determinable by any number of methods involving either the measurement of the projecting device or the measurement of the final resulting plane of light. Every image point determines a single "line of sight" in three-space upon which the world point that produces the image point must lie. This line is determined by the focal point of the imaging system and the image point upon which the world point projects. In a light-striping system, any point that is sensed in the image is also guaranteed to lie on the light plane in three-space. But the light plane and the line of sight intersect in just one point (as long as

Fig. 2.25 Light striping. (a) A typical arrangement; (b) raw data; (c) data segmented into strips; (d) strips segmented into two surfaces.

the camera's focal point is not in the light plane). Thus by computation of the intersection of the line of sight with the plane of light, we derive the three-dimensional point that corresponds to any image point visible as part of a stripe.

The plane of light may result from a laser or from the projection of a slit. Only the light stripe should be visible to the imaging device; unless a laser is used, this implies a darkened room. If a camera is fitted with the proper filter, a laser-based system can be operated in normal light. Another advantage of the laser is that it can be focused into a narrower plane than can a slit image.

The only points whose three-dimensional coordinates can be computed are those that can be "seen" by both the light-stripe source and the camera at once. Since there must be a nonzero baseline if triangulation is to derive three-dimensional information, the camera cannot be too close to the projector, and thus concavities in the scene are potential trouble spots, since both the strip and the

camera may not be able to “see” into them. Surfaces in the scene that are nearly parallel with the light plane will have a relatively small number of stripes projected onto them by any uniform stripe placement strategy. This problem is ameliorated by striping with two sets of parallel planes at right angles to each other [Agin 1972]. A major advantage of light striping over spot ranging is that (barring shadows) its continuity and discontinuity indicate similar conditions on the surface. It is easy to “segment” stripe images (Part II): Stripes falling on the same surface may easily be gathered together. This set of related stripes may be used in a number of ways to derive further information on the characteristics of the surface (Fig. 2.25b).

Spot Ranging

Civil engineers have used laser-based “spot range finders” for some time. In laboratory-size environments, they are a relatively new development. There are two basic techniques. First, one can emit a very sharp pulse and time its return (“lidar,” the light equivalent of radar). This requires a sophisticated laser and electronics, since light moves 1 ft every billionth of a second, approximately. The second technique is to modulate the laser light in amplitude and upon its return compare the phase of the returning light with that of the modulator. The phase differences are related to the distance traveled [Nitzan et al. 1977]. A representative image is shown in Fig. 2.26.

Both these techniques produce results that are accurate to within about 1% of the range. Both of them allow the laser to be placed close to a camera, and thus “intensity maps” (images) and range maps may be produced from single viewpoints. The laser beam can easily poke into holes, and the return beam may be sensed close to the emitted one, so concavities do not present a serious problem. Since the laser beam is attenuated by absorption, it can yield intensity information as well. If the laser produces light of several wavelengths, it is possible to use filters and obtain multispectral reflectance information as well as depth information from the same device [Garvey 1976; Nitzan et al. 1977].

The usual mode of use of a spot ranging device is to produce a range map that corresponds to an intensity map. This has its advantages in that the correspondence may be close. The structural properties of light stripes are lost: It can be hard to “segment” the image into surfaces (to tell which “range pixels” are associated with the same surface). Range maps are amenable to the same sorts of segmentation techniques that are used for intensity images: Hough techniques, region growing, or differentiation-based methods of edge finding (Part II).

Ultrasonic Ranging

Just as light can be pulsed to determine range, so can sound and ultrasound (frequencies much higher than the audible range). Ultrasound has been used extensively in medicine to produce images of human organs (e.g., [Waag and Gramiak 1976]). The time between the transmitted and received signal determines range; the sound signal travels much slower than light, making the problem of timing the returning signal rather easier than it is in pulsed laser devices. However, the signal is severely attenuated as it travels through biological tissue, so that the detection apparatus must be very sensitive.

(a)

(b)

Fig. 2.26 Intensity and range images. (a) A (synthesized) intensity image of a street scene with potholes. The roofs all have the same intensity, which is different from the walls; (b) a corresponding range image. The wall and roof of each house have similar ranges, but the ranges differ from house to house.

One basic difference between sound and visible light ranging is that a light beam is usually reflected off just one surface, but that a sound beam is generally partially transmitted and partially reflected by “surfaces.” The returning sound pulse has structure determined by the discontinuities in impedance to sound found in the medium through which it has passed. Roughly, a light beam returns information about a spot, whereas a sound beam can return information about the medium in the entire column of material. Thus, although sound itself travels relatively slowly, the data rate implicit in the returning structured sound pulse is quite high. Figure 2.27 shows an image made using the range data from ultrasound. The

Fig. 2.27 Image made from ultrasound ranging.

sound pulses emanate from the top of the image and proceed toward the bottom, being partially reflected and transmitted along the way. In the figure, it is as if we were looking perpendicular to the beams, which are being displayed as brighter where strong reflectance is taking place. A single “scan line” of sound thus produces an image of an entire planar slice of medium.

