R400 Sequencer Specification

SEQ

Version 0.1

Overview: This is an architectural specification for the R400 Sequencer block (SEQ). It provides an overview of the required capabilities and expected uses of the block. It also describes the block interfaces, internal sub-blocks, and provides internal state diagrams.

Revision Changes:

Rev 0.1 (Laurent Lefebvre) Date: May 7, 2001	First draft.

1. Overview

The sequencer first arbitrates between vectors of 16 vertices that arrive directly from primitive assembly and vectors of 8 quads (32 pixels) that are generated in the raster engine.

The vertex or pixel program specifies how many GPR's it needs to execute. The sequencer will not start the next vector until the needed space is available.

The sequencer is based on the R300 design. It chooses an ALU clause and a texture clause to execute, and execute all of the instructions in a clause before looking for a new clause of the same type. Each vector will have eight texture and eight alu clauses, but clauses do not need to contain instructions. A vector of pixels or vertices ping-pongs along the sequencer FIFO, bouncing from texture reservation station to alu reservation station. A FIFO exists between each reservation stage, holding up vectors until the vector currently occupying a reservation station has left. A vector at a reservation station can be chosen to execute. The sequencer looks at all eight alu reservation stations to choose an alu clause to execute and all eight texture stations to choose a texture clause to execute. The arbitrator will give priority to clauses/reservation stations closer to the top of the pipeline. It will not execute an alu clause until the texture fetches initiated by the previous texture clause have completed.

To support the shader pipe the raster engine also contains the shader instruction cache and constant store.

The rasterizer always checks the vertices FIFO first and if allowed by the sequencer sends the data to the shader. If the vertex FIFO is empty then, the rasterizer takes the first entry of the pixel FIFO (a vector of 32 pixels) and sends it to the interpolators. Then the sequencer takes control of the packet.

On receipt of a packet, the input state machine (not pictured but just before the first FIFO) allocated enough space in the registers to store the interpolatoted values and temporaries. Following this, the input state machine stacks the packet in the first FIFO.

On receipt of a command, the level 0 texture machine issues a texure request and corresponding register address for the texture address (ta). A small command (tcmd) is passed to the texture system identifying the current level number

(0) as well as the register set being used. One texture request is sent every 4 clocks causing the texturing of four 2x2s worth of data.

Uppon recept of the return data (identified by the tcmd containing the level number 0), the level 0 texture machine issues a register address for the return value (td). Then, it puts the finished packet in FIFO 1.

On receipt of a command, the level 0 ALU machine issues a complete set of level 0 shader instructions. For each instruction, the state machine generates 3 source addresses, one destination address (2 cycles later) and an instruction id wich is used to index into the instruction store. Once the last instruction as been issued, the packet is put into FIFO 2. Note that in the case of a pixel packet, the two vectors of 16 pixels are interleaved in order to hide the latency of the ALUs (8 cycles).

All other level process in the same way until the packet finally reaches the last ALU machine (8). On completion of the level 8 ALU clause, a valid bit is sent to the Render Backend wich picks up the color data. This requires that the last instruction writes to the output register – a condition that is almost always true. If the packet was a vertex packet, instead of sending the valid bit to the RB, it is sent to the PA, which picks up the data a puts it into the vertex store.

Only one ALU state machine may have access to the SRAM address bus or the instruction decode bus at one time. Similarly, only one texture state machine may have access to the SRAM address bus at one time. Arbitration is performed by two arbitrer blocks (one for the ALU state machines and one for the texture state machines). The arbitrers always favor the higher number state machines, preventing a bunch of half finished jobs from clogging up the SRAMS.

Each state machine maintains an address pointer specifying where the 16 (or 32) entries vector is located in the SRAM (the texture machine has two pointers one for the read address and one for the write). Upon completion of its job, the address pointer is incremented by a predefined amount equal to the total number of registers required by the shading code. A comparison of the address pointer for the first state machine in the chain (the input state machine), and the last machine in the chain (the level 8 ALU machine), gives an indication of how much unallocated SRAM memory is available. When this number falls below a preset watermark, the input state machine will stall the rasterizer preventing new data from entering the chain.

2. Texture Arbitration

The texture arbitration logic chooses one of the 8 potentially pending texture clauses to be executed. The choice is made by looking at the fifos from 8 to 0 and picking the first one ready to execute. Once chosen, the clause state machine will send one 2x2 texture fetch per 4 clocks until all the texture fetch instructions of the clause are sent. This means that there cannot be any dependencies between two texture fetches of the same clause.

3. ALU Arbitration

ALU arbitration proceeds in almost the same way than texture arbitration. The ALU arbitration logic chooses one of the 8 potentially pending ALU clauses to be executed. The choice is made by looking at the fifos from 8 to 0 and picking the first one ready to execute. If the packet chosen is a packet of vertices, the state machine issues one instruction every 4 clocks until the clause is finished. This means that the compiler has to insert nops between two dependent successive instructions. If the packet is a pixel packet it is made out of two sub-vectors of 16. Thus the state machine issues the first instruction for the first sub-vector and then, 4 clocks later, the first instruction of the second sub-vector and so on until the clause is finished. Proceeding this way hides the latency of 8 clocks of the ALUs.

4. Input Interface

4.1 Rasterizer to Register File (interpolated data)

Name	Direction	bits	Description
SND	SEQ→SP	1	High when sending data
Interpolated data	SEQ→SP	512	512 bits transferred every 4 cycles

4.2 Texture Unit to Register File (texture return)

Name	Direction	bits	Description
SND	SEQ→TU	1	High when sending data
Texture colors	TU→SP	512	512 bits transferred every 4 cycles

4.3 ALU Unit to Register File (ALU op result)

Name	Direction	bits	Description
SND	SEQ→SP	1	High when sending data
Blend result ALU	SP→SP	512	512 bits transferred every 4 cycles
Write Mask	SP→SP	16	The four write masks

4.4 Scalar Unit to Register File (Scalar op result)

Name	Direction	bits	Description
SND	SEQ→SP	1	High when sending data
Scalar result	SP→SP	512	512 bits transferred every 4 cycles
Write Mask	SP→SP	16	The four write masks

5. Output Interface

5.1 Sequencer to Shader Engine Bus

This is a bus that sends the instruction and constant data to all 4 Sub-Engines of the Shader. Because a new instruction is needed only every 4 clocks, the width of the bus is divided by 4 and both constants and instruction are sent over those 4 clocks.

Name	Direction	Bits	Description
Instruction Start	SEQ-> SP	1	High on first cycle of transfer
Constant 0	SEQ-> SP	32	128 bits transferred over 4 cycles, alpha first…blue last
Constant 1	SEQ-> SP	32	128 bits transferred over 4 cycles, alpha first…blue last
Instruction	SEQ-> SP	40	160 bits transferred over 4 cycles

5.2 Shader Engine to Texture Unit Bus

One quad’s worth of addresses is transferred to Texture Unit every clock. These are sourced fro a different pixel within each of the sub-engines repeating every 4 clocks. The register file index to read must precede the data by 2 clocks. The Read address associated with Quad 0 must be sent 1 clock after the Instruction Start signal is sent, so that data is read 3 clocks after the Instruction Start.

One Quad’s worth of Texture Data may be written to the Register File every clock. These are directed to a different pixel of the sub-engines repeating every 4 clocks. The register file index to write must accompany the data. Data and Index associated with the Quad 0 must be sent 3 clocks after the Instruction Start signal is sent.

Name	Direction	Bits	Description
Tex_Read_Register_Index	SEQ->SP	8	Index into Register Files for reading Texture Address
Tex_RegFile_Read_Data	SP->TEX	512	4 Texture Addresses read from the Register File
Tex_Write_Register_Index	SEQ->SP	8	Index into Register file for write of returned Texture Data

6. Open issues

There is currently an issue with constants. If the constants are not the same for the whole vector of vertices, we don’t have the bandwith from the texture store to feed the ALUs. Two solutions exists for this problem:

1) Let the compiler handle the case and put those instructions in a texture clause so we can use the bandwith there to operate. This requires a significant amount of temporary storeage in the register store.
2) Waterfall down the pipe allowing only at a given time the vertices having the same constants to operate in parralel. This might in the worst case slow us down by a factor of 16.

Revision Changes:

Rev 0.1 (Laurent Lefebvre) Date: May 7, 2001	First draft.
Rev 0.2 (Laurent Lefebvre) Date : July 9, 2001	Changed the interfaces to reflect the changes in the SP. Added some details in the arbitration section.
Rev 0.3 (Laurent Lefebvre) Date : August 6, 2001	Reviewed the Sequencer spec after the meeting on August 3, 2001.

1. Overview

The sequencer first arbitrates between vectors of 16 ~~(maybe 32)~~ vertices that arrive directly from primitive assembly and vectors of ~~8~~4 quads (16 pixels) ~~(32 pixels)~~ that are generated in the raster engine.

The vertex or pixel program specifies how many GPR's it needs to execute. The sequencer will not start the next vector until the needed space is available.

The sequencer is based on the R300 design. It chooses ~~an~~ two ALU clauses and a texture clause to execute, and executes all of the instructions in ~~a~~a clause before looking for a new clause of the same type. Two ALU clauses are executed interleaved to hide the ALU latency. Each vector will have eight texture and eight ALU clauses, but clauses do not need to contain instructions. A vector of pixels or vertices ping-pongs along the sequencer FIFO, bouncing from texture reservation station to alu reservation station. A FIFO exists between each reservation stage, holding up vectors until the vector currently occupying a reservation station has left. A vector at a reservation station can be chosen to execute. The sequencer looks at all eight alu reservation stations to choose an alu clause to execute and all eight texture stations to choose a texture clause to execute. The arbitrator will give priority to clauses/reservation stations closer to the ~~top~~ bottom of the pipeline. It will not execute an alu clause until the texture fetches initiated by the previous texture clause have completed. There are two separate sets of reservation stations, one for pixel vectors and one for vertices vectors. This way a pixel can pass a vertex and a vertex can pass a pixel.

To support the shader pipe the raster engine also contains the shader instruction cache and constant store. There are only one constant store for the whole chip and one instruction store. These will be shared among the four shader pipes.

There are two sets of the above figure, one for vertices and one for pixels.

The rasterizer always checks the vertices FIFO first and if allowed by the sequencer sends the data to the shader. If the vertex FIFO is empty then, the rasterizer takes the first entry of the pixel FIFO (a vector of ~~32~~ 16 pixels) and sends it to the interpolators. Then the sequencer takes control of the packet. The packet consists of 3 bits of state, 6-7 bits for the base address of the Shader program and some information on the coverage to determine texture LOD. All other information (2x2 adresses) is put in a FIFO (one for the pixels and one for the vertices) and retrieved when the packet finishes its last clause.

On receipt of a packet, the input state machine (not pictured but just before the first FIFO) allocated enough space in the registers to store the interpolated values and temporaries. Following this, the input state machine stacks the packet in the first FIFO.

On receipt of a command, the level 0 texture machine issues a texure request and corresponding register address for the texture address (ta). A small command (tcmd) is passed to the texture system identifying the current level number (0) as well as the register ~~set being used~~write address for the texture return data. One texture request is sent every 4 clocks causing the texturing of four 2x2s worth of data (or 16 vertices). Once all the requests are sent the packet is put in FIFO 1.

Upon recept of the return data (identified by the tcmd containing the level number 0), the level 0 texture machine issues a register address for the return value (td). Then, it increments the counter of FIFO ~~one~~ 1 to signify to the ALU 1 that the data is ready to be processed.

On receipt of a command, the level 0 ALU machine first decrements the input FIFO counter and then issues a complete set of level 0 shader instructions. For each instruction, the state machine generates 3 source addresses, one destination address (~~2~~ 3 cycles later) and an instruction~~ id wich is used to index into the instruction store~~. Once the last instruction as been issued, the packet is put into FIFO 2.~~ Note that in the case of a pixel packet, the two vectors of 16 pixels are consecutive in order to hide the latency of the ALUs (8 cycles).~~

There will always be two active ALU clauses at any given time (and two arbitrers)~~ In this case, the instructions of a vector are interleaved with the instructions of the other vector~~. One arbitrer will arbitrate over the odd clock cycles and the other one will arbitrate over the even clock cycles. The only constraints between the two arbitrers is that they are not allowed to pick the same clause number as they other one is currently working on if the packet os of the same type.

If the packet is a vertex packet, upon reaching ALU clause 4, it can export the position if the position is ready. So the arbitrer must prevent ALU clause 4 to be selected if the positional buffer is full (or can't be accessed). Along with the positional data, the location where the vertex data is to be put is also sent (parameter data pointers).

All other level process in the same way until the packet finally reaches the last ALU machine (8). On completion of the level 8 ALU clause, a valid bit is sent to the Render Backend which picks up the color data. This requires that the last instruction writes to the output register – a condition that is almost always true. If the packet was a vertex packet, instead of sending the valid bit to the RB, it is sent to the PA~~, which picks up the data and puts it into the vertex store~~ so it can know that the data present in the parameter store is valid.

