

The concept that tumors can be controlled by directly targeting their vascular supply has finally come of age, because clinical trials using a humanized monoclonal antibody that blocks VEGF have demonstrated exciting efficacy in cancer patients, as well as in vascular eye diseases that can lead to blindness. However, data suggest that these current regimens may not provide complete VEGF inhibition and, thus, that the maximum therapeutic potential of VEGF blockade has not yet been achieved. We describe the status of a very potent and high-affinity VEGF blocker, termed the VEGF Trap, that may provide the opportunity to maximize the potential of VEGF blockade in cancer as well as in vascular eye diseases. We also describe use of the VEGF Trap as a research tool, when coupled to high-throughput mouse genetics approaches such as *VelociGene*® that can be exploited in strategies to discover and validate the next generation of angiogenesis targets.

The concept that tumors can be controlled by directly targeting their vascular supply has finally come of age. The first antiangiogenesis approach to be validated in human cancer patients involves blocking vascular endothelial growth factor (VEGF-A). In this regard, the most advanced clinical data have been generated with a humanized monoclonal antibody termed bevacizumab (Avastin) that directly binds and blocks all isoforms of VEGF-A (Ferrara et al. 2004). Despite the promising data achieved to date, dose-response studies suggest that higher doses of bevacizumab may provide even greater benefit (Yang et al. 2003; Yang 2004), implying that current bevacizumab regimens may not provide optimal VEGF inhibition and thus may not have yet demonstrated the maximum potential of VEGF blockade in cancer. In addition to the promise of anti-VEGF approaches in cancer, blocking VEGF-A has also been impressive in maintaining and improving vision in wet age-related macular degeneration (AMD), a disease marked by leaky and proliferating vessels which distort the retina, and these data suggest that VEGF blockade may provide benefit in other eye diseases involving vascular leak and proliferation (Bergsland 2004). Efficacy in wet AMD has most notably been achieved using a modified fragment of the bevacizumab antibody, termed ranibizumab (Lucentis), delivered via monthly intraocular injections (Brown et al. 2006; Heier et al. 2006).

In this paper, we focus on the development and status of a novel VEGF-blocking agent, termed the VEGF Trap, that retains many of the advantages of a blocking antibody but may offer further potential (Holash et al. 2002). The VEGF Trap consists of portions of VEGF receptors that have been fused to the constant region of an antibody, resulting in a fully human biologic with exceedingly high affinity that blocks not only all isoforms of VEGF-A, but also related VEGF family members such as placental

growth factor (PlGF). The VEGF Trap also displays extended pharmacological half-life, allowing long-term as well as very high affinity blockade. The VEGF Trap performed impressively in extensive animal studies in cancer and eye diseases, and initial clinical trials are promising. The VEGF Trap may provide the opportunity to explore the potential of more complete VEGF blockade in cancer, as well as the opportunity for more complete blockade and even longer-interval dosing regimens in eye diseases. To conclude this paper, we describe how the VEGF Trap can be used as a research tool in efforts to discover and validate the next generation of targets in the field of angiogenesis.

DISCOVERY OF VEGF AND ITS REQUIREMENTS FOR FUNCTIONAL ROLES DURING NORMAL DEVELOPMENT AND IN DISEASE SETTINGS

Initial studies by Dvorak and his colleagues (Senger et al. 1986; Dvorak et al. 1999) identified a protein in tumor ascites fluid that was capable of inducing vascular leakage and permeability, which they termed vascular permeability factor (VPF). Independent efforts by Ferrara and his colleagues to identify secreted factors that could promote tumor angiogenesis led to the discovery of a protein in bovine pituitary follicular cell conditioned medium with mitogenic properties for endothelial cells which they termed vascular endothelial cell growth factor (VEGF) (Ferrara and Henzel 1989; Leung et al. 1989). Upon sequencing and further studies, this VEGF protein was expectedly found to correspond to the VPF previously identified by the Dvorak lab. These findings set the stage for a concerted effort to define the role of VEGF/VPF (human VEGF) in cancer angiogenesis as well as other settings of vascular disease, which have led to the realization that one of its initially realized actions—i.e., promoting vas-