2.3.3 Reconstruction Imaging

Two-dimensional reconstruction has been the focus of much research attention because of its important medical applications. High-quality images such as that shown in Fig. 1.2b can be formed by multiple images of x-ray projection data. This section contains the principles behind the most important reconstruction algorithms. These techniques are discussed in more detail with an expanded list of references in [Gordon and Herman 1974]. For a view of the many applications of two-dimensional reconstruction other than transmission scanning, the reader is referred to [Gordon et al. 1975].

Figure 2.28 shows the basic geometry to collect one-dimensional projections of two-dimensional data. (Most systems construct the image in a plane and repeat this technique for other planes; there are few true three-dimensional reconstruction systems that use planes of projection data simultaneously to construct volumes.)

In many applications sensors can measure the one-dimensional *projection* of two-dimensional image data. The projection $g(x')$ of an ideal image $f(x, y)$ in the direction θ is given by $\int f(x', y') dy'$ where $\mathbf{x}' = R_\theta \mathbf{x}$. If enough different projections are obtained, a good approximation to the image can be obtained with two-dimensional reconstruction techniques.

From Fig. 2.28, with the source at the first position along line AA' , we can obtain the first projection datum from the detector at the first position along BB' . The line AB is termed a ray and the measurement at B a ray sum. Moving the source

Fig. 2.28 Projection geometry.

and detector along lines AA' and BB' in synchrony allows us to obtain the entire data for projection 1. Now the lines AA' and BB' are rotated by a small angle $d\theta$ about 0 and the process is repeated. In the original x-ray systems $d\theta$ was 1° of angle, and 180 projections were taken. Each projection comprised 160 transmission measurements. The reconstruction problem is simply this: Given the projection data $g_k(x')$, $k = 0, \dots, N - 1$, construct the original image $f(\mathbf{x})$.

Systems in use today use a fan beam rather than the parallel rays shown. However, the mathematics is simpler for parallel rays and illustrates the fundamental ideas. We describe three related techniques: summation, Fourier interpolation, and convolution.

The Summation Method

The summation method is simple: Distribute every ray sum $g_k(x')$ over the image cells along the ray. Where there are N cells along a ray, each such cell is incremented by $\frac{1}{N}g(x')$. This step is termed *back projection*. Repeating this process for every ray results in an approximate version of the original [DeRosier 1971]. This technique is equivalent (within a scale factor) to blurring the image, or convolving it with a certain point-spread function. In the continuous case of infinitely many projections, this function is simply the radially symmetric $h(r) = 1/r$.

Fig. 2.29 Basis of Fourier techniques. (a) Projection axis x' ; (b) corresponding axis in Fourier Space.

Fourier Algorithms

If a projection is Fourier-transformed, it defines a line through the origin in frequency space (Fig. 2.29). To show this formally, consider the expression for the two-dimensional transform

$$F(\mathbf{u}) = \iint f(x, y) \exp [j2\pi(ux + vy)] dx dy \quad (2.47)$$

Now consider $y = 0$ (projection onto the x axis): $x' = x$ and

$$g_0(x') = \int f(x, y) dy \quad (2.48)$$

The Fourier transform of this equation is

$$\begin{aligned} \mathfrak{F}[g_0(x')] &= \iint [f(x, y) dy] \exp j2\pi ux dx \\ &= \iint f(x, y) \exp j2\pi ux dy dx \end{aligned} \quad (2.49)$$

which, by comparison with (2.47), is

$$\mathfrak{F}[g_0(x')] = F(u, 0) \quad (2.50)$$

Generalizing to any θ , the transform of an arbitrary $g(x')$ defines a line in the Fourier space representation of the cross section. Where $S_k(\omega)$ is the cross section of the Fourier transform along this line,

$$\begin{aligned} S_k(\omega) &= F(u \cos \theta, u \sin \theta) \\ &= \int g_k(x') \exp [-j2\pi u(x')] dx' \end{aligned} \quad (2.51)$$

Thus one way of reconstructing the original image is to use the Fourier transform of the projections to define points in the transform of $f(x)$, interpolate the undefined points of the transform from the known points, and finally take the inverse transform to obtain the reconstructed image.

Fig. 2.30 Convolution method.

This technique can be applied with transforms other than the Fourier transform, and such methods are discussed in [DeRosier 1971; Crowther and Klug 1971].

The Convolution Method

The convolution method is the natural extension of the summation method. Since the summation method produces an image degraded from its convolution with some function h , one can remove the degradation by a "deconvolution." The straightforward way to accomplish this is to Fourier-transform the degraded image, multiply the result by an estimate of the transformed h^{-1} , and inverse-Fourier-transform the result. However, since all the operations are linear, a faster approach is to deconvolve the projections before performing the back projection. To show this formally, we use the inverse transform

$$f(\mathbf{x}) = \iint F(u, v) \exp [j2\pi(ux + vy)] du dv \quad (2.52)$$

Changing to cylindrical coordinates (ω, θ) yields

$$f(\mathbf{x}) = \iint F_\theta(\omega) \exp [j2\pi\omega(x \cos \theta + y \sin \theta)] |\omega| d\omega d\theta \quad (2.53)$$