Only ~~one~~ two ALU state machine may have access to the ~~SRAM~~register file address bus or the instruction decode bus at one time. Similarly, only one texture state machine may have access to the ~~SRAM~~register file address bus at one time. Arbitration is performed by ~~two~~ three arbitrer blocks (~~one~~ two for the ALU state machines and one for the texture state machines). The arbitrers always favor the higher number state machines, preventing a bunch of half finished jobs from clogging up the ~~SRAM~~register ~~S~~files.

Each state machine maintains an address pointer specifying where the 16~~ (or 32)~~ entries vector is located in the ~~SRAM~~register file (the texture machine has two pointers one for the read address and one for the write). Upon completion of its job, the address pointer is incremented by a predefined amount equal to the total number of registers required by the shading code. A comparison of the address pointer for the first state machine in the chain (the input state machine), and the last machine in the chain (the level 8 ALU machine), gives an indication of how much unallocated ~~SRAM~~register file memory is available

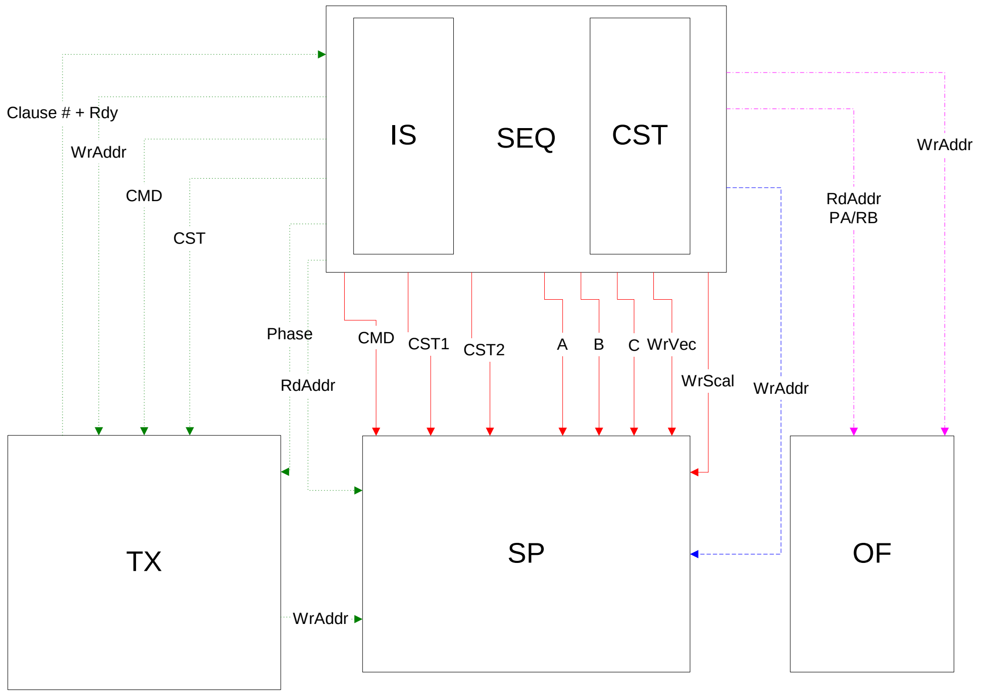
1.3 Control Graph



In green is represented the Texture control interface, in red the ALU control interface, in blue the Interpolated/Vector control interface and in purple is the output file control interface.

2. Interpolated data bus

Formatted: Bullets and Numbering

Since each of the register file is actually physically divided (one 32x128 per MAC) and we don't have the place to hold a maximum size vector of vertices in the parameter buffer, we need to interpolate on a parameter basis rather than on a quad basis. So the order to the register file will be:

Q0P0 Q1P0 Q2P0 Q3P0 Q0P1 Q1P1 Q2P1 Q3P2 Q0P3 Q1P3 …

3. Instruction Store

Formatted: Bullets and Numbering

There is going to be only one instruction store for the whole chip. It may contain up to 2000 instructions of 96 bits each. The instruction store is loaded by the sequencer using the memory hub. The read bandwith from this store is 24 bits/clock/pipe. To achieve this this instruction store is likely to be broken up into 4 blocks. An ALU instruction section (1R/1W) split in two and a texture section (1R/1W) also split in two. The bandwith out of those memories is 96 bits/clock.

4. Constant Store

Formatted: Bullets and Numbering

The constant store is managed by the CP. The sequencer is aware of where the constants are using a remaping table also managed by the CP. A likely size for the constant store is 512x128 bits. The constant store is also planned to be shared. The read BW from the constant store is 512/4 bits/clock/pipe and the write bandwith is 32/4 bits/clock.

5. Looping and Branches

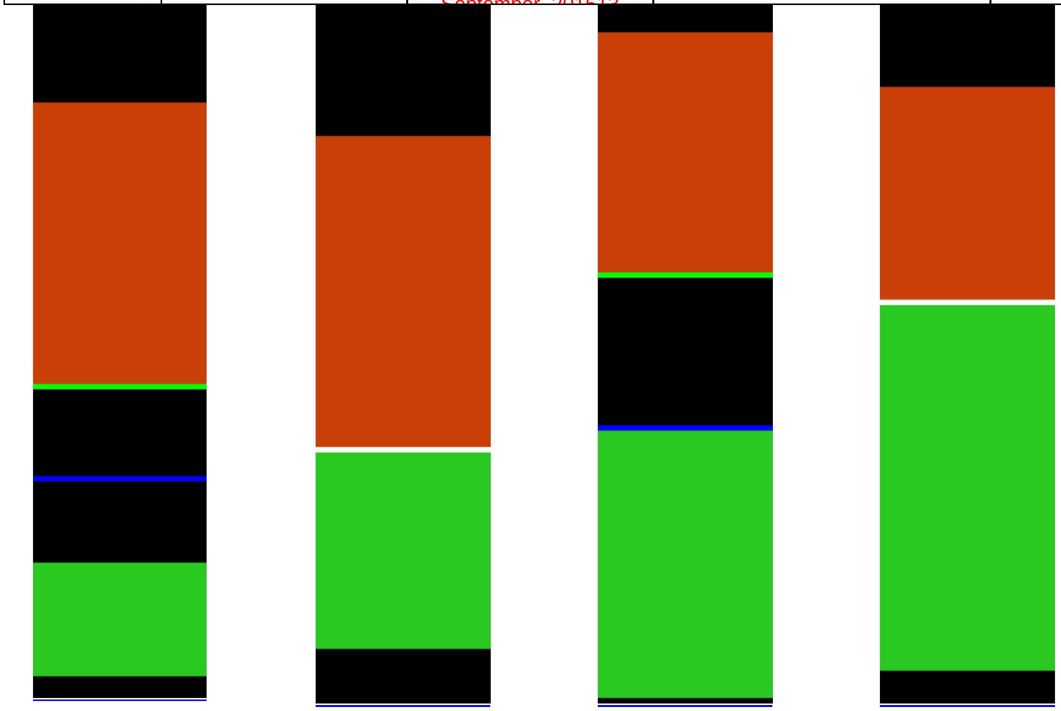
Formatted: Bullets and Numbering

Loops and branches are planned to be supported and will have to be dealt with at the sequencer level. However, it is still unclear if we plan on supporting data dependent branches or not.

6. Register file allocation

Formatted: Bullets and Numbering

The register file allocation for vertices and pixels can either be static or dynamic. In both cases, the register file in managed using two round robins (one for pixels and one for vertices). In the dynamic case the boundary between pixels and vertices is allowed to move, in the static case it is fixed to VERTEX_REG_SIZE for vertices and 256-VERTEX_REG_SIZE for pixels.



Above is an example of how the algorithm works. Vertices come in from top to bottom; pixels come in from bottom to top. Vertices are in orange and pixels in green. The blue line is the tail of the vertices and the green line is the tail of the pixels. Thus anything between the two lines is shared. When pixels meets vertices the line turns white and the boundary is static until both vertices and pixels share the same “unallocated bubble”. Then the boundary as allowed to move again.

Formatted: Bullets and Numbering

~~2.~~7. Texture Arbitration

The texture arbitration logic chooses one of the 8 potentially pending texture clauses to be executed. The choice is made by looking at the fifos from 7 to 0 and picking the first one ready to execute. Once chosen, the clause state machine will send one 2x2 texture fetch per clock (or 4 fetches in one clock every 4 clocks) until all the texture fetch instructions of the clause are sent. This means that there cannot be any dependencies between two texture fetches of the same clause.

The arbitrator will not wait for the texture fetches to return prior to selecting another clause for execution. The texture pipe will be able to handle up to ~~100~~X(?) in flight texture fetches and thus there can be a fair number of active clauses waiting for their texture return data.

Formatted: Bullets and Numbering

~~3.~~8. ALU Arbitration

ALU arbitration proceeds in almost the same way than texture arbitration. The ALU arbitration logic chooses one of the 8 potentially pending ALU clauses to be executed. The choice is made by looking at the fifos from 7 to 0 and picking the first one ready to execute~~execute. If the packet chosen is a packet of vertices, the state machine issues one instruction every 4 clocks until the clause is finished. This means that the compiler has to insert nops between two dependent successive instructions. If the packet is a pixel packet it is made out of two sub-vectors of 16. Thus the state machine issues the first instruction for the first sub-vector and then, 4 clocks later, the first instruction of the second sub-vector and so on until the clause is finished. ~~. There are two ALU arbitrers, one for the even clocks and

one for the odd clocks. For exemple, here is the sequencing of two interleaved ALU clauses (E and O stands for Even and Odd):

Einst0 Oinst0 Einst1 Oinst1 Einst2 Oinst2 Einst0 Oinst3 Einst1 Oinst4 Einst2 Oinst0…
Proceeding this way hides the latency of 8 clocks of the ALUs.

Formatted: Bullets and Numbering

~~4.~~9. Handling Stalls

When the output file is full, the sequencer prevents the ALU arbitration logic to select the last clause (this way nothing can exit the shader pipe until there is place in the output file. If ~~we have the ability to export at any clause~~the packet is a vertex packet and the position buffer is full (POS_FULL) then the sequencer also prevents a thread to enter the exporting clause (4?). The sequencer will set the OUT_FILE_FULL signal n clocks before the output file is actually full and thus the ALU arbitrer will be able read this signal and act accordingly by not preventing exporting clauses to proceed.

Formatted: Bullets and Numbering

~~5.~~10. Content of the reservation station FIFOs

3 bits of Render State ~~and~~ 6-7 bits for the base address of the instruction store and some bits for LOD correction. Every other information (such as the coverage mask, quad address, etc.) is put in a FIFO and is retrieved when the quad exits the shader pipe to enter in the output file buffer. Since pixels and vertices are kept in order in the shader pipe, we only need two fifos (one for vertices and one for pixels) deep enough to cover the shader pipe latency. This size will be determined later when we will know the size of the small fifos between the reservation stations.

Formatted: Bullets and Numbering

~~6.~~11. The Output File (RB FIFO and Parameter Cache)

The output file is where program results are exported when the pixel/vertex shader finishes. It constists of a 512x128 memory cell that is statically divided between pixels and vertices. ~~Each section is a regular FIFO.~~ The output file has 1 write port and 1 read port. The sequencer is responsible for managing the addresses of this output file and for stalling the shader pipe should this output file fill up. The management is done by keeping the tail and head pointers of each sections (pixels and vertices) and incrementing them using a simple RoundRobin allocation policy. The sequencer must also arbitrate between the PA and the RB for the use of the read port. This arbitration will either be priority based or just interleaved evenly (1 read every 2 clocks for each of the blocks).

Formatted: Bullets and Numbering

~~7.~~12. Interfaces

~~7.1~~12.1 External Interfaces

~~7.1.1~~12.1.1 *Sequencer to Shader Engine Bus*

This is a bus that sends the instruction and constant data to all 4 Sub-Engines of the Shader. Because a new instruction is needed only every 4 clocks, the width of the bus is divided by 4 and both constants and instruction are sent over those 4 clocks.

Name	Direction	Bits	Description
Instruction Start	SEQ-> SP	1	High on first cycle of transfer
Constant 0	SEQ-> SP	32	128 bits transferred over 4 cycles, alpha first…blue last
Constant 1	SEQ-> SP	32	128 bits transferred over 4 cycles, alpha first…blue last
Instruction	SEQ-> SP	30	120 bits transferred over 4 cycles (order TBD) ?

Formatted: Bullets and Numbering

~~7.1.2~~12.1.2 *Shader Engine to Output File*

Every clock each Sub-Engine can output 128 bits of 'vector' data and 32 bits of 'scalar' data to an output file (?). This data will be compressed into 128 bits total prior to storage in output file.