stages of blood vessel development. Still more remarkably, disruption of even a single VEGF allele in developing mice, which decreases VEGF levels by half, also results in embryonic lethality due to severe vascular abnormalities (Carmeliet et al. 1996; Ferrara et al. 1996), demonstrating the need for exquisite regulation of VEGF levels to form normal vessels. Reciprocally, modest increases in VEGF levels during development also lead to vascular disaster and lethality (Miquerol et al. 2000). VEGF continues to be critical during early postnatal growth and development, as evidenced by the lethality and major growth disturbances caused by conditional disruption of the VEGF gene or by administration of VEGF blockers (Ravindranath et al. 1992; Carmeliet et al. 1996; Ferrara et al. 1996, 1998; Gerber et al. 1999a; Ryan et al. 1999; Fraser et al. 2000; Zimmermann et al. 2001; Hazzard et al. 2002; Eremina et al. 2003). However, VEGF blockade in older animals is much less traumatic, affecting only those structures that continue to depend on ongoing vascular remodeling, such as occurs in bone growth plates or during remodeling of the female reproductive organs (Ferrara et al. 1998; Gerber et al. 1999a,b). As discussed in greater detail below, vascular remodeling is absolutely required in a variety of pathological settings, such as during tumor growth, providing major therapeutic opportunities for VEGF blockade in the adult setting in which such blockade can be tolerated.

VEGF ISOFORMS, VEGF FAMILY MEMBERS, AND VEGF RECEPTORS

Further study of the gene encoding human VEGF revealed eight exons separated by seven introns, which results in the generation of four isoforms of increasing size—VEGF₁₂₁, VEGF₁₆₅, VEGF₁₈₉, and VEGF₂₀₆ (subscripts refer to number of amino acids comprising the isoform, with the VEGF isoforms varying in length at their carboxyl termini). The main purpose of these isoforms appears to relate to their bioavailability such that the 121 isoform is diffusible, whereas the higher-molecular-weight isoforms remain bound to the extracellular matrix, requiring cleavage to be released (Houck et al. 1992; Park et al. 1993; Keyt et al. 1996).

Because of the discovery of additional members of the VEGF family, VEGF is now often referred to as VEGF-A. Other members of the VEGF family were

with VEGF blockade (Persico et al. 1999; Cao 2000). Little is known about VEGF-B, and mice lacking VEGF-B are overtly healthy and fertile. VEGF-B seems to play more critical roles in the lymphatic vasculature than in the blood vasculature, showing specificity for a VEGF receptor (see below) expressed on the lymphatic vasculature; administration of both of these factors results in lymphatic vessel hyperplasia (Joukov et al. 1996; d'Amico et al. 1996; Olofsson et al. 1999).

Following rapidly on the heels of the discovery of VEGF came the identification of two closely related high-affinity receptors for VEGF—FLT1 (FMS-like tyrosine kinase) now termed VEGFR1 (de Vries et al. 1992), and KDR or Flk1, now termed VEGFR2 (Carmeliet et al. 1990; Terman et al. 1992; Millauer et al. 1993). These high-affinity receptors share features common to other growth factor receptors, in that they contain an extracellular domain which binds and is dimerized upon binding of ligand, and a cytoplasmic tyrosine kinase domain that is activated upon binding of ligand to the extracellular domain. VEGFR2 seems to be the receptor which mediates the major growth and permeability actions of VEGF, whereas VEGFR1 may have a negative role, either acting as a decoy receptor or by suppressing signaling through VEGFR2. Thus, mice engineered to lack VEGFR2 fail to develop a vasculature and have vascular defects in endothelial cells (Shalaby et al. 1995), phenocopying mice lacking VEGF, whereas mice lacking VEGFR1 seem to have excess formation of endothelial cells which abnormally coalesce into disorganized tubules (Carmeliet et al. 1995). Mice engineered to express only a truncated form of VEGFR1, lacking its kinase domain, develop a rather normal vasculature, consistent with the notion that the role of VEGFR1 may be that of a decoy receptor (Carmeliet et al. 1998), and supporting only a minor role for its cytoplasmic kinase domain. The third member of the VEGF receptor family, initially called Flt-4 and now termed VEGFR3, does not bind to VEGF-A nor PlGF, but instead binds to VEGF-C and VEGF-D and seems to mediate the actions of these latter two factors on the lymphatic vasculature (Taipale et al. 1999).

In addition to these primary receptors, a number of potential accessory receptors for the VEGFs have been identified, although the requisite roles of these receptors in mediating VEGF responses have not been elucidated. These potential accessory receptors include neuropilins (Soker et al. 1998).