Since $x' = x \cos \theta + y \sin \theta$, rewrite Eq. (2.53) as

$$f(\mathbf{x}) = \int \mathcal{F}^{-1}\{F_\theta(\omega)H(\omega)\} d\theta \quad (2.54)$$

Since the image is bandlimited at some interval $(-\omega_m, \omega_m)$ one can define $H(\omega)$ arbitrarily outside of this interval. Therefore, $H(\omega)$ can be defined as a constant minus a triangular peak as shown in Fig. 2.30. Finally, the operation inside the integral in Eq. (2.54) is a convolution. Using the transforms shown in Fig. 2.30,

$$f(\mathbf{x}) = \int [f_\theta(x') - f_\theta(x')\omega_m \text{sinc}^2(\omega_m x')] d\theta \quad (2.55)$$

Owing to its speed and the fact that the deconvolutions can be performed while the data are being acquired, the convolution method is the method employed in the majority of systems.

EXERCISES

- 2.1 In a binocular animal vision system, assume a focal length f of an eye of 50 mm and a separation distance d of 5 cm. Make a plot of Δx vs. $-z$ using Eq. (2.9). If the resolution of each eye is on the order of 50 line pairs/mm, what is the useful range of the binocular system?

2.2 In an opponent-process color vision system, assume that the following relations hold:

For example, if the $(R-G, B-Y, W-Bk)$ components of the opponent-process system are $(0.5, 3, 4)$, the perceived color will be blue.

Work out the perceived colors for the following (R,G,B) measurements:

- (a) $(0.2, 0.3, 0.4)$ (b) $(0.2, 0.3, 0)$ (c) $(7, 4, 1)$

2.3 Develop an indexing scheme for a hexagonal array and define a Euclidean distance measure between points in the array.

2.4 Assume that a one-dimensional image has the following form:

$$f(x) = \cos(2\pi u_0 x)$$

and is sampled with $u_s = u_0$. Using the graphical method of Section 2.2.6, find an expression for $f(x)$ as given by Eq. (2.49). Is this expression equal to the original image? Explain.

2.5 A certain image has the following Fourier transform:

$$F(\mathbf{u}) = \begin{cases} \text{nonzero} & \text{inside a hexagonal domain} \\ 0 & \text{otherwise} \end{cases}$$

- (a) What are the smallest values for u and v so that $F(\mathbf{u})$ can be reconstructed from $F_x(\mathbf{u})$?
- (b) Suppose now that rectangular sampling is *not* used but that now the u and v directions subtend an angle of $\pi/3$. Does this change your answer as to the smallest u and v ? Explain.
- 2.6 Extend the binocular imaging model of Fig. 2.3 to include convergence: Let the two imaging systems pivot in the $y = 0$ plane about the viewpoint. Let the system have a baseline of $2d$ and be converged at some angle θ such that a point (x, y, z) appears at the origin of each image plane.

- (a) Solve for z in terms of r and θ .
- (b) Solve for z in this situation for points with nonzero disparity.

2.7 Compute the convolution of two Rect functions, where

$$\text{Rect}(x) = \begin{cases} 1 & 0 < x < 1 \\ 0 & \text{otherwise} \end{cases}$$

Show the steps in your calculations.

2.8

$$\text{Rect}(x) = \begin{cases} b & \text{for } |x| < a \\ 0 & \text{otherwise} \end{cases}$$

- (a) What is $\text{Rect}(x) * \delta(x-a)$?
- (b) What is the Fourier transform of $f(x)$ where $f(x) = \text{Rect}(x+c) + \text{Rect}(x-c)$ and $c > a$?
- 2.9 A digitizer has a sampling interval of $\Delta x = \Delta y = \Delta$. Which of the following images can be represented unambiguously by their samples? (Assume that effects of a finite image domain can be neglected.)
- (a) $(\sin(\pi x/\Delta))/(\pi x/\Delta)$
- (b) $\cos(\pi x/2\Delta)\cos(3\pi x/4\Delta)$
- (c) $\text{Rect}(x)$ (see Problem 2.8)
- (d) e^{-ax^2}

Early Processing

3

3.1 RECOVERING INTRINSIC STRUCTURE

The imaging process confounds much useful physical information into the gray-level array. In this respect, the imaging process is a collection of degenerate transformations. However, this information is not irrevocably lost, because there is much spatial redundancy: Neighboring pixels in the image have the same or nearly the same physical parameters. A collection of techniques, which we call *early processing*, exploits this redundancy in order to undo the degeneracies in the imaging process. These techniques have the character of transformations for changing the image into “parameter images” or *intrinsic images* [Barrow and Tenenbaum 1978; 1981] which reflect the spatial properties of the scene. Common intrinsic parameters are surface discontinuities, range, surface orientation, and velocity.

In this chapter we neglect high-level internal model information even though it is important and can affect early processing. Consider the case of the perceived central edge in Fig. 3.1a. As shown by Fig. 3.1b, which shows portions of the same image, the central edge of Fig. 3.1a is not present in the data. Nevertheless, the human perceiver “sees” the edge, and one reasonable explanation is that it is a product of an internal block model. Model-directed activity is taken up in later chapters. These examples show how high level models (e.g., circles) can affect low-level processors (e.g., edge finders). However, for the purposes of study it is often helpful to neglect these effects. These simplifications make it easier to derive the fundamental constraints between the physical parameters and gray levels. Once these are understood, they can be modified using the more abstract structures of later chapters.