Name	Direction	Bits	Description
UL_Vector_Out	SP-> OF	128	Vector Data out

UL_Scalar_Out	SP-> OF	32	Vector Data out
UR_Vector_Out	SP-> OF	128	Vector Data out
UR_Scalar_Out	SP-> OF	32	Vector Data out

Name	Direction	Bits	Description
LL_Vector_Out	SP-> OF	128	Vector Data out
LL_Scalar_Out	SP-> OF	32	Vector Data out
LR_Vector_Out	SP-> OF	128	Vector Data out
LR_Scalar_Out	SP-> OF	32	Vector Data out

~~7.1.3~~12.1.3 *Shader Engine to Texture Unit Bus (Fast Bus)*

Formatted: Bullets and Numbering

One quad's worth of addresses is transferred to Texture Unit every clock. These are sourced from a different pixel within each of the sub-engines repeating every 4 clocks. The ~~register file~~register file index to read must precede the data by 2 clocks. The Read address associated with Quad 0 must be sent 1 clock after the Instruction Start signal is sent, so that data is read 3 clocks after the Instruction Start.

One Quad's worth of Texture Data may be written to the ~~Register File~~Register file every clock. These are directed to a different pixel of the sub-engines repeating every 4 clocks. The ~~register file~~register file index to write must accompany the data. Data and Index associated with the Quad 0 must be sent 3 clocks after the Instruction Start signal is sent.

Name	Direction	Bits	Description
Tex_Read_Register_Index	SEQ->SP	8	Index into ~~Register File~~Register files for reading Texture Address
Tex_RegFile_Read_Data	SP->TEX	512	4 Texture Addresses read from the ~~Register File~~Register file
Tex_Write_Register_Index	SEQ->TEX	8	Index into ~~Register file~~Register file for write of returned Texture Data

~~7.1.4~~12.1.4 *Sequencer to Texture Unit bus (Slow Bus)*

Formatted: Bullets and Numbering

Once every four clock, the texture unit sends to the sequencer on wich clause it is now working and if the data in the registers is ready or not. This way the sequencer can update the texture counters for the reservation station fifos. The sequencer also provides the intruction and constants for the texture fetch to execute and the address in the ~~register file~~register file where to write the texture return data.

Name	Direction	Bits	Description
Tex_Ready	TEX→ SEQ	1	Data ready
Tex_Clause_Num	TEX→ SEQ	3	Clause number
Tex_cst	SEQ→TEX	?	Texture constants X bits sent over 4 clocks
Tex_Inst	SEQ→TEX	?	Texture fetch instruction X bits sent over 4 clocks

~~7.1.5~~12.1.5 *Shader Engine to RE/PA Bus*

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
Interpolator_Register_Index	SEQ->SP	8	Index into ~~Register File~~Register files for write of Interpolator/Index Data
Interpolator_Write_Mask	SEQ->SP	1	Write Mask. The same write mask is used for all 4 pixels
Interpolator_Write_Data	RE/PA->SP	512	4 interpolated vectors or vectors of indices

12.1.6 *PA to sequencer*

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
Adress	PA→SEQ	?	Dealocation adress sent by the PA telling the Sequencer that it is now possible to free this space in the parameter buffer. This token is a pointer in the parameter cache and 4 bits to tell the size wich is to be freed up.

~~8.~~13. Open issues

There is currently an issue with constants. If the constants are not the same for the whole vector of vertices, we don't have the bandwith from the texture store to feed the ALUs. Two solutions exists for this problem:

1) Let the compiler handle the case and put those instructions in a texture clause so we can use the bandwith there to operate. This requires a significant amount of temporary storage in the register store.
2) Waterfall down the pipe allowing only at a given time the vertices having the same constants to operate in parrallel. This might in the worst case slow us down by a factor of 16.

Need to do some testing on the size of the ~~register file~~register file as well as on the ~~register file~~register file allocation method (dynamic VS static).

~~Ability to export at any clause?~~

Saving power?

~~Are we working on 32 vertices at a time or 16?~~

Size of the fifo containing the information of a vector of pixels/vertices. And size of the fifos before the reservation stations.

Sequencer Instruction memory, and constant memory.

Arbitration policy for the output file.

Loops and branches.

The parameter cache may end up in the PA rather than in the RS. Parameter cache management thus may change.

R400 Sequencer Specification

SEQ

Version 0.4~~2~~

Overview: This is an architectural specification for the R400 Sequencer block (SEQ). It provides an overview of the required capabilities and expected uses of the block. It also describes the block interfaces, internal sub-blocks, and provides internal state diagrams.

Revision Changes:

Rev 0.1 (Laurent Lefebvre) Date: May 7, 2001	First draft.
Rev 0.2 (Laurent Lefebvre) Date : July 9, 2001	Changed the interfaces to reflect the changes in the SP. Added some details in the arbitration section.
Rev 0.3 (Laurent Lefebvre) Date : August 6, 2001	Reviewed the Sequencer spec after the meeting on August 3, 2001.
Rev 0.4 (Laurent Lefebvre) Date : August 24, 2001	Added the dynamic allocation method for register file and an example (written in part by Vic) of the flow of pixels/vertices in the sequencer.

1. Overview

The sequencer first arbitrates between vectors of 16~~ (maybe 32)~~ vertices that arrive directly from primitive assembly and vectors of ~~8~~4 quads (16 pixels) ~~(32 pixels)~~ that are generated in the raster engine.

The vertex or pixel program specifies how many GPR's it needs to execute. The sequencer will not start the next vector until the needed space is available.

The sequencer is based on the R300 design. It chooses ~~an~~ two ALU clauses and a texture clause to execute, and executes all of the instructions in ~~a~~a clause before looking for a new clause of the same type. Two ALU clauses are executed interleaved to hide the ALU latency. Each vector will have eight texture and eight ALU clauses, but clauses do not need to contain instructions. A vector of pixels or vertices ping-pongs along the sequencer FIFO, bouncing from texture reservation station to alu reservation station. A FIFO exists between each reservation stage, holding up vectors until the vector currently occupying a reservation station has left. A vector at a reservation station can be chosen to execute. The sequencer looks at all eight alu reservation stations to choose an alu clause to execute and all eight texture stations to choose a texture clause to execute. The arbitrator will give priority to clauses/reservation stations closer to the ~~top~~ bottom of the pipeline. It will not execute an alu clause until the texture fetches initiated by the previous texture clause have completed. There are two separate sets of reservation stations, one for pixel vectors and one for vertices vectors. This way a pixel can pass a vertex and a vertex can pass a pixel.

To support the shader pipe the raster engine also contains the shader instruction cache and constant store. There are only one constant store for the whole chip and one instruction store. These will be shared among the four shader pipes.

texture arbitrator
texture arbitrator

There are two sets of the above figure, one for vertices and one for pixels.

The rasterizer always checks the vertices FIFO first and if allowed by the sequencer sends the data to the shader. If the vertex FIFO is empty then, the rasterizer takes the first entry of the pixel FIFO (a vector of ~~32~~ 16 pixels) and sends it to the interpolators. Then the sequencer takes control of the packet. The packet consists of 3 bits of state, 6-7 bits for the base address of the Shader program and some information on the coverage to determine texture LOD. All other information (2x2 adresses) is put in a FIFO (one for the pixels and one for the vertices) and retrieved when the packet finishes its last clause.

On receipt of a packet, the input state machine (not pictured but just before the first FIFO) allocated enough space in the registers to store the interpolated values and temporaries. Following this, the input state machine stacks the packet in the first FIFO.

On receipt of a command, the level 0 texture machine issues a texure request and corresponding register address for the texture address (ta). A small command (tcmd) is passed to the texture system identifying the current level number (0) as well as the register ~~set being used~~write address for the texture return data. One texture request is sent every 4 clocks causing the texturing of four 2x2s worth of data (or 16 vertices). Once all the requests are sent the packet is put in FIFO 1.

Upon recept of the return data~~ (identified by the tcmd containing the level number 0), the level 0 texture machine issues a register address for the return value (td)~~, the texture unit writes the data to the register file using the write address that was provided by the level 0 texture machine and sends the clause number (0) to the level 0 texture state machine to signify that the write is done and thus the data is ready. Then, the level 0 texture machine~~ it~~ increments the counter of FIFO ~~one~~ 1 to signify to the ALU 1 that the data is ready to be processed.

On receipt of a command, the level 0 ALU machine first decrements the input FIFO counter and then issues a complete set of level 0 shader instructions. For each instruction, the state machine generates 3 source addresses, one destination address (~~2~~ 3 cycles later) and an instruction~~ id wich is used to index into the instruction store~~. Once the last instruction as been issued, the packet is put into FIFO 2.~~ Note that in the case of a pixel packet, the two vectors of 16 pixels are consecutive in order to hide the latency of the ALUs (8 cycles).~~

There will always be two active ALU clauses at any given time (and two arbitrers)~~ In this case, the instructions of a vector are interleaved with the instructions of the other vector.~~ One arbiter will arbitrate over the odd clock cycles and the other one will arbitrate over the even clock cycles. The only constraints between the two arbitrers is that they are not allowed to pick the same clause number as they other one is currently working on if the packet os of the same type.

Formatted

If the packet is a vertex packet, upon reaching ALU clause 4, it can export the position if the position is ready. So the arbitrer must prevent ALU clause 4 to be selected if the positional buffer is full (or can't be accessed). Along with the positional data, the location where the vertex data is to be put is also sent (parameter data pointers).

All other level process in the same way until the packet finally reaches the last ALU machine (8). On completion of the level 8 ALU clause, a valid bit is sent to the Render Backend which picks up the color data. This requires that the last instruction writes to the output register – a condition that is almost always true. If the packet was a vertex packet, instead of sending the valid bit to the RB, it is sent to the PA~~, which picks up the data and puts it into the vertex store~~ so it can know that the data present in the parameter store is valid.

Only ~~one~~ two ALU state machine may have access to the ~~SRAM~~register file address bus or the instruction decode bus at one time. Similarly, only one texture state machine may have access to the ~~SRAM~~register file address bus at one time. Arbitration is performed by ~~two~~ three arbitrer blocks (~~one~~ two for the ALU state machines and one for the texture state machines). The arbitrers always favor the higher number state machines, preventing a bunch of half finished jobs from clogging up the ~~SRAM~~register ~~S~~files.

Each state machine maintains an address pointer specifying where the 16~~ (or 32)~~ entries vector is located in the ~~SRAM~~register file (the texture machine has two pointers one for the read address and one for the write). Upon completion of its job, the address pointer is incremented by a predefined amount equal to the total number of registers required by the shading code. A comparison of the address pointer for the first state machine in the chain (the input state machine), and the last machine in the chain (the level 8 ALU machine), gives an indication of how much unallocated ~~SRAM~~register file memory is available

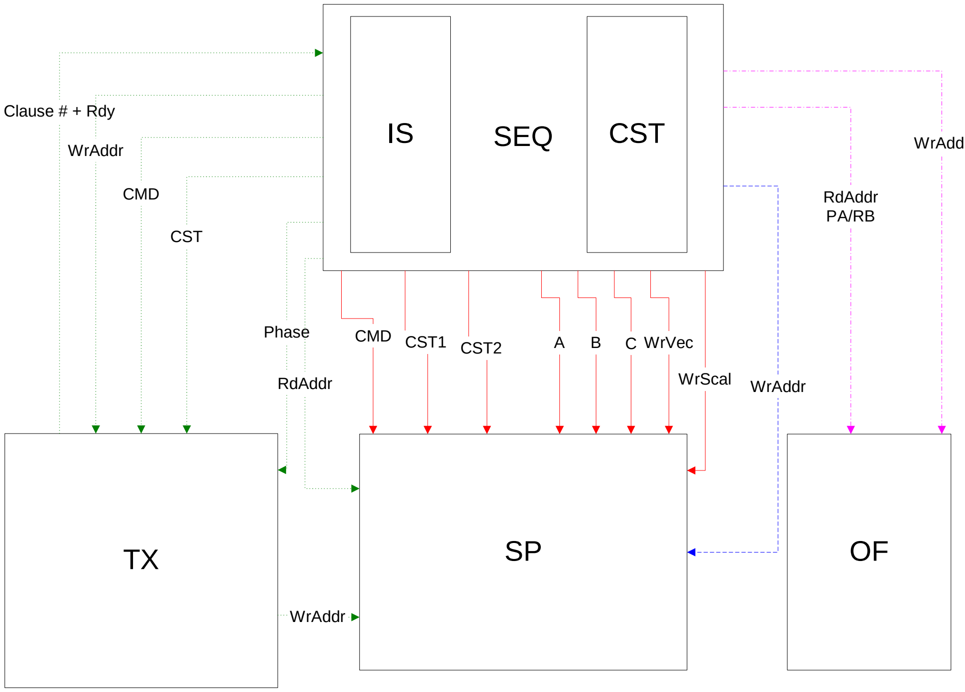
1.3 Control Graph



In green is represented the Texture control interface, in red the ALU control interface, in blue the Interpolated/Vector control interface and in purple is the output file control interface.