1997; Ellis et al. 1998; Tomisawa et al. 1999). However, out of these studies came the interesting finding that one tumor type, renal cell carcinoma, had particularly high VEGF expression which correlated with inactivation of the von Hippel Lindau locus, resulting in loss of control of the tumor's oxygen sensor, hypoxia-inducible factor (HIF) (Iliopoulos et al. 1996; Lonser et al. 2003). The up-regulation of VEGF in an attempt to reoxygenate the tumor through revascularization led to the belief that this tumor may either be highly sensitive to anti-VEGF therapy or highly refractory. Fortunately, the former seems to be the case (Yang et al. 2003).

Concomitant with the analysis of human tumors for VEGF expression came the development of animal models of cancer where the hypothesis that VEGF was required for tumor vasculature, and thus tumor growth, could be tested. In 1993, 4 years after their discovery of VEGF, Ferrara and colleagues demonstrated that a mouse monoclonal antibody to human VEGF (A.4.6.1) could inhibit the growth of several human tumor types in nude mice with inhibition ranging from 70% to more than 90% (Kim et al. 1993). Subsequent to this observation, a number of laboratories using different strategies to inhibit VEGF signaling have shown to a greater or lesser extent that inhibition of VEGF can have a major impact on tumor growth in mice. In addition to numerous studies using the VEGF-blocking antibody, other strategies to block VEGF in tumor models included blocking antibodies targeting VEGFR2 (Prewett et al. 1999), soluble VEGF receptors acting as circulating decoys to capture VEGF and preventing it from binding cell-surface receptors (Ferrara et al. 1998; Gerber et al. 1999a,b; Liang et al. 2006), dominant-negative VEGF receptors expressed at high levels on tumor surfaces, small-molecule inhibitors of VEGF receptor kinases and other kinases (Smith et al. 2004), antisense oligonucleotides targeting VEGF, and VEGF siRNA (Grunweller and Hartmann 2005; Lu et al. 2005).

As the number of studies increased comparing the different modes of inhibiting VEGF, it became apparent that blocking tumor-derived VEGF without blocking stromal VEGF was not as efficacious, implicating stromal VEGF as a crucial player in tumor growth and angiogenesis. Thus, antibodies such as A.4.6.1 which only block human VEGF did not fare as well in blocking human tumor growth in immunocompromised mice as reagents blocking both tumor and host stroma-derived VEGF (Gerber et al. 2000; Liang et al. 2006).

with 5–20 picomolar binding affinity for VEGF. In tumor experiments this VEGFR1-Fc reagent was efficacious at approximately 500-fold lower concentration than a similar VEGFR2-Fc construct (Kuo et al. 2002). Despite its high affinity, the VEGFR1-Fc was not a viable clinical candidate because of its poor pharmacokinetic profile; in rodent studies, this protein had to be administered frequently and at very high doses to achieve efficacious levels. In addition, this agent appeared to have nonspecific toxicity effects that seem to be accounted for by its blocking of VEGFR2 (Kuo et al. 2001). We decided to exploit our Trap technology platform (Economides et al. 2003), which involves defining and fusing minimal binding units from different receptor components to generate chimeric proteins that act as high-affinity soluble blockers. In an attempt to create a potent and well-behaved Trap for VEGF, the result was a chimeric fusion protein containing a modified domain 2 of VEGFR1 and the C₁ Ig domain of VEGFR2 fused to the Fc region of human IgG1, resulting in a fully human protein that we called VEGF Trap (Holash et al. 2002). This reagent has the advantage of being fully human and thus potentially non-immunogenic, as well as being substantially smaller than previous fusion proteins and anti-VEGF antibodies, raising the possibility that it might allow improved tissue and tumor penetration. In addition, this VEGF Trap had greatly improved pharmacological bioavailability, as compared to the initial VEGFR1-Fc reagent, resulting in about a 300-fold increase in the maximum concentration achieved in the circulation (i.e., C_{max}), as well as about a 1000-fold increase in total circulation exposure (i.e., AUC) (Holash et al. 2002). Importantly, the efficacy of VEGF Trap binding to both mouse and human VEGF isoforms (0.58 pM, 0.46 pM) was superior to that of the parental VEGFR1-Fc (~ 5–20 pM) (Holash et al. 2002). In addition, the VEGF Trap also bound to VEGFR2 with high affinity (1.8 pM).