Most early computer vision processing can be done with parallel computations whose inputs tend to be spatially localized. When computing intrinsic images

Fig. 3.1 (a) A perceived edge. (b) Portions of image in (a) showing the lack of image data.

the parallel computations are iterated until the intrinsic parameter measurements converge to a set of values. A computation that falls in the parallel-iterative category is known in computer vision as *relaxation* [Rosenfeld et al. 1976]. Relaxation is a very general computational technique that is useful in computer vision. Specific examples of relaxation computations appear throughout the book; general observations on relaxation appear in Chapter 12.

This chapter covers six categories of early processing techniques:

1. *Filtering* is a generic name for techniques of changing image gray levels to enhance the appearance of objects. Most often this means transformations that make the intensity discontinuities between regions more prominent. These transformations are often dependent on gross object characteristics. For example, if the objects of interest are expected to be relatively large, the image can be blurred to erase small intensity discontinuities while retaining those of the object's boundary. Conversely, if the objects are relatively small, a transformation that selectively removes large discontinuities may be appropriate. Filtering can also compensate for spatially varying illumination.
2. *Edge operators* detect and measure very local discontinuities in intensity or its gradient. The result of an edge operator is usually the magnitude and orientation of the discontinuity.
3. *Range transforms* use known geometry about stereo images to infer the distance of points from the viewer. These transforms make use of the inverse perspective transform to interpret how points in three-dimensional space project onto stereo pairs. A correspondence between points in two stereo images of known geometry determines the range of those points. Relative range may also be derived from local correspondences without knowing the imaging geometry precisely.
4. *Surface orientation* can be calculated if the source illumination and reflectance properties of the surface are known. This calculation is sometimes called

“shape from shading.” Surface orientation is particularly simple to calculate when the source illumination can be controlled.

5. *Optical flow*, or velocity fields of image points, can be calculated from local temporal and spatial variations in sequences of gray-level images.
6. A *pyramid* is a general structure for representing copies of the image at multiple resolutions. A pyramid is a “utility structure” which can dramatically improve the speed and effectiveness of many early processing and later segmentation algorithms.

3.2 FILTERING THE IMAGE

Filtering is a very general notion of transforming the image intensities in some way so as to enhance or deemphasize certain features. We consider only transforms that leave the image in its original format: a spatial array of gray levels. Spurred on by the needs of planetary probes and aerial reconnaissance, filtering initially received more attention than any other area of image processing and there are excellent detailed reference works (e.g., [Andrews and Hunt 1977; Pratt 1978; Gonzalez and Wintz 1977]). We cannot afford to examine these techniques in great detail here; instead, our intent is to describe a set of techniques that conveys the principal ideas.

Almost without exception, the best time to filter an image is at the image formation stage, before it has been sampled. A good example of this is the way chemical stains improve the effectiveness of microscopic tissue analysis by changing the image so that diagnostic features are obvious. In contrast, filtering after sampling often emphasizes random variations in the image, termed *noise*, that are undesirable effects introduced in the sampling stage. However, for cases where the image formation process cannot be changed, digital filtering techniques do exist. For example, one may want to suppress low spatial frequencies in an image and sharpen its edges. An image filtered in this way is shown in Fig. 3.2.

Note that in Fig. 3.2 the work of recognizing real-world objects still has to be done. Yet the edges in the image, which constitute object boundaries, have been made more prominent by the filtering operation. Good filtering functions are not easy to define. For example, one hazard with Fourier techniques is that sharp edges in the filter will produce unwanted “ringing” in the spatial domain, as evidenced by Fig. 2.5. Unfortunately, it would be too much of a digression to discuss techniques of filter design. Instead, the interested reader should refer to the references cited earlier.

3.2.1 Template Matching

Template matching is a simple filtering method of detecting a particular feature in an image. Provided that the appearance of this feature in the image is known accu-

Fig. 3.2 Effects of high frequency filtering. (a) Original image. (b) Filtered image.

rately, one can try to detect it with an operator called a *template*. This template is, in effect, a subimage that looks just like the image of the object. A similarity measure is computed which reflects how well the image data match the template for each possible template location. The point of maximal match can be selected as the location of the feature. Figure 3.3 shows an industrial image and a relevant template.