Formatted: Bullets and Numbering

2. Interpolated data bus

Since each of the register file is actually physically divided (one 128x128 per MAC) and we don't have the place to hold a maximum size vector of vertices in the parameter buffer, we need to interpolate on a parameter basis rather than on a quad basis. So the order to the register file will be:

Q0P0 Q1P0 Q2P0 Q3P0 Q0P1 Q1P1 Q2P1 Q3P1 Q0P2 Q1P2 …

Formatted: Bullets and Numbering

3. Instruction Store

There is going to be only one instruction store for the whole chip. It may contain up to 2000 instructions of 96 bits each.

{ISSUE : The instruction store is loaded by the sequencer using the memory hub ?}.

The read bandwith from this store is 24 bits/clock/pipe. To achieve this this instruction store is likely to be broken up into 4 blocks. An ALU instruction section (1R/1W) split in two and a texture section (1R/1W) also split in two. The bandwith out of those memories is 96 bits/clock.

4. Constant Store

Formatted: Bullets and Numbering

The constant store is managed by the CP. The sequencer is aware of where the constants are using a remaping table also managed by the CP. A likely size for the constant store is 512x128 bits. The constant store is also planned to be shared. The read BW from the constant store is 512/4 bits/clock/pipe and the write bandwith is 32/4 bits/clock.

5. Looping and Branches

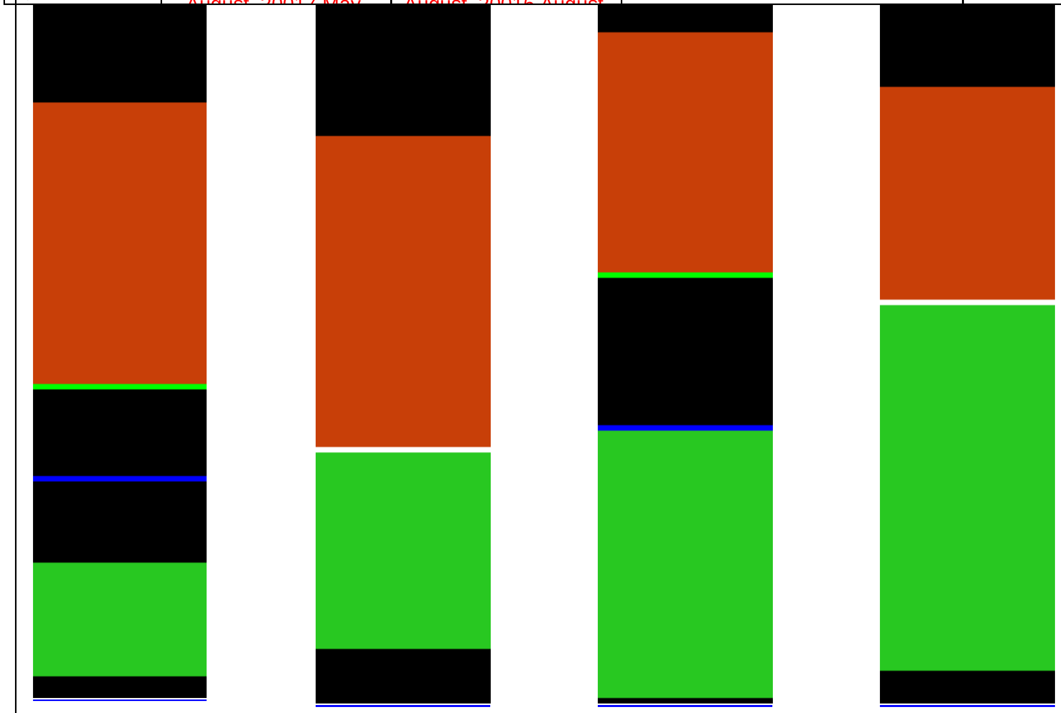
Formatted: Bullets and Numbering

Loops and branches are planned to be supported and will have to be dealt with at the sequencer level. However, it is still unclear if we plan on supporting data dependent branches or not.

6. Register file allocation

Formatted: Bullets and Numbering

The register file allocation for vertices and pixels can either be static or dynamic. In both cases, the register file in managed using two round robins (one for pixels and one for vertices). In the dynamic case the boundary between pixels and vertices is allowed to move, in the static case it is fixed to VERTEX_REG_SIZE for vertices and 256-VERTEX_REG_SIZE for pixels.



Above is an example of how the algorithm works. Vertices come in from top to bottom; pixels come in from bottom to top. Vertices are in orange and pixels in green. The blue line is the tail of the vertices and the green line is the tail of the pixels. Thus anything between the two lines is shared. When pixels meets vertices the line turns white and the boundary is static until both vertices and pixels share the same “unallocated bubble”. Then the boundary as allowed moving again.

Formatted: Bullets and Numbering

~~2.~~7. Texture Arbitration

The texture arbitration logic chooses one of the 8 potentially pending texture clauses to be executed. The choice is made by looking at the fifos from 7 to 0 and picking the first one ready to execute. Once chosen, the clause state machine will send one 2x2 texture fetch per clock (or 4 fetches in one clock every 4 clocks) until all the texture fetch instructions of the clause are sent. This means that there cannot be any dependencies between two texture fetches of the same clause.

The arbitrator will not wait for the texture fetches to return prior to selecting another clause for execution. The texture pipe will be able to handle up to ~~100~~X(?) in flight texture fetches and thus there can be a fair number of active clauses waiting for their texture return data.

Formatted: Bullets and Numbering

~~3.~~8. ALU Arbitration

ALU arbitration proceeds in almost the same way than texture arbitration. The ALU arbitration logic chooses one of the 8 potentially pending ALU clauses to be executed. The choice is made by looking at the fifos from 7 to 0 and picking the first one ready to execute~~execute. If the packet chosen is a packet of vertices, the state machine issues one instruction every 4 clocks until the clause is finished. This means that the compiler has to insert nops between two dependent successive instructions. If the packet is a pixel packet it is made out of two sub-vectors of 16. Thus the state machine issues the first instruction for the first sub-vector and then, 4 clocks later, the first instruction of the second sub-vector and so on until the clause is finished. ~~. There are two ALU arbitrers, one for the even clocks and

one for the odd clocks. For exemple, here is the sequencing of two interleaved ALU clauses (E and O stands for Even and Odd):

Einst0 Oinst0 Einst1 Oinst1 Einst2 Oinst2 Einst0 Oinst3 Einst1 Oinst4 Einst2 Oinst0…
Proceeding this way hides the latency of 8 clocks of the ALUs.

Formatted: Bullets and Numbering

~~4.~~9. Handling Stalls

When the output file is full, the sequencer prevents the ALU arbitration logic to select the last clause (this way nothing can exit the shader pipe until there is place in the output file. If ~~we have the ability to export at any clause~~the packet is a vertex packet and the position buffer is full (POS_FULL) then the sequencer also prevents a thread to enter the exporting clause (4?). The sequencer will set the OUT_FILE_FULL signal n clocks before the output file is actually full and thus the ALU arbitrer will be able read this signal and act accordingly by not preventing exporting clauses to proceed.

Formatted: Bullets and Numbering

~~5.~~10. Content of the reservation station FIFOs

3 bits of Render State ~~and~~ 6-7 bits for the base address of the instruction store and some bits for LOD correction. Every other information (such as the coverage mask, quad address, etc.) is put in a FIFO and is retrieved when the quad exits the shader pipe to enter in the output file buffer. Since pixels and vertices are kept in order in the shader pipe, we only need two fifos (one for vertices and one for pixels) deep enough to cover the shader pipe latency. This size will be determined later when we will know the size of the small fifos between the reservation stations.

Formatted: Bullets and Numbering

~~6.~~11. The Output File (RB FIFO and Parameter Cache)

The output file is where program results are exported when the pixel/vertex shader finishes. It constists of a 512x128 memory cell that is statically divided between pixels and vertices. ~~Each section is a regular FIFO.~~ The output file has 1 write port and 1 read port. The sequencer is responsible for managing the addresses of this output file and for stalling the shader pipe should this output file fill up. The management is done by keeping the tail and head pointers of each sections (pixels and vertices) and incrementing them using a simple RoundRobin allocation policy. The sequencer must also arbitrate between the PA and the RB for the use of the read port. This arbitration will either be priority based or just interleaved evenly (1 read every 2 clocks for each of the blocks).

Formatted: Bullets and Numbering

~~7.~~12. Interfaces

~~7.1~~12.1 External Interfaces

~~7.1.1~~12.1.1 *Sequencer to Shader Engine Bus*

This is a bus that sends the instruction and constant data to all 4 Sub-Engines of the Shader. Because a new instruction is needed only every 4 clocks, the width of the bus is divided by 4 and both constants and instruction are sent over those 4 clocks.

Name	**Direction**	**Bits**	**Description**
Instruction Start	SEQ-> SP	1	High on first cycle of transfer
Constant 0	SEQ-> SP	32	128 bits transferred over 4 cycles, alpha first…blue last
Constant 1	SEQ-> SP	32	128 bits transferred over 4 cycles, alpha first…blue last
Instruction	SEQ-> SP	30	120 bits transferred over 4 cycles (order TBD) ?

Formatted: Bullets and Numbering

~~7.1.2~~12.1.2 *Shader Engine to Output File*

Every clock each Sub-Engine can output 128 bits of 'vector' data and 32 bits of 'scalar' data to an output file (?). This data will be compressed into 128 bits total prior to storage in output file.

Name	**Direction**	**Bits**	**Description**
UL_Vector_Out	SP-> OF	128	Vector Data out

UL_Scalar_Out	SP-> OF	32	Vector Data out
UR_Vector_Out	SP-> OF	128	Vector Data out
UR_Scalar_Out	SP-> OF	32	Vector Data out

Name	Direction	Bits	Description
LL_Vector_Out	SP-> OF	128	Vector Data out
LL_Scalar_Out	SP-> OF	32	Vector Data out
LR_Vector_Out	SP-> OF	128	Vector Data out
LR_Scalar_Out	SP-> OF	32	Vector Data out

~~7.1.3~~12.1.3 *Shader Engine to Texture Unit Bus (Fast Bus)*

Formatted: Bullets and Numbering

One quad's worth of addresses is transferred to Texture Unit every clock. These are sourced from a different pixel within each of the sub-engines repeating every 4 clocks. The ~~register file~~register file index to read must precede the data by 2 clocks. The Read address associated with Quad 0 must be sent 1 clock after the Instruction Start signal is sent, so that data is read 3 clocks after the Instruction Start.

One Quad's worth of Texture Data may be written to the ~~Register File~~Register file every clock. These are directed to a different pixel of the sub-engines repeating every 4 clocks. The ~~register file~~register file index to write must accompany the data. Data and Index associated with the Quad 0 must be sent 3 clocks after the Instruction Start signal is sent.

Name	Direction	Bits	Description
Tex_Read_Register_Index	SEQ->SP	8	Index into ~~Register File~~Register files for reading Texture Address
Tex_RegFile_Read_Data	SP->TEX	512	4 Texture Addresses read from the ~~Register File~~Register file
Tex_Write_Register_Index	SEQ->TEX	8	Index into ~~Register file~~Register file for write of returned Texture Data

~~7.1.4~~12.1.4 *Sequencer to Texture Unit bus (Slow Bus)*

Formatted: Bullets and Numbering

Once every four clock, the texture unit sends to the sequencer on wich clause it is now working and if the data in the registers is ready or not. This way the sequencer can update the texture counters for the reservation station fifos. The sequencer also provides the intruction and constants for the texture fetch to execute and the address in the ~~register file~~register file where to write the texture return data.

Name	Direction	Bits	Description
Tex_Ready	TEX→ SEQ	1	Data ready
Tex_Clause_Num	TEX→ SEQ	3	Clause number
Tex_cst	SEQ→TEX	?	Texture constants X bits sent over 4 clocks
Tex_Inst	SEQ→TEX	?	Texture fetch instruction X bits sent over 4 clocks

~~7.1.5~~12.1.5 *Shader Engine to RE/PA Bus*

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
Interpolator_Register_Index	SEQ->SP	8	Index into ~~Register File~~Register files for write of Interpolator/Index Data
Interpolator_Write_Mask	SEQ->SP	1	Write Mask. The same write mask is used for all 4 pixels
Interpolator_Write_Data	RE/PA->SP	512	4 interpolated vectors or vectors of indices

12.1.6 *PA? to sequencer*

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
Adress	PA→SEQ	?	Dealocation adress sent by the PA telling the Sequencer that it is now possible to free this space in the parameter buffer. This token is a pointer in the parameter cache and 4 bits to tell the size wich is to be freed up.