To determine whether the improved pharmacokinetics, bioavailability and high-affinity binding of VEGF Trap translated into superior performance in vivo, we used a short-term and quantitative in vivo model of VEGF activity in which a single dose of VEGF results in a stereotypic reduction in blood pressure. In this assay model, we found that equivalent doses of VEGF Trap were indeed far superior to that of the parental VEGFR1-Fc (Holash et al. 2002).

many different investigators, with impressive results in almost every case. In addition to its activity in multiple subcutaneous models of melanoma, glioma, and rhabdomyosarcoma tumors (Holash et al. 2002), the VEGF Trap has been shown to work in multiple pancreatic cancer models (Fukasawa and Korc 2004), Wilms' tumor (Huang et al. 2003), Ewing's sarcoma (Dalal et al. 2005), glioblastoma (Wachsberger et al. 2005), and models of ovarian cancer as well as associated malignant ascites (Hu et al. 2005).

In addition to the above published studies, recent unpublished temporal studies indicate that vascular regression can be seen in most tumors within hours of VEGF Trap treatment, resulting in marked and widespread hypoxia within the tumors. In addition, transcription profiling studies during these temporal studies have revealed a set of endothelial-specific genes that are rapidly and profoundly regulated in response to VEGF Trap treatment. Further studies on some of these genes have led to their identification as potential targets for new antiangiogenesis therapies (see below).

In summary, animal tumor studies have indicated that treatment with VEGF Trap effectively inhibited tumor growth of a wide variety of murine, rat, and human tumor cell lines implanted either subcutaneously or orthotopically in mice. VEGF Trap treatment inhibited the growth of tumors representing a variety of tumor types, including melanoma, glioma, rhabdomyosarcoma, ovarian, pancreatic, renal, and mammary tumor tissue, with a broad therapeutic index. Growth of small established tumors was also inhibited. Histological analysis indicated that treatment with VEGF Trap resulted in the formation of largely avascular and necrotic tumors, demonstrating that tumor-induced angiogenesis was blocked. VEGF Trap was also active in blocking tumor growth in similar animal tumor models in combination with paclitaxel, docetaxel, or radiation, and was synergistic with 5-fluorouracil. VEGF Trap as a single agent and in combination with paclitaxel also prevented the formation of ascites in mouse tumor models (Byrne et al. 2003; Hu et al. 2005).

VEGF TRAP IN CLINICAL TRIALS FOR CANCER

The above results in animal tumor models supported the exploration of the VEGF Trap in human studies. Initial clinical studies are promising (Dupont et al. 2005;

VEGF TRAP EXHIBITS IMPRESSIVE EFFICACY IN PRECLINICAL MODELS OF VASCULAR EYE DISEASES

In addition to the role for VEGF in tumor angiogenesis, a variety of studies have indicated that VEGF may play a key pathological role in vascular eye diseases, in particular in diabetic edema and retinopathy settings, and in related macular degeneration (AMD), which are major causes of vision loss and blindness. In these diseases, excess VEGF is thought to result in vascular leakage that contributes to abnormal swelling of the retina and resulting vision impairment, as well as in the abnormal growth of choroidal and retinal vessels that can destroy normal retinal architecture. Consistent with these possibilities, VEGF Trap has demonstrated impressive efficacy in an assortment of animal models of these eye diseases.

Preclinical studies in rodents have shown that VEGF Trap can inhibit choroidal (Saishin et al. 2003) and corneal (Wiegand et al. 2003) neovascularization, as well as suppress vascular leak into the retina (Quaranta 2001), and that the VEGF Trap can also promote the survival of corneal transplants by inhibiting associated choroidal vascularization (Cursiefen et al. 2004). In addition, in a primate model of AMD, in which choroidal neovascular lesions and vascular leak are induced by using a laser to create small lesions in the retinas of adult cynomolgus macaques, both systemically and intravitreally delivered VEGF Trap not only prevented development of choroidal leak and neovascular membranes when administered prior to laser lesion, but also induced regression of neovascularization after lesions had developed (Wiegand et al. 2005). These preclinical results support a role for VEGF blockade, and in particular for local delivery of the VEGF Trap, in multiple vascular eye diseases ranging from AMD and diabetic eye diseases to corneal injury and transplantation.