Correlation

One standard similarity measure between a function $f(\mathbf{x})$ and a template $t(\mathbf{x})$ is the Euclidean distance $d(\mathbf{y})$ squared, given by

$$d(\mathbf{y})^2 = \sum_{\mathbf{x}} [f(\mathbf{x}) - t(\mathbf{x} - \mathbf{y})]^2 \quad (3.1)$$

By $\sum_{\mathbf{x}}$ we mean $\sum_{\mathbf{x}=-M}^M \sum_{\mathbf{y}=-N}^N$, for some M, N which define the size of the template extent. If the image at point \mathbf{y} is an exact match, then $d(\mathbf{y}) = 0$; otherwise, $d(\mathbf{y}) > 0$. Expanding the expression for d^2 , we can see that

$$d^2(\mathbf{y}) = \sum_{\mathbf{x}} [f^2(\mathbf{x}) - 2f(\mathbf{x})t(\mathbf{x} - \mathbf{y}) + t^2(\mathbf{x} - \mathbf{y})] \quad (3.2)$$

Notice that $\sum_{\mathbf{x}} t^2(\mathbf{x} - \mathbf{y})$ is a constant term and can be neglected. When $\sum_{\mathbf{x}} f^2(\mathbf{x})$ is approximately constant it too can be discounted, leaving what is called the *cross correlation* between f and t .

$$R_{ft}(\mathbf{y}) = \sum_{\mathbf{x}} f(\mathbf{x})t(\mathbf{x} - \mathbf{y}) \quad (3.3)$$

This is maximized when the portion of the image “under” t is identical to t .

Fig. 3.3 An industrial image and template for a hexagonal nut.

One may visualize the template-matching calculations by imagining the template being *shifted* across the image to different offsets; then the superimposed values at this offset are *multiplied* together, and the products are *added*. The resulting sum of products forms an entry in the “correlation array” whose coordinates are the offsets attained by the source template.

If the template is allowed to take *all* offsets with respect to the image such that some overlap takes place, the correlation array is larger than either the template or the image. An $n \times n$ image with an $m \times m$ template yields an $(n + m - 1 \times n + m - 1)$ correlation array. If the template is not allowed to shift off the image, the correlation array is $(n - m + 1 \times n - m + 1)$; for $m < n$. Another form of correlation results from computing the offsets modulo the size of the image; in other words, the template “wraps around” the image. Being shifted off to the right, its right portion reappears on the left of the image. This sort of correlation is called *periodic* correlation, and those with no such wraparound properties are called *aperiodic*. We shall be concerned exclusively with aperiodic correlation. One can always modify the input to a periodic correlation algorithm by padding the outside with zeros so that the output is the aperiodic correlation.

Figure 3.4 provides an example of (aperiodic) “shift, add, multiply” template matching. This figure illustrates some difficulties with the simple correlation measure of similarity. Many of the advantages and disadvantages of this measure stem from the fact that it is linear. The advantages of this simplicity have mainly to do with the existence of algorithms for performing the calculation efficiently (in a transform domain) for the entire set of offsets. The disadvantages have to do with

Template	Image	Correlation
1 1 1	1 1 0 0 0	7 4 2 x x
1 1 1	1 1 1 0 0	5 3 2 x x
1 1 1	1 0 1 0 0	2 1 9 x x
	0 0 0 0 0	x x x x x
	0 0 0 0 8	x x x x x
		x = undefined

Fig. 3.4 (a) A simple template. (b) An image with noise. (c) The aperiodic correlation array of the template and image. Ideally peaks in the correlation indicate positions of good match. Here the correlation is only calculated for offsets that leave the template entirely within the image. The correct peak is the upper left one at 0, 0 offset. The “false alarm” at offset 2, 2 is caused by the bright “noise point” in the lower right of the image.

the fact that the metric is sensitive to properties of the image that may vary with the offset, such as its average brightness. Slight changes in the shape of the object, its size, orientation, or intensity values can also disturb the match.

Nonetheless, the idea of template matching is important, particularly if Eq. (3.3) is viewed as a *filtering* operation instead of an algorithm that does all the work of object detection. With this viewpoint one chooses one or more templates (filters) that transform the image so that certain features of an object are more readily apparent. These templates generally highlight subparts of the objects. One such class of templates is edge templates (discussed in detail in Section 3.3).

We showed in Section 2.2.4 that convolution and multiplication are Fourier transform pairs. Now note that the correlation operation in (3.3) is essentially the same as a convolution with a function $t'(\mathbf{x}) \equiv t(-\mathbf{x})$. Thus in a mathematical sense cross correlation and convolution are equivalent. Consequently, if the size of the template is sufficiently large, it is cheaper to perform the template matching operation in the spatial frequency domain, by the same transform techniques as for filtering.

Normalized Correlation

A crucial assumption in the development of Eq. (3.3) was that the image energy covered by the matching template at any offset was constant; this leads to a linear correlation matching technique. This assumption is approximately correct if the average image intensity varies slowly compared to the template size, but a bright spot in the image can heavily influence the correlation by affecting the sum of products violently in a small area (Fig. 3.4). Even if the image is well behaved, the range of values of the metric can vary with the size of the matching template. Are there ways of normalizing the correlation metric to make it insensitive to these variations?

There is a well-known treatment of the normalized correlation operation. It has been used for a variety of tasks involving registration and stereopsis of images [Quam and Hannah 1974]. Let us say that two input images are being matched to find the best offset that aligns them.

Let $f_1(\mathbf{x})$ and $f_2(\mathbf{x})$ be the images to be matched. q_2 is the patch of f_2 (possibly all of it) that is to be matched with a similar-sized patch of f_1 . q_1 is the patch of f_1 that is covered by q_2 when q_2 is offset by \mathbf{y} .