Formatted

Formatted

Formatted

13. Examples of program executions

13.1.1 *Sequencer Control of a Vector of Vertices*

1. PA sends a vector of 16 vertices (actually vertex indices – 32 bits/index for 512 bit total) to the RE's Vertex FIFO
   - state pointer as well as tag into position cache is sent along with vertices
   - space was allocated in the position cache for transformed position before the vector was sent
   - **also before the vector is sent to the RE, the CP has loaded the global instruction store with the vertex shader program (using the MH?)**
   - The vertex program is assumed to be loaded when we receive the vertex vector.
     - the SEQ then accesses the IS base for this shader using the local state pointer (provided to all sequencers by the RBBM when the CP is done loading the program)
2. SEQ arbitrates between the Pixel FIFO and the Vertex FIFO – basically the Vertex FIFO always has priority
   - at this point the vector is removed from the Vertex FIFO
   - the arbitrer is not going to select a vector to be transformed if the parameter cache is full unless the pipe as nothing else to do (ie no pixels are in the pixel fifo).
3. SEQ allocates space in the SP register file for index data plus GPRs used by the program
   - the number of GPRs required by the program is stored in a local state register, which is accessed using the state pointer that came down with the vertices
   - SEQ will not send vertex data until space in the register file has been allocated
4. SEQ sends the vector to the SP register file over the RE_SP interface (which has a bandwidth of 512 bits/cycle)
   - the 16 vertex indices are sent to the 16 register files over 4 cycles
     - RF0 of SU0, SU1, SU2, and SU3 is written the first cycle
     - RF1 of SU0, SU1, SU2, and SU3 is written the second cycle
     - RF2 of SU0, SU1, SU2, and SU3 is written the third cycle
     - RF3 of SU0, SU1, SU2, and SU3 is written the fourth cycle
   - the index is written to the least significant 32 bits **(floating point format?) (what about compound indices)** of the 128-bit location within the register file (w); the remaining data bits are set to zero (x, y, z)
5. SEQ constructs a control packet for the vector and sends it to the first reservation station (the FIFO in front of texture state machine 0, or TSM0 FIFO)
   - the control packet contains the state pointer, the tag to the position cache and a register file base pointer.
6. TSM0 accepts the control packet and fetches the instructions for texture clause 0 from the global instruction store
   - TSM0 was first selected by the TSM arbiter before it could start
7. all instructions of texture clause 0 are issued by TSM0
8. the control packet is passed to the next reservation station (the FIFO in front of ALU state machine 0, or ASM0 FIFO)
   - TSM0 does not wait for requests made to the Texture Unit to complete; it passes the register file write index for the texture data to the TU, which will write the data to the RF as it is received
   - once the TU has written all the data to the register files, it increments a counter that is associated with ASM0 FIFO; a count greater than zero indicates that the ALU state machine can go ahead start to execute the ALU clause
9. ASM0 accepts the control packet (after being selected by the ASM arbiter) and gets the instructions for ALU clause 0 from the global instruction store
10. all instructions of ALU clause 0 are issued by ASM0, then the control packet is passed to the next reservation station (the FIFO in front of texture state machine 1, or TSM1 FIFO)
11. the control packet continues to travel down the path of reservation stations until all clauses have been executed
    - position can be exported in ALU clause 3 (or 4?); the data (and the tag) is sent over a position bus (which is shared with all four shader pipes) back to the PA's position cache
    - A parameter cache pointer is also sent along with the position data. This tells to the PA where the data is going to be in the parameter cache.
      - there is a position export FIFO in the SP that buffers position data before it gets sent back to the PA

    - the ASM arbiter will prevent a packet from starting an exporting clause if the position export FIFO is full
- parameter data is exported in clause 7 (as well as position data if it was not exported earlier)
    - parameter data is sent to the Parameter Cache over a dedicated bus
    - the SEQ allocates storage in the Parameter Cache, and the SEQ deallocates that space when there is no longer a need for the parameters (it is told by the PA when using a token).
    - the ASM arbiter will prevent a packet from starting on ASM7 if the parameter cache (or the position buffer if position is being exported) is full

12. after the shader program has completed, the SEQ will free up the GPRs so that they can be used by another shader program

13.1.2 *Sequencer Control of a Vector of Pixels*

1. **As with vertex shader programs, pixel shaders are loaded into the global instruction store by the CP**
    - At this point it is assumed that the pixel program is loaded into the instruction store and thus ready to be read.
2. the RE's Parameter Buffer is loaded from the Parameter Cache before the SEQ takes control of the vector
    - after the HZ culling stage a request is made by the RE to send parameter data to the Parameter buffer
    - the Parameter buffer is wide enough to source 3 vertices worth of a particular parameter in one cycle
    - **at this moment the right sequencer will free up the parameter store locations not used anymore using the token provided by the PA**.
3. the RE's Pixel FIFO is loaded with the barycentric coordinates for pixel quads by the detailed walker
    - the state pointer and the LOD correction bits are also placed in the Pixel FIF0
    - the Pixel FIFO is wide enough to source one quad's worth of barycentrics per cycle
4. SEQ arbitrates between Pixel FIFO and Vertex FIFO – when there are no vertices pending OR there is no space left in the register files for vertices, the Pixel FIFO is selected
5. SEQ allocates space in the SP register file for all the GPRs used by the program
    - the number of GPRs required by the program is stored in a local state register, which is accessed using the state pointer
    - SEQ will not allow interpolated data to be sent to the shader until space in the register file has been allocated
6. SEQ control starts with the interpolation of parameters (up to 16 per thread) by sending the barycentric coordinates from the Pixel FIFO and the parameters from the Parameter Buffer to the interpolator
    - P0i, P0j, and P0k (the value of P0 at each vertex) are loaded into the interpolator from the Parameter buffer
    - Q0 i, j, and k are loaded into the interpolator from the Pixel FIFO
    - The interpolator then generates the parameter value for each pixel in Q0 (Q0P0)
    - **P0i, P0j, and P0k are sent to the interpolator for Q1 only if Q1 is from a different primitive; if Q1 is from the same primitive as Q0, then the P0i, P0j, and P0k values loaded for Q0 are held by the interpolator and reused for Q1**
        - **a "different_prim" control bit is passed with the barycentric data for each quad in the Pixel FIFO that indicates whether new parameter data needs to be loaded into the interpolator**
    - Q1 i, j, and k are then loaded into the interpolator from the Pixel FIFO
    - The interpolator then generates the parameter value for each pixel in Q1 (Q1P0)
    - Q2P0 and Q3P0 are generated in a similar manner
    - The next set of parameter data - P1i, P1j, and P1k - is then loaded into the interpolator
    - Q0 i, j, and k now must be re-read from the Pixel FIFO – this means that the output of the Pixel FIFO loops through the top four entries on each read command until at the end a final "block_pop" signal is asserted, causing the top four sets of barycentric coordinates to finally be removed
    - so the order of parameter info generated is Q0P0, Q1P0, Q2P0, Q3P0, Q0P1, Q1P1, etc.
7. SEQ controls the transfer of interpolated data to the SP register file over the RE_SP interface (which has a bandwidth of 512 bits/cycle)
    - 16 pixels worth of interpolated parameter data is sent to the 16 register files over 4 cycles
        - RF0 of SU0, SU1, SU2, and SU3 is written with Q0P0 the first cycle
        - RF1 of SU0, SU1, SU2, and SU3 is written with Q1P0 second cycle
        - RF2 of SU0, SU1, SU2, and SU3 is written with Q2P0 third cycle
        - RF3 of SU0, SU1, SU2, and SU3 is written with Q3P0 fourth cycle

8. SEQ constructs a control packet for the vector and sends it to the first reservation station (the FIFO in front of texture state machine 0, or TSM0 FIFO)
   - note that there is a separate set of reservation stations/arbiters/state machines for vertices and for pixels
   - the control packet contains the state pointer, the register file base pointer, and the LOD correction bits
   - all other informations (such as quad address for example) travels in a separate FIFO
9. TSM0 accepts the control packet and fetches the instructions for texture clause 0 from the global instruction store
   - TSM0 was first selected by the TSM arbiter before it could start
10. all instructions of texture clause 0 are issued by TSM0
11. the control packet is passed to the next reservation station (the FIFO in front of ALU state machine 0, or ASM0 FIFO)
    - TSM0 does not wait for texture requests made to the Texture Unit to complete; it passes the register file write index for the texture data to the TU, which will write the data to the RF as it is received
    - once the TU has written all the data for a particular clause to the register files, it increments a counter that is associated with the ASM0 FIFO; a count greater than zero indicates that the ALU state machine can go ahead and pop the FIFO and start to execute the ALU clause
12. ASM0 accepts the control packet (after being selected by the ASM arbiter) and gets the instructions for ALU clause 0 from the global instruction store
13. all instructions of ALU clause 0 are issued by ASM0, then the control packet is passed to the next reservation station (the FIFO in front of texture state machine 1, or TSM1 FIFO)
14. the control packet continues to travel down the path of reservation stations until all clauses have been executed
    - pixel data is exported in the last ALU clause (clause 7)
      - it is sent to an output FIFO where it will be picked up by the render backend
      - the ASM arbiter will prevent a packet from starting on ASM7 if the output FIFO is full
15. after the shader program has completed, the SEQ will free up the GPRs so that they can be used by another shader program

13.1.3 *Notes*

Formatted: Bullets and Numbering

16. the state machines and arbitrers will operate ahead of time so that they will be able to immediately start the real threads or stall.
17. the register file base pointer for a vector needs to travel with the vector through the reservation stations, but the instruction store base pointer does not – this is because the RF pointer is different for all threads, but the IS pointer is only different for each state and thus can be accessed via the state pointer
18. Waterfalling, parameter buffer allocation, loops and branches and parameter cache de-allocation still needs to be specked out.

~~8.~~14. Open issues

There is currently an issue with constants. If the constants are not the same for the whole vector of vertices, we don't have the bandwith from the texture store to feed the ALUs. Two solutions exists for this problem:

1) Let the compiler handle the case and put those instructions in a texture clause so we can use the bandwith there to operate. This requires a significant amount of temporary storage in the register store.
2) Waterfall down the pipe allowing only at a given time the vertices having the same constants to operate in parrallel. This might in the worst case slow us down by a factor of 16.

Need to do some testing on the size of the ~~register file~~register file as well as on the ~~register file~~register file allocation method (dynamic VS static).

~~Ability to export at any clause?~~

Saving power?

~~Are we working on 32 vertices at a time or 16?~~

Size of the fifo containing the information of a vector of pixels/vertices. And size of the fifos before the reservation stations.

Sequencer Instruction memory, and constant memory.

Arbitration policy for the output file.

Loops and branches.

The parameter cache may end up in the PA rather than in the RS. Parameter cache management thus may change.

R400 Sequencer Specification

SEQ

Version 0.5~~2~~

Overview: This is an architectural specification for the R400 Sequencer block (SEQ). It provides an overview of the required capabilities and expected uses of the block. It also describes the block interfaces, internal sub-blocks, and provides internal state diagrams.

Revision Changes:

Rev 0.1 (Laurent Lefebvre) Date: May 7, 2001	First draft.
Rev 0.2 (Laurent Lefebvre) Date : July 9, 2001	Changed the interfaces to reflect the changes in the SP. Added some details in the arbitration section.
Rev 0.3 (Laurent Lefebvre) Date : August 6, 2001	Reviewed the Sequencer spec after the meeting on August 3, 2001.
Rev 0.4 (Laurent Lefebvre) Date : August 24, 2001	Added the dynamic allocation method for register file and an example (written in part by Vic) of the flow of pixels/vertices in the sequencer.
Rev 0.4 (Laurent Lefebvre) Date : September 7, 2001	Added timing diagrams (Vic)

1. Overview

The sequencer first arbitrates between vectors of 16~~ (maybe 32)~~ vertices that arrive directly from primitive assembly and vectors of ~~8~~4 ~~-~~quads (16 pixels) ~~(32 pixels) ~~that are generated in the raster engine.

The vertex or pixel program specifies how many GPR's it needs to execute. The sequencer will not start the next vector until the needed space is available.

The sequencer is based on the R300 design. It chooses ~~an~~ two ALU clauses and a texture clause to execute, and executes all of the instructions in ~~a~~a clause before looking for a new clause of the same type. Two ALU clauses are executed interleaved to hide the ALU latency. Each vector will have eight texture and eight ALU clauses, but clauses do not need to contain instructions. A vector of pixels or vertices ping-pongs along the sequencer FIFO, bouncing from texture reservation station to alu reservation station. A FIFO exists between each reservation stage, holding up vectors until the vector currently occupying a reservation station has left. A vector at a reservation station can be chosen to execute. The sequencer looks at all eight alu reservation stations to choose an alu clause to execute and all eight texture stations to choose a texture clause to execute. The arbitrator will give priority to clauses/reservation stations closer to the ~~top~~ bottom of the pipeline. It will not execute an alu clause until the texture fetches initiated by the previous texture clause have completed. There are two separate sets of reservation stations, one for pixel vectors and one for vertices vectors. This way a pixel can pass a vertex and a vertex can pass a pixel.