VEGF TRAP IN CLINICAL TRIALS FOR VASCULAR EYE DISEASES

The above results in animal models have supported the exploration of the VEGF Trap in human studies of vascular eye diseases. Initial clinical studies in human subjects suffering from both AMD and diabetic eye diseases and retinopathy appear quite promising, with evidence from early trials that the VEGF Trap can rapidly and effectively decrease retinal swelling, and that these

marked regression and/or very long term stabilization, other tumors can continue to grow even in the face of anti-VEGF treatments. The realization that some tumors can be relatively resistant to anti-VEGF approaches raises the need for additional antiangiogenesis approaches that might be useful in such settings. Toward this end, as noted above, we performed transcriptional profiling screens to identify endothelial-specific targets that are markedly regulated either by VEGF blockade or by excess VEGF activity, reasoning that such targets might prove interesting as new antiangiogenesis targets. Confirming the potential of such a screen, one target that was “rediscovered” via such screens was Angiopoietin-2. We had previously independently identified the Angiopoietins as key new angiogenic regulators that seemed to work in tandem with the VEGFs (Davis et al. 1996; Suri et al. 1996; Maisonpierre et al. 1997; Valenzuela et al. 1999; Yancopoulos et al. 2000; Gale et al. 2002), and moreover, obtained substantial data that Angiopoietin-2 in particular was specifically induced in tumor vasculature and that it was important for tumor angiogenesis (Holash et al. 1999); a recent study employing Angiopoietin-2-blocking antibodies confirmed notable antitumor effects (Oliner et al. 2004). On the basis of the confidence in these transcriptional profiling screens engendered by the reidentification of Angiopoietin-2, we explored additional potential targets identified by the screens. Among these targets we have reported the identification of Delta-like ligand 4 (Dll4) (a ligand for the Notch family of receptors) as a gene that is markedly and specifically induced in tumor vasculature (Gale et al. 2004). Moreover, Dll4 is strikingly up-regulated in VEGF-overexpressing tumors and down-regulated in tumors by VEGF blockade. Using VelociGene® technology, which provides a high-throughput approach to create mouse mutants for genes of interest (Valenzuela et al. 2003), we found that mice lacking Dll4 exhibit profound vascular defects early in development (Gale et al. 2004). Remarkably, and as previously seen only for VEGF (see above), deletion of even just one of the two Dll4 alleles in developing embryos resulted in embryonic lethality due to vascular defects (Gale et al. 2004). All this evidence for a critical role for Dll4 in normal as well as tumor angiogenesis provided a rationale to develop blockers for Dll4. Recent testing in tumor models indicates that Dll4 may indeed prove to be an important new antiangiogenesis target, either alone or in combination with the VEGF Trap, or in settings of relative resistance to anti-VEGF therapies.

types of tumors and can even cause frank tumor regression in some settings. In other preclinical cancer models we have found that combination of VEGF Trap with a cytotoxic agent can result in potency far greater than either single agent. Furthermore, the VEGF Trap is very effective in animal models of vascular eye disease. The impressive efficacy in preclinical models of cancer and eye diseases provided a rationale for advancing the VEGF Trap into clinical trials, where it is producing promising initial results in both cancer and eye disease.

In addition to its potential therapeutic value in cancer and vascular eye diseases, the VEGF Trap is also a valuable research tool. Transcription profiling screens using VEGF Trap have allowed a number of strategies designed to identify new antiangiogenesis targets. We hoped that these strategies are helping to identify the next generation of antiangiogenesis targets, which may be used either alone or in combination with the VEGF Trap in settings of relative resistance to anti-VEGF therapies.

Explore Litigation Insights

Docket Alarm provides insights to develop a more informed litigation strategy and the peace of mind of knowing you're on top of things.

Real-Time Litigation Alerts

Keep your litigation team up-to-date with **real-time alerts** and advanced team management tools built for the enterprise, all while greatly reducing PACER spend.

Our comprehensive service means we can handle Federal, State, and Administrative courts across the country.

Advanced Docket Research

With over 230 million records, Docket Alarm's cloud-native docket research platform finds what other services can't. Coverage includes Federal, State, plus PTAB, TTAB, ITC and NLRB decisions, all in one place.

Identify arguments that have been successful in the past with full text, pinpoint searching. Link to case law cited within any court document via Fastcase.

Analytics At Your Fingertips

Learn what happened the last time a particular judge, opposing counsel or company faced cases similar to yours.

Advanced out-of-the-box PTAB and TTAB analytics are always at your fingertips.

API

Docket Alarm offers a powerful API (application programming interface) to developers that want to integrate case filings into their apps.

LAW FIRMS

Build custom dashboards for your attorneys and clients with live data direct from the court.

Automate many repetitive legal tasks like conflict checks, document management, and marketing.

FINANCIAL INSTITUTIONS

Litigation and bankruptcy checks for companies and debtors.

E-DISCOVERY AND LEGAL VENDORS

Sync your system to PACER to automate legal marketing.