Let $E()$ be the expectation operator. Then

$$\sigma(q_1) = [E(q_1^2) - (E(q_1))^2]^{1/2} \quad (3.4)$$

$$\sigma(q_2) = [E(q_2^2) - (E(q_2))^2]^{1/2} \quad (3.5)$$

give the standard deviations of points in patches q_1 and q_2 . (For notational convenience, we have dropped the spatial arguments of q_1 and q_2 .) Finally, the normalized correlation is

$$N(\mathbf{y}) = \frac{E(q_1 q_2) - E(q_1)E(q_2)}{\sigma(q_1)\sigma(q_2)} \quad (3.6)$$

and $E(q_1 q_2)$ is the expected value of the product of intensities of points that are superimposed by the translation by \mathbf{y} .

The normalized correlation metric is less dependent on the local properties of the reference and input images than is the unnormalized correlation, but it is sensitive to the signal-to-noise content of the images. High uncorrelated noise in the two images, or the image and the reference, decreases the value of the correlation. As a result, one should exercise some care in interpreting the metric. If the noise properties of the image are known, one indication of reliability is given by the “(signal + noise)-to-noise” ratio. For the normalized correlation to be useful, the standard deviation of the patches of images to be matched (i.e., of the areas of image including noise) should be significantly greater than that of the noise. Then a correlation value may be considered significant if it is approximately equal to the theoretically expected one. Consider uncorrelated noise of identical standard deviation, in a patch of true value $f(x, y)$. Let the noise component of the image be $n(x, y)$. Then the theoretical maximum correlation is

$$1 - \frac{\sigma^2(n)}{\sigma^2(f+n)} \quad (3.7)$$

In matching an idealized, noise-free reference pattern, the best expected value of the cross correlation is

$$\frac{\sigma(f)}{\sigma(f+n)} \quad (3.8)$$

If the noise and signal characteristics of the data are known, the patch size may be optimized by using that information and the simple statistical arguments above. However, such considerations leave out the effects of systematic, nonstatistical error (such as imaging distortions, rotations, and scale differences between images). These systematic errors grow with patch size, and may swamp the statistical advantages of large patches. In the worst case, they may vitiate the advantages of the correlation process altogether.

Since correlation is expensive, it is advantageous to ensure that there is enough information in the patches chosen for correlation before the operation is done. One way to do this is to apply a cheap “interest operator” before the relatively expensive correlation. The idea here is to make sure that the image varies enough to give a usable correlation image. If the image is of uniform intensity, even its correlation with itself (autocorrelation) is flat everywhere, and no information about where the image is registered with itself is derivable. The “interest operator” is a way of finding areas of image with high variance. In fact, a common and useful interest measure is exactly the (directional) variance over small areas of image. One directional variance algorithm works as follows.

The Moravec interest operator [Moravec 1977] produces candidate match points by measuring the distinctness of a local piece of the image from its surround. To explain the operator, we first define a variance measure at a pixel (x) as

$$\text{var}(x, y) = \left\{ \sum_{k, l \text{ in } s} [f(x, y) - f(x+k, y+l)]^2 \right\}^{1/2} \quad (3.9)$$

$$s = \left\{ (0, a), (0, -a), (a, 0), (-a, 0) \right\}$$

where a is a parameter. Now the interest operator value is initially the minimum of itself and surrounding points:

$$\text{IntOpVal}(x) := \min_{y < 1} [\text{var}(x + y)] \quad (3.10)$$

Next a check is made to see if the operator is a local maximum by checking neighbors again. Only local maxima are kept.

$$\begin{aligned} \text{IntOpVal}(x) &:= 0 \text{ if} \\ \text{IntOpVal}(x) &\geq \text{IntOpVal}(x + y) \\ &\text{for } y \leq 1 \end{aligned} \quad (3.11)$$

Finally, candidate points are chosen from the IntOpVal array by thresholding.

$$x \text{ is a candidate point iff } \text{IntOpVal}(x) > T \quad (3.12)$$

The threshold is chosen empirically to produce some fraction of the total image points.

3.2.2 Histogram Transformations

A gray-level histogram of an image is a function that gives the frequency of occurrence of each gray level in the image. Where the gray levels are quantized from 0 to n , the value of the histogram at a particular gray level p , denoted $h(p)$, is the number or fraction of pixels in the image with that gray level. Figure 3.5 shows an image with its histogram.

A histogram is useful in many different ways. In this section we consider the histogram as a tool to guide gray-level transformation algorithms that are akin to filtering. A very useful image transform is called *histogram equalization*. Histogram equalization defines a mapping of gray levels p into gray levels q such that the distribution of gray levels q is uniform. This mapping stretches contrast (expands the

(a)

(b)

Fig. 3.5 (a) An image. (b) Its intensity histogram.

range of gray levels) for gray levels near histogram maxima and compresses contrast in areas with gray levels near histogram minima. Since contrast is expanded for most of the image pixels, the transformation usually improves the detectability of many image features.