To support the shader pipe the raster engine also contains the shader instruction cache and constant store. There are only one constant store for the whole chip and one instruction store. These will be shared among the four shader pipes.

There are two sets of the above figure, one for vertices and one for pixels.

The rasterizer always checks the vertices FIFO first and if allowed by the sequencer sends the data to the shader. If the vertex FIFO is empty then, the rasterizer takes the first entry of the pixel FIFO (a vector of ~~32~~ 16 pixels) and sends it to the interpolators. Then the sequencer takes control of the packet. The packet consists of 3 bits of state, 6-7 bits for the base address of the Shader program and some information on the coverage to determine texture LOD. All other information (2x2 adresses) is put in a FIFO (one for the pixels and one for the vertices) and retrieved when the packet finishes its last clause.

On receipt of a packet, the input state machine (not pictured but just before the first FIFO) allocated enough space in the registers to store the interpolated values and temporaries. Following this, the input state machine stacks the packet in the first FIFO.

On receipt of a command, the level 0 texture machine issues a texure request and corresponding register address for the texture address (ta). A small command (tcmd) is passed to the texture system identifying the current level number (0) as well as the register ~~set being used~~write address for the texture return data. One texture request is sent every 4 clocks causing the texturing of four 2x2s worth of data (or 16 vertices). Once all the requests are sent the packet is put in FIFO 1.

Upon recept of the return data ~~(identified by the tcmd containing the level number 0), the level 0 texture machine issues a register address for the return value (td)~~, the texture unit writes the data to the register file using the write address that was provided by the level 0 texture machine and sends the clause number (0) to the level 0 texture state machine to signify that the write is done and thus the data is ready. Then, the level 0 texture machine ~~it~~ increments the counter of FIFO ~~one~~ 1 to signify to the ALU 1 that the data is ready to be processed.

On receipt of a command, the level 0 ALU machine first decrements the input FIFO counter and then issues a complete set of level 0 shader instructions. For each instruction, the state machine generates 3 source addresses, one destination address (~~2~~ 3 cycles later) and an instruction ~~id wich is used to index into the instruction store~~. Once the last instruction as been issued, the packet is put into FIFO 2. ~~Note that in the case of a pixel packet, the two vectors of 16 pixels are consecutive in order to hide the latency of the ALUs (8 cycles).~~

There will always be two active ALU clauses at any given time (and two arbitrers) ~~In this case, the instructions of a vector are interleaved with the instructions of the other vector.~~ One arbiter will arbitrate over the odd clock cycles and the other one will arbitrate over the even clock cycles. The only constraints between the two arbitrers is that they are not allowed to pick the same clause number as they other one is currently working on if the packet os of the same type.

Formatted

If the packet is a vertex packet, upon reaching ALU clause 4, it can export the position if the position is ready. So the arbitrer must prevent ALU clause 4 to be selected if the positional buffer is full (or can't be accessed). Along with the positional data, the location where the vertex data is to be put is also sent (parameter data pointers).

All other level process in the same way until the packet finally reaches the last ALU machine (8). On completion of the level 8 ALU clause, a valid bit is sent to the Render Backend which picks up the color data. This requires that the last instruction writes to the output register – a condition that is almost always true. If the packet was a vertex packet, instead of sending the valid bit to the RB, it is sent to the PA~~, which picks up the data and puts it into the vertex store~~ so it can know that the data present in the parameter store is valid.

Only ~~one~~ two ALU state machine may have access to the ~~SRAM~~register file address bus or the instruction decode bus at one time. Similarly, only one texture state machine may have access to the ~~SRAM~~register file address bus at one time. Arbitration is performed by ~~two~~ three arbitrer blocks (~~one~~ two for the ALU state machines and one for the texture state machines). The arbitrers always favor the higher number state machines, preventing a bunch of half finished jobs from clogging up the ~~SRAM~~register ~~S~~files.

Each state machine maintains an address pointer specifying where the 16 ~~(or 32)~~ entries vector is located in the ~~SRAM~~register file (the texture machine has two pointers one for the read address and one for the write). Upon completion of its job, the address pointer is incremented by a predefined amount equal to the total number of registers required by the shading code. A comparison of the address pointer for the first state machine in the chain (the input state machine), and the last machine in the chain (the level 8 ALU machine), gives an indication of how much unallocated ~~SRAM~~register file memory is available

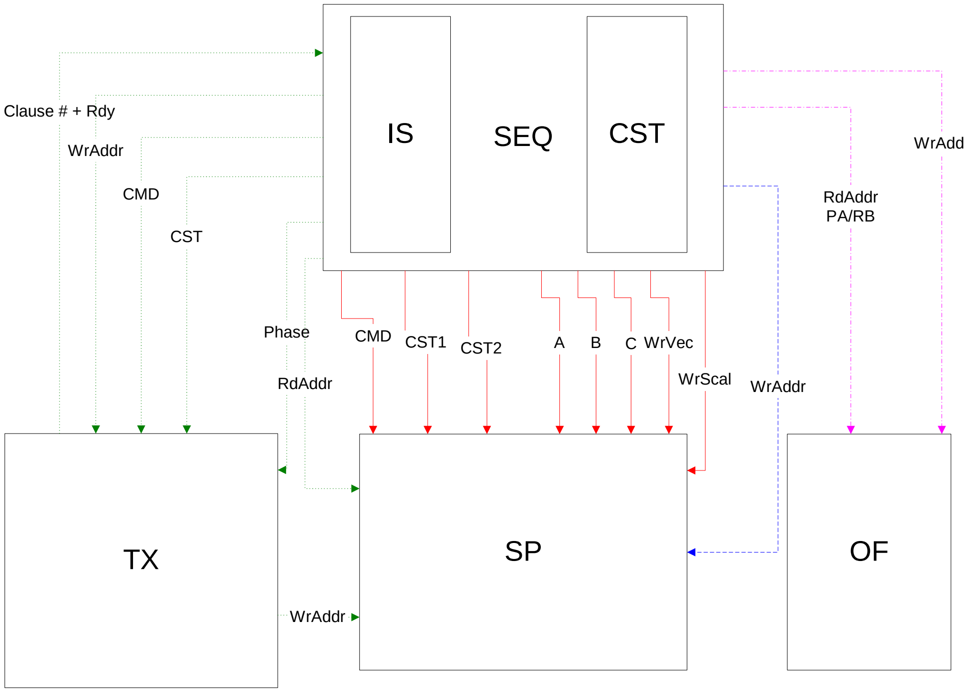
1.3 Control Graph



In green is represented the Texture control interface, in red the ALU control interface, in blue the Interpolated/Vector control interface and in purple is the output file control interface.

2. Interpolated data bus

Formatted: Bullets and Numbering

Since each of the register file is actually physically divided (one 128x128 per MAC) and we don't have the place to hold a maximum size vector of vertices in the parameter buffer, we need to interpolate on a parameter basis rather than on a quad basis. So the order to the register file will be:

Q0P0 Q1P0 Q2P0 Q3P0 Q0P1 Q1P1 Q2P1 Q3P1 Q0P2 Q1P2 …

3. Instruction Store

Formatted: Bullets and Numbering

There is going to be only one instruction store for the whole chip. It may contain up to 2000 instructions of 96 bits each.

{ISSUE : The instruction store is loaded by the sequencer using the memory hub ?}.

The read bandwith from this store is 24 bits/clock/pipe. To achieve this this instruction store is likely to be broken up into 4 blocks. An ALU instruction section (1R/1W) split in two and a texture section (1R/1W) also split in two. The bandwith out of those memories is 96 bits/clock.

4. Constant Store

Formatted: Bullets and Numbering

The constant store is managed by the CP. The sequencer is aware of where the constants are using a remaping table also managed by the CP. A likely size for the constant store is 512x128 bits. The constant store is also planned to be shared. The read BW from the constant store is 512/4 bits/clock/pipe and the write bandwith is 32/4 bits/clock.

5. Looping and Branches

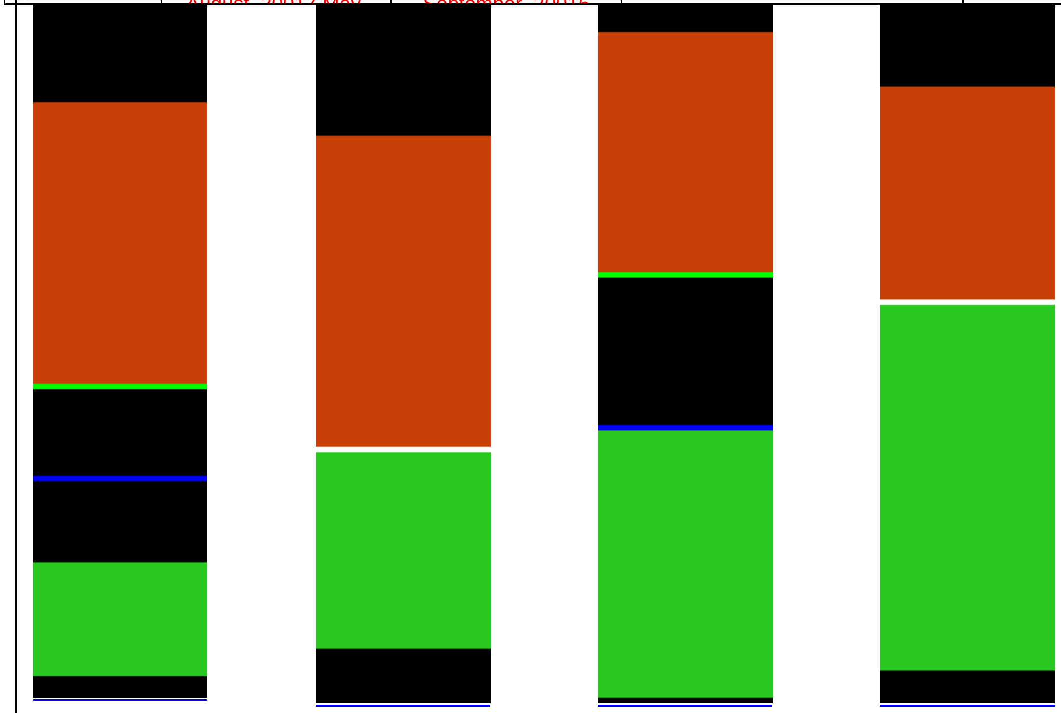
Formatted: Bullets and Numbering

Loops and branches are planned to be supported and will have to be dealt with at the sequencer level. However, it is still unclear if we plan on supporting data dependent branches or not.

6. Register file allocation

Formatted: Bullets and Numbering

The register file allocation for vertices and pixels can either be static or dynamic. In both cases, the register file in managed using two round robins (one for pixels and one for vertices). In the dynamic case the boundary between pixels and vertices is allowed to move, in the static case it is fixed to VERTEX_REG_SIZE for vertices and 256-VERTEX_REG_SIZE for pixels.



Above is an example of how the algorithm works. Vertices come in from top to bottom; pixels come in from bottom to top. Vertices are in orange and pixels in green. The blue line is the tail of the vertices and the green line is the tail of the pixels. Thus anything between the two lines is shared. When pixels meets vertices the line turns white and the boundary is static until both vertices and pixels share the same "unallocated bubble". Then the boundary as allowed moving again.

Formatted: Bullets and Numbering

~~2.~~7. Texture Arbitration

The texture arbitration logic chooses one of the 8 potentially pending texture clauses to be executed. The choice is made by looking at the fifos from 7 to 0 and picking the first one ready to execute. Once chosen, the clause state machine will send one 2x2 texture fetch per clock (or 4 fetches in one clock every 4 clocks) until all the texture fetch instructions of the clause are sent. This means that there cannot be any dependencies between two texture fetches of the same clause.

The arbitrator will not wait for the texture fetches to return prior to selecting another clause for execution. The texture pipe will be able to handle up to ~~100~~X(?) in flight texture fetches and thus there can be a fair number of active clauses waiting for their texture return data.

Formatted: Bullets and Numbering

~~3.~~8. ALU Arbitration

ALU arbitration proceeds in almost the same way than texture arbitration. The ALU arbitration logic chooses one of the 8 potentially pending ALU clauses to be executed. The choice is made by looking at the fifos from 7 to 0 and picking the first one ready to execute~~execute. If the packet chosen is a packet of vertices, the state machine issues one instruction every 4 clocks until the clause is finished. This means that the compiler has to insert nops between two dependent successive instructions. If the packet is a pixel packet it is made out of two sub-vectors of 16. Thus the state machine issues the first instruction for the first sub-vector and then, 4 clocks later, the first instruction of the second sub-vector and so on until the clause is finished. ~~. There are two ALU arbitrers, one for the even clocks and

one for the odd clocks. For exemple, here is the sequencing of two interleaved ALU clauses (E and O stands for Even and Odd):

Einst0 Oinst0 Einst1 Oinst1 Einst2 Oinst2 Einst0 Oinst3 Einst1 Oinst4 Einst2 Oinst0…
Proceeding this way hides the latency of 8 clocks of the ALUs.