The histogram equalization mapping may be defined in terms of the *cumulative* histogram for the image. To see this, consider Fig. 3.6a. To map a small interval of gray levels dp onto an interval dq in the general case, it must be true that

$$g(q) dq = h(p) dp \quad (3.13)$$

where $g(q)$ is the new histogram. If, in the histogram equalization case, $g(q)$ is to be uniform, then

$$g(q_2) = \frac{N^2}{M} \quad (3.14)$$

Fig. 3.6 (a) Basis for a histogram equalization technique. (b) Results of histogram equalization.

where N^2 is the number of pixels in the image and M is the number of gray levels. Thus combining Eqs. (3.13) and (3.14) and integrating, we have

$$g(q) = \frac{M}{N^2} \int_0^q h(p) dp \quad (3.15)$$

But Eq. (3.15) is simply the equation for the normalized cumulative histogram. Figure 3.6b shows the histogram-equalized image.

3.2.3 Background Subtraction

Background subtraction can be another important filtering step in early processing. Many images can have slowly varying background gray levels which are incidental to the task at hand. Examples of such variations are:

- Solution gradients in cell slides
- Lighting variations on surfaces in office scenes
- Lung images in a chest radiograph

Note that the last example is only a “background” in the context of looking for some smaller variations such as tumors or pneumoconiosis.

Background subtraction attempts to remove these variations by first approximating them (perhaps analytically) with a background image f_b and then subtracting this approximation from the original image. That is, the new image f_n is

$$f_n(\mathbf{x}) = f(\mathbf{x}) - f_b(\mathbf{x}) \quad (3.16)$$

Various functional forms have been tried for analytic representations of slowly varying backgrounds. In the simplest cases, $f_b(\mathbf{x})$ may be a constant,

$$f_b(\mathbf{x}) = c \quad (3.17)$$

or linear,

$$f_b(\mathbf{x}) = \mathbf{m} \cdot \mathbf{x} + c \quad (3.18)$$

A more sophisticated background model is to use a low-pass filtered variant of the original image:

$$f_b(\mathbf{x}) = \mathcal{F}^{-1}[H(\mathbf{u}) F(\mathbf{u})] \quad (3.19)$$

where $H(\mathbf{u})$ is a low-pass filtering function. The problem with this technique is that it is global; one cannot count on the “best” effect in any local area since the filter treats all parts of the image identically. For the same reason, it is difficult to design a Fourier filter that works for a number of very different images.

A workable alternative is to approximate $f_b(\mathbf{x})$, using *splines*, which are piecewise polynomial approximation functions. The mathematics of splines is treated in Chapter 8 since they find more general application as representations of shape. The filtering application is important but specialized. The attractive feature of a spline approximation for filtering is that it is *variation diminishing* and *spatially variant*. The spline approximation is guaranteed to be “smoother” than the origi-

nal function and will approximate the background differently in different parts of the image. The latter feature distinguishes the method from Fourier-domain techniques which are spatially invariant. Figure 3.7 shows the results of spline filtering.

3.2.4 Filtering and Reflectance Models

Leaving the effects of imaging geometry implicit (Section 2.2.2), the definitions in Section 2.2.3 imply that the image irradiance (gray level) at the image point x' is proportional to the product of the scene irradiance E and the *reflectance* r at its corresponding world point x .

$$f(x') = E(x)r(x) \quad (3.20)$$

The irradiance at x is the sum of contributions from all illumination sources, and the reflectance is that portion of the irradiance which is reflected toward the observer (camera). Usually E changes slowly over a scene, whereas r changes quickly over edges, due to varying face angles, paint, and so forth. In many cases one would like to detect these changes in r while ignoring changes in E . One way of doing this is to filter the image $f(x')$ to eliminate the slowly varying component. However, as f is the *product* of illumination and reflectance, it is difficult to define an operation that selectively diminishes E while retaining r . Furthermore, such an operation must retain the positivity of f . One solution is to take the logarithm of Eq. (3.20). Then

$$\log f = \log E + \log r \quad (3.21)$$

Equation (3.21) shows two desirable properties of the logarithmic transformation: (1) the logarithmic image is positive in sign, and (2) the image is a superposition of the irradiance component and reflectance component. Since reflectance is an in-

Fig. 3.7 The results of spline filtering to remove background variation.

trinsic characteristic of objects, the obvious goal of image analysis is to recognize the reflectance component under various conditions of illumination. Since the separation of two components is preserved under linear transformations and the irradiance component is usually of low spatial frequency compared to the reflectance component, filtering techniques can suppress the irradiance component of the signal relative to the reflectance component.

If the changes in r occur over very short distances in the images, r may be isolated by a three-step process [Horn 1974]. First, to enhance reflectance changes, the image function is differentiated (Section 3.3.1). The second step removes the low irradiance gradients by thresholding. Finally, the resultant image is integrated to obtain an image of perceived “lightness” or reflectance. Figure 3.8 shows these steps for the one-dimensional case.

A basic film parameter is density, which is proportional to the logarithm of transmitted intensity; the logarithmically transformed image is effectively a *density image*. In addition to facilitating the extraction of lightness, another advantage of the density image is that it is well matched to our visual experience. The ideas for many image analysis programs stem from our visual inspection of the image. However, the human visual system responds logarithmically to light intensity and also enhances high spatial frequencies [Stockham 1972]. Algorithms derived from

Fig. 3.8 Steps in processing an image to detect reflectance. (a) Original image. (b) Differentiation followed by thresholding. (c) Integration of function in (b).

introspective reasoning about the perceived image (which has been transformed by our visual system) will not necessarily be successful when applied to an unmodified intensity image. Thus one argument for using a density transformation followed by high spatial frequency emphasis filtering is that the computer is then “seeing” more like the human image analyzer.

3.3 FINDING LOCAL EDGES

Boundaries of objects tend to show up as intensity discontinuities in an image. Experiments with the human visual system show that boundaries in images are extremely important; often an object can be recognized from only a crude outline [Attneave 1954]. This fact provides the principal motivation for representing objects by their boundaries. Also, the boundary representation is easy to integrate into a large variety of object recognition algorithms.

One might expect that algorithms could be designed that find the boundaries of objects directly from the gray-level values in the image. But when the boundaries have complicated shapes, this is difficult. Much greater success has been obtained by first transforming the image into an intermediate image of *local* gray-level discontinuities, or edges, and then composing these into a more elaborate boundary. This strategy reflects the principle: When the gap between representations becomes too large, introduce intermediate representations. In this case, boundaries that are highly model-dependent may be decomposed into a series of local edges that are highly model-independent.

A local edge is a small area in the image where the local gray levels are changing rapidly in a simple (e.g., monotonic) way. An *edge operator* is a mathematical operator (or its computational equivalent) with a small spatial extent designed to detect the presence of a local edge in the image function.

It is difficult to specify a priori which local edges correspond to relevant boundaries in the image. Depending on the particular task domain, different local changes will be regarded as likely edges. Plots of gray level versus distance along the direction perpendicular to the edge for some hypothetical edges (Fig. 3.9a-e) demonstrate some different kinds of “edge profiles” that are commonly encountered. Of course, in most practical cases, the edge is noisy (Fig. 3.9d) and may appear as a composite of profile types. The fact that different kinds of edge operators perform best in different task domains has prompted the development of a variety of operators. However, the unifying feature of most useful edge operators is that they compute a *direction* which is aligned with the direction of maximal gray-level change, and a *magnitude* describing the severity of this change. Since edges are a high-spatial-frequency phenomenon, edge finders are also usually sensitive to high-frequency noise, such as “snow” on a TV screen or film grain.

Operators fall into three main classes: (1) operators that approximate the mathematical gradient operator, (2) template matching operators that use multiple templates at different orientations, and (3) operators that fit local intensities with parametric edge models. Representative examples from the first two of these categories appear in this section. The computer vision literature abounds with edge

Fig. 3.9 Edge profiles.

operators, and we make no attempt to summarize them all here. For a guide to this literature, see [Rosenfeld and Kak 1976].

Parametric models generally capture more detailed edge structure than the two-parameter direction and magnitude vector; as a result, they can be more computationally complicated. For this reason and others discussed in Section 3.3.4, we shall omit a detailed discussion of these kinds of edge operators. One of the best known parametric models is Hueckel's [Hueckel 1971, 1973], but several others have been developed since [Mero and Vassy 1975; Nevatia 1977; Abdou 1978; Tretiak 1979].

3.3.1 Types of Edge Operators

Gradient and Laplacian

The most common and historically earliest edge operator is the gradient [Roberts 1965]. For an image function $f(\mathbf{x})$, the gradient magnitude $s(\mathbf{x})$ and direction $\phi(\mathbf{x})$ can be computed as

$$s(\mathbf{x}) = (\Delta_1^2 + \Delta_2^2)^{1/2} \quad (3.22)$$

$$\phi(\mathbf{x}) = \text{atan}(\Delta_2, \Delta_1) \quad (3.23)$$

where

$$\Delta_1 = f(x + n, y) - f(x, y) \quad (3.24)$$

$$\Delta_2 = f(x, y + n) - f(x, y)$$

n is a small integer, usually unity, and $\text{atan}(x, y)$ returns $\tan^{-1}(x/y)$ adjusted to the proper quadrant. The parameter n is called the “span” of the gradient. Roughly, n should be small enough so that the gradient is a good approximation to the local changes in the image function, yet large enough to overcome the effects of small variations in f .

Equation (3.24) is only one *difference operator*, or way of measuring gray-level intensities along orthogonal directions using Δ_1 and Δ_2 . Figure 3.10 shows the gradient difference operators compared to other operators [Roberts 1965; Prewitt 1970]. The reason for the modified operators of Prewitt and Sobel is that the local averaging tends to reduce the effects of noise. These operators do, in fact, perform better than the Roberts operator for a step edge model.

One way to study an edge operator’s performance is to use an ideal edge such as the step edge shown in Fig. 3.11. This edge has two gray levels: zero and h units. If the edge goes through the finite area associated with a pixel, the pixel is given a value between zero and h , depending on the proportion of its area covered. Comparative edge operator performance has been carried out [Abdou 1978]. In the case of the Sobel operator (Fig. 3.10c) the measured orientation ϕ' is given by

Fig. 3.10 Gradient operators.