~~4.~~9. Handling Stalls

Formatted: Bullets and Numbering

When the output file is full, the sequencer prevents the ALU arbitration logic to select the last clause (this way nothing can exit the shader pipe until there is place in the output file. If ~~we have the ability to export at any clause~~the packet is a vertex packet and the position buffer is full (POS_FULL) then the sequencer also prevents a thread to enter the exporting clause (4?). The sequencer will set the OUT_FILE_FULL signal n clocks before the output file is actually full and thus the ALU arbitrer will be able read this signal and act accordingly by not preventing exporting clauses to proceed.

~~5.~~10. Content of the reservation station FIFOs

Formatted: Bullets and Numbering

3 bits of Render State ~~and~~ 6-7 bits for the base address of the instruction store and some bits for LOD correction. Every other information (such as the coverage mask, quad address, etc.) is put in a FIFO and is retrieved when the quad exits the shader pipe to enter in the output file buffer. Since pixels and vertices are kept in order in the shader pipe, we only need two fifos (one for vertices and one for pixels) deep enough to cover the shader pipe latency. This size will be determined later when we will know the size of the small fifos between the reservation stations.

~~6.~~11. The Output File (RB FIFO and Parameter Cache)

Formatted: Bullets and Numbering

The output file is where program results are exported when the pixel/vertex shader finishes. It constists of a 512x128 memory cell that is statically divided between pixels and vertices. ~~Each section is a regular FIFO.~~ The output file has 1 write port and 1 read port. The sequencer is responsible for managing the addresses of this output file and for stalling the shader pipe should this output file fill up. The management is done by keeping the tail and head pointers of each sections (pixels and vertices) and incrementing them using a simple RoundRobin allocation policy. The sequencer must also arbitrate between the PA and the RB for the use of the read port. This arbitration will either be priority based or just interleaved evenly (1 read every 2 clocks for each of the blocks).

~~7.~~12. Interfaces

Formatted: Bullets and Numbering

~~7.1~~12.1 External Interfaces

~~7.1.1~~12.1.1 *Sequencer to Shader Engine Bus*

This is a bus that sends the instruction and constant data to all 4 Sub-Engines of the Shader. Because a new instruction is needed only every 4 clocks, the width of the bus is divided by 4 and both constants and instruction are sent over those 4 clocks.

Name	Direction	Bits	Description
Instruction Start	SEQ-> SP	1	High on first cycle of transfer
Constant 0	SEQ-> SP	32	128 bits transferred over 4 cycles, alpha first…blue last
Constant 1	SEQ-> SP	32	128 bits transferred over 4 cycles, alpha first…blue last
Instruction	SEQ-> SP	30	120 bits transferred over 4 cycles (order TBD) ?

~~7.1.2~~12.1.2 *Shader Engine to Output File*

Formatted: Bullets and Numbering

Every clock each Sub-Engine can output 128 bits of 'vector' data and 32 bits of 'scalar' data to an output file (?). This data will be compressed into 128 bits total prior to storage in output file.

Name	Direction	Bits	Description
UL_Vector_Out	SP-> OF	128	Vector Data out

UL_Scalar_Out	SP-> OF	32	Vector Data out
UR_Vector_Out	SP-> OF	128	Vector Data out
UR_Scalar_Out	SP-> OF	32	Vector Data out

Name	Direction	Bits	Description
LL_Vector_Out	SP-> OF	128	Vector Data out
LL_Scalar_Out	SP-> OF	32	Vector Data out
LR_Vector_Out	SP-> OF	128	Vector Data out
LR_Scalar_Out	SP-> OF	32	Vector Data out

~~7.1.3~~12.1.3 *Shader Engine to Texture Unit Bus (Fast Bus)*

Formatted: Bullets and Numbering

One quad's worth of addresses is transferred to Texture Unit every clock. These are sourced from a different pixel within each of the sub-engines repeating every 4 clocks. The ~~register file~~register file index to read must precede the data by 2 clocks. The Read address associated with Quad 0 must be sent 1 clock after the Instruction Start signal is sent, so that data is read 3 clocks after the Instruction Start.

One Quad's worth of Texture Data may be written to the ~~Register File~~Register file every clock. These are directed to a different pixel of the sub-engines repeating every 4 clocks. The ~~register file~~register file index to write must accompany the data. Data and Index associated with the Quad 0 must be sent 3 clocks after the Instruction Start signal is sent.

Name	Direction	Bits	Description
Tex_Read_Register_Index	SEQ->SP	8	Index into ~~Register File~~Register files for reading Texture Address
Tex_RegFile_Read_Data	SP->TEX	512	4 Texture Addresses read from the ~~Register File~~Register file
Tex_Write_Register_Index	SEQ->TEX	8	Index into ~~Register file~~Register file for write of returned Texture Data

~~7.1.4~~12.1.4 *Sequencer to Texture Unit bus (Slow Bus)*

Formatted: Bullets and Numbering

Once every four clock, the texture unit sends to the sequencer on wich clause it is now working and if the data in the registers is ready or not. This way the sequencer can update the texture counters for the reservation station fifos. The sequencer also provides the intruction and constants for the texture fetch to execute and the address in the ~~register file~~register file where to write the texture return data.

Name	Direction	Bits	Description
Tex_Ready	TEX→ SEQ	1	Data ready
Tex_Clause_Num	TEX→ SEQ	3	Clause number
Tex_cst	SEQ→TEX	?	Texture constants X bits sent over 4 clocks
Tex_Inst	SEQ→TEX	?	Texture fetch instruction X bits sent over 4 clocks

~~7.1.5~~12.1.5 *Shader Engine to RE/PA Bus*

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
Interpolator_Register_Index	SEQ->SP	8	Index into ~~Register File~~Register files for write of Interpolator/Index Data
Interpolator_Write_Mask	SEQ->SP	1	Write Mask. The same write mask is used for all 4 pixels
Interpolator_Write_Data	RE/PA->SP	512	4 interpolated vectors or vectors of indices

12.1.6 *PA? to sequencer*

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
Adress	PA→SEQ	?	Dealocation adress sent by the PA telling the Sequencer that it is now possible to free this space in the parameter buffer. This token is a pointer in the parameter cache and 4 bits to tell the size wich is to be freed up.

Formatted: Bullets and Numbering

13. Examples of program executions

13.1.1 *Sequencer Control of a Vector of Vertices*

1. PA sends a vector of 16 vertices (actually vertex indices – 32 bits/index for 512 bit total) to the RE's Vertex FIFO
   - state pointer as well as tag into position cache is sent along with vertices
   - space was allocated in the position cache for transformed position before the vector was sent
   - **also before the vector is sent to the RE, the CP has loaded the global instruction store with the vertex shader program (using the MH?)**
   - The vertex program is assumed to be loaded when we receive the vertex vector.
     - the SEQ then accesses the IS base for this shader using the local state pointer (provided to all sequencers by the RBBM when the CP is done loading the program)
2. SEQ arbitrates between the Pixel FIFO and the Vertex FIFO – basically the Vertex FIFO always has priority
   - at this point the vector is removed from the Vertex FIFO
   - the arbitrer is not going to select a vector to be transformed if the parameter cache is full unless the pipe as nothing else to do (ie no pixels are in the pixel fifo).
3. SEQ allocates space in the SP register file for index data plus GPRs used by the program
   - the number of GPRs required by the program is stored in a local state register, which is accessed using the state pointer that came down with the vertices
   - SEQ will not send vertex data until space in the register file has been allocated
4. SEQ sends the vector to the SP register file over the RE_SP interface (which has a bandwidth of 512 bits/cycle)
   - the 16 vertex indices are sent to the 16 register files over 4 cycles
     - RF0 of SU0, SU1, SU2, and SU3 is written the first cycle
     - RF1 of SU0, SU1, SU2, and SU3 is written the second cycle
     - RF2 of SU0, SU1, SU2, and SU3 is written the third cycle
     - RF3 of SU0, SU1, SU2, and SU3 is written the fourth cycle
   - the index is written to the least significant 32 bits **(floating point format?) (what about compound indices)** of the 128-bit location within the register file (w); the remaining data bits are set to zero (x, y, z)
5. SEQ constructs a control packet for the vector and sends it to the first reservation station (the FIFO in front of texture state machine 0, or TSM0 FIFO)
   - the control packet contains the state pointer, the tag to the position cache and a register file base pointer.
6. TSM0 accepts the control packet and fetches the instructions for texture clause 0 from the global instruction store
   - TSM0 was first selected by the TSM arbiter before it could start
7. all instructions of texture clause 0 are issued by TSM0
8. the control packet is passed to the next reservation station (the FIFO in front of ALU state machine 0, or ASM0 FIFO)
   - TSM0 does not wait for requests made to the Texture Unit to complete; it passes the register file write index for the texture data to the TU, which will write the data to the RF as it is received
   - once the TU has written all the data to the register files, it increments a counter that is associated with ASM0 FIFO; a count greater than zero indicates that the ALU state machine can go ahead start to execute the ALU clause
9. ASM0 accepts the control packet (after being selected by the ASM arbiter) and gets the instructions for ALU clause 0 from the global instruction store
10. all instructions of ALU clause 0 are issued by ASM0, then the control packet is passed to the next reservation station (the FIFO in front of texture state machine 1, or TSM1 FIFO)
11. the control packet continues to travel down the path of reservation stations until all clauses have been executed
    - position can be exported in ALU clause 3 (or 4?); the data (and the tag) is sent over a position bus (which is shared with all four shader pipes) back to the PA's position cache
    - A parameter cache pointer is also sent along with the position data. This tells to the PA where the data is going to be in the parameter cache.
      - there is a position export FIFO in the SP that buffers position data before it gets sent back to the PA

    - the ASM arbiter will prevent a packet from starting an exporting clause if the position export FIFO is full
- parameter data is exported in clause 7 (as well as position data if it was not exported earlier)
    - parameter data is sent to the Parameter Cache over a dedicated bus
    - the SEQ allocates storage in the Parameter Cache, and the SEQ deallocates that space when there is no longer a need for the parameters (it is told by the PA when using a token).
    - the ASM arbiter will prevent a packet from starting on ASM7 if the parameter cache (or the position buffer if position is being exported) is full

12. after the shader program has completed, the SEQ will free up the GPRs so that they can be used by another shader program

13.1.2 *Sequencer Control of a Vector of Pixels*

1. **As with vertex shader programs, pixel shaders are loaded into the global instruction store by the CP**
    - At this point it is assumed that the pixel program is loaded into the instruction store and thus ready to be read.
2. the ~~RE's~~ Parameter Buffer is loaded from the Parameter Cache before the SEQ takes control of the vector
    - after the HZ culling stage a request is made by the RE to send parameter data to the Parameter buffer
    - the Parameter buffer is wide enough to source 3 vertices worth of a particular parameter in one cycle
    - **at this moment the right sequencer will free up the parameter store locations not used anymore using the token provided by the PA**.
3. the RE's Pixel FIFO is loaded with the barycentric coordinates for pixel quads by the detailed walker
    - the state pointer and the LOD correction bits are also placed in the Pixel FIF0
    - the Pixel FIFO is wide enough to source one quad's worth of barycentrics per cycle
4. SEQ arbitrates between Pixel FIFO and Vertex FIFO – when there are no vertices pending OR there is no space left in the register files for vertices, the Pixel FIFO is selected
5. SEQ allocates space in the SP register file for all the GPRs used by the program
    - the number of GPRs required by the program is stored in a local state register, which is accessed using the state pointer
    - SEQ will not allow interpolated data to be sent to the shader until space in the register file has been allocated
6. SEQ control starts with the interpolation of parameters (up to 16 per thread) by sending the barycentric coordinates from the Pixel FIFO and the parameters from the Parameter Buffer to the interpolator
    - P0i, P0j, and P0k (the value of P0 at each vertex) are loaded into the interpolator from the Parameter buffer
    - Q0 i, j, and k are loaded into the interpolator from the Pixel FIFO
    - The interpolator then generates the parameter value for each pixel in Q0 (Q0P0)
    - **P0i, P0j, and P0k are sent to the interpolator for Q1 only if Q1 is from a different primitive; if Q1 is from the same primitive as Q0, then the P0i, P0j, and P0k values loaded for Q0 are held by the interpolator and reused for Q1**
        - **a "different_prim" control bit is passed with the barycentric data for each quad in the Pixel FIFO that indicates whether new parameter data needs to be loaded into the interpolator**
    - Q1 i, j, and k are then loaded into the interpolator from the Pixel FIFO
    - The interpolator then generates the parameter value for each pixel in Q1 (Q1P0)
    - Q2P0 and Q3P0 are generated in a similar manner
    - The next set of parameter data - P1i, P1j, and P1k - is then loaded into the interpolator
    - Q0 i, j, and k now must be re-read from the Pixel FIFO – this means that the output of the Pixel FIFO loops through the top four entries on each read command until at the end a final "block_pop" signal is asserted, causing the top four sets of barycentric coordinates to finally be removed
    - so the order of parameter info generated is Q0P0, Q1P0, Q2P0, Q3P0, Q0P1, Q1P1, etc.
7. SEQ controls the transfer of interpolated data to the SP register file over the RE_SP interface (which has a bandwidth of 512 bits/cycle)
    - 16 pixels worth of interpolated parameter data is sent to the 16 register files over 4 cycles
        - RF0 of SU0, SU1, SU2, and SU3 is written with Q0P0 the first cycle
        - RF1 of SU0, SU1, SU2, and SU3 is written with Q1P0 second cycle
        - RF2 of SU0, SU1, SU2, and SU3 is written with Q2P0 third cycle
        - RF3 of SU0, SU1, SU2, and SU3 is written with Q3P0 fourth cycle

8. SEQ constructs a control packet for the vector and sends it to the first reservation station (the FIFO in front of texture state machine 0, or TSM0 FIFO)
    - note that there is a separate set of reservation stations/arbiters/state machines for vertices and for pixels
    - the control packet contains the state pointer, the register file base pointer, and the LOD correction bits
    - all other informations (such as quad address for example) travels in a separate FIFO

9. TSM0 accepts the control packet and fetches the instructions for texture clause 0 from the global instruction store
    - TSM0 was first selected by the TSM arbiter before it could start

10. all instructions of texture clause 0 are issued by TSM0

11. the control packet is passed to the next reservation station (the FIFO in front of ALU state machine 0, or ASM0 FIFO)
    - TSM0 does not wait for texture requests made to the Texture Unit to complete; it passes the register file write index for the texture data to the TU, which will write the data to the RF as it is received
    - once the TU has written all the data for a particular clause to the register files, it increments a counter that is associated with the ASM0 FIFO; a count greater than zero indicates that the ALU state machine can go ahead and pop the FIFO and start to execute the ALU clause

12. ASM0 accepts the control packet (after being selected by the ASM arbiter) and gets the instructions for ALU clause 0 from the global instruction store

13. all instructions of ALU clause 0 are issued by ASM0, then the control packet is passed to the next reservation station (the FIFO in front of texture state machine 1, or TSM1 FIFO)

14. the control packet continues to travel down the path of reservation stations until all clauses have been executed
    - pixel data is exported in the last ALU clause (clause 7)
        - it is sent to an output FIFO where it will be picked up by the render backend
        - the ASM arbiter will prevent a packet from starting on ASM7 if the output FIFO is full

15. after the shader program has completed, the SEQ will free up the GPRs so that they can be used by another shader program

13.1.3 *Notes*

Formatted: Bullets and Numbering

16. the state machines and arbitrers will operate ahead of time so that they will be able to immediately start the real threads or stall.

17. the register file base pointer for a vector needs to travel with the vector through the reservation stations, but the instruction store base pointer does not – this is because the RF pointer is different for all threads, but the IS pointer is only different for each state and thus can be accessed via the state pointer

18. Waterfalling, parameter buffer allocation, loops and branches and parameter cache de-allocation still needs to be specked out.

Timing Diagram 3: Sequencer - Texture Unit Interface and Texture Unit - Shader Pipe Data Transfer

14.4 Timing diagrams explanations

Formatted: Bullets and Numbering

The numbering of the four shader pipes, the four shader units, and the four MACs is from left to right and from 0 to 3. So for example the most significant 512 bits of a SP goes to SU0 and the least significant 512 bits go to SU3; within SU0, the most significant 128 bits go to MAC0 and the least significant 128 bits go to MAC3.
The following assumptions are made:

1. all block to block signals are register to register
2. for register file reads, the RF read data is available in the MAC one clock after a RF read address is registered into the MAC (this is the same as saying the read data is valid out of the RF two clocks after the address is asserted on the SEQ to SP interface)

Formatted: Bullets and Numbering

14.4.1 *Timing Diagram 1: Sequencer to Shader Pipe 0, Shader Unit 0, MAC 0*

This diagram shows the basics of the Sequencer to Shader Pipe interface. For simplicity only the timing relative to MAC0 is shown. The timing for MAC1 is one clock later than MAC0, MAC2 one clock later than MAC1, etc. This means that most of the signals need to be delayed in the SP by one cycle for MAC1, two cycles for MAC2, and three cycles for MAC3.
SEQ_SP_constant0: Constant 0 (128 bits over 4 cycles). Pipelined in SP for other MACs.
SEQ_SP_constant1: Constant 1 (128 bits over 4 cycles). Pipelined in SP for other MACs.
SEQ_SP_read_addr: Register File Read Address (8 bits). Pipelined in SP for other MACs.
SEQ_SP_phase: This signal syncs the data transfer to the RF from the RE, as well as defining the order of all writes into the RF. It is asserted during the cycle that interpolated data (ID) is valid on the RE_SP_ID bus. Pipelined in SP for other MACs.
RE_SP_ID[511:384]: This is the most significant 128 bits of the RE_SP data interface (meaning that this MAC0 is in SU0).
SEQ_SP_instruction: 96 bits of instruction are sent over 4 cycles. Pipelined in SP for other MACs.
SEQ_SP_instr_start: control bit that signals the first cycle of the instruction transfer. Pipelined in SP for other MACs.
mac0_phase: registered version of SEQ_SP_phase used in MAC0 (this may not be he actual signal name).
mac0_cycle_count: a counter inside the MAC that keeps track of the RF write cycles; 0 here corresponds to the cycle RE interpolated data is written (this may not be he actual signal name).
RF0_read_data: data that is read out of MAC0's register file (this may not be he actual signal name).
mac0_vector_result: the 32-bit output of the vector ALU (PV is built up over 4 cycles) (this may not be he actual signal name).
SEQ_SP_write_addr: Register File Write Address (8 bits). Note that the SEQ does not send the Texture Data write address over this bus. Pipelined in SP for other MACs.
RF0 write cycle: the cycles allocated to the different write sources (ID = Interpolated Data, TD = Texture Data, PV = Previous Vector, PS = Previous Scalar) (not a signal – just a reference point on the diagram).

14.4.2 *Timing Diagram 2: RE Interpolator to Shader Pipe Data Transfer*

Formatted: Bullets and Numbering

This diagram shows how pixel data (barycentric coordinates i, j, and k) is sent from the Pixel FIFO to the interpolator under SEQ control, and how parameter data (for each vertex) is also sent to the interpolator under SEQ control. The output of the Interpolator is then shown being sent over the RE_SP interface.
PXF_SEQ_rts: Indicates that the output of the pixel FIFO is valid.
PXF_SEQ_new_prim: The current output of the Pixel FIFO is from a different primitive that the previous output. Tells the SEQ that new parameter info must be fetched (if its not from a new prim, then new parameter data is not needed).
PXF_INT_data: Data output of the Pixel FIFO – goes to the Interpolator.
SEQ_PXF_rtr: Indicates that the current Pixel FIFO output will be taken by the Interpolator (driven by SEQ). Then next quad of data will be driven the next cycle.
SEQ_PXF_vector_pop: SEQ tells the Pixel FIFO to pop a vector of pixels (otherwise RTRs cause the data to be cycled between the four quads).

PMB_INT_data: Data from the Parameter Buffer to the Interpolator. (Note that the control of the parameter buffer is TBD).

SEQ_INT_pm_load: controls the loading of parameter data into the Interpolator.

INT_param_reg: register in the Interpolator that holds the per-vertex parameter data while the per-pixel parameters are generated for one or more quads (may not be the actual signal name).
SEQ_INT_px_load: controls the loading of pixel data into the Interpolator.
INT_quad_reg: : register in the Interpolator that holds one quad's worth of pixel data(may not be the actual signal name).

SEQ_SP_phase: see above under TD1.
SEQ_SP_write_addr: see above under TD1.
RE_SP_valid: Interpolator Data Valid – indicates that the SP should write the ID on the appropriate cycle.
RE_SP_data: Data from the RE interpolator to the SP.
RF0 write cycle: see above under TD1.
mac*_phase: see above under TD1. These phase signals help to show the timing offset between the MACs. Note also that each Shader Unit has a set of these signals (all with the same timing).

14.4.3 *Timing Diagram 3: Sequencer - Texture Unit Interface and Texture Unit - Shader Pipe Data Transfer*

Formatted: Bullets and Numbering

This diagram starts with the texture coordinate read from the register file and its transfer to the TX. The instruction transfer is then shown, followed by the texture data transfer to the shader pipe.
SEQ_SP_read_addr: see above. Here shows the cycle that the texture coordinate read address is asserted.
RF0_read_addr: see above.
SP_TX_tc: Texture coordinate data sent from the shader pipe to the texture unit.
SEQ_TX_instr_start: Asserted on the first cycle of a SEQ to TX instruction transfer.
SEQ_TX_instruction: 96 bits of texture instruction transferred over 4 cycles.
SEQ_TX_clause: the clause number associated with this instruction.
SEQ_TX_write_addr: RF write index used by TX for returned texture data.
SEQ_TX_last: indicates that this is the last texture instruction of a clause.
SEQ_TX_phase: syncs the texture data write. Note that it is asserted early enough to be registered into TX and still allow TX to source the texture data to the SP on the correct cycle.

tx_phase: the phase signal after being registered into TX.
TX_SP_write_addr: RF write index for texture data.
TX_SP_valid: indicates that valid texture data is being driven to the SP.
TX_SP_data: the texture data.
TX_SEQ_clause: the clause number associated with the texture data.
TX_SEQ_done: indicates to the SEQ that the texture data transfer is complete for the clause number that is on the TX_SEQ_clause bus.

SEQ_SP_phase: see above under TD1 - shown here for reference.
SEQ_SP_write_addr: see above under TD1- shown here for reference.
RF0 write cycle: see above under TD1- shown here for reference.

Formatted: Bullets and Numbering

There is currently an issue with constants. If the constants are not the same for the whole vector of vertices, we don't have the bandwith from the texture store to feed the ALUs. Two solutions exists for this problem:

1) Let the compiler handle the case and put those instructions in a texture clause so we can use the bandwith there to operate. This requires a significant amount of temporary storage in the register store.
2) Waterfall down the pipe allowing only at a given time the vertices having the same constants to operate in parrallel. This might in the worst case slow us down by a factor of 16.

Need to do some testing on the size of the ~~register file~~register file as well as on the ~~register file~~register file allocation method (dynamic VS static).

~~Ability to export at any clause?~~

Saving power?

~~Are we working on 32 vertices at a time or 16?~~

Size of the fifo containing the information of a vector of pixels/vertices. And size of the fifos before the reservation stations.

Sequencer Instruction memory, and constant memory.

Arbitration policy for the output file.

Loops and branches.

The parameter cache may end up in the PA rather than in the RS. Parameter cache management thus may change.

R400 Sequencer Specification

SEQ

Version 0.6~~5~~

Overview: This is an architectural specification for the R400 Sequencer block (SEQ). It provides an overview of the required capabilities and expected uses of the block. It also describes the block interfaces, internal sub-blocks, and provides internal state diagrams.

Revision Changes:

Rev 0.1 (Laurent Lefebvre) Date: May 7, 2001	First draft.
Rev 0.2 (Laurent Lefebvre) Date : July 9, 2001	Changed the interfaces to reflect the changes in the SP. Added some details in the arbitration section.
Rev 0.3 (Laurent Lefebvre) Date : August 6, 2001	Reviewed the Sequencer spec after the meeting on August 3, 2001.
Rev 0.4 (Laurent Lefebvre) Date : August 24, 2001	Added the dynamic allocation method for register file and an example (written in part by Vic) of the flow of pixels/vertices in the sequencer.
Rev 0.~~4~~ 5 (Laurent Lefebvre) Date : September 7, 2001	Added timing diagrams (Vic)
Rev 0.6 (Laurent Lefebvre) Date : September 24, 2001	Changed the spec to reflect the new R400 architecture.

1. Overview

The sequencer first arbitrates between vectors of ~~16~~ 64 vertices that arrive directly from primitive assembly and vectors of ~~4~~ 16 quads (~~16~~ 64 pixels) that are generated in the raster engine.

The vertex or pixel program specifies how many GPR's it needs to execute. The sequencer will not start the next vector until the needed space is available.

The sequencer is based on the R300 design. It chooses two ALU clauses and a texture clause to execute, and executes all of the instructions in a clause before looking for a new clause of the same type. Two ALU clauses are executed interleaved to hide the ALU latency. Each vector will have eight texture and eight ALU clauses, but clauses do not need to contain instructions. A vector of pixels or vertices ping-pongs along the sequencer FIFO, bouncing from texture reservation station to alu reservation station. A FIFO exists between each reservation stage, holding up vectors until the vector currently occupying a reservation station has left. A vector at a reservation station can be chosen to execute. The sequencer looks at all eight alu reservation stations to choose an alu clause to execute and all eight texture stations to choose a texture clause to execute. The arbitrator will give priority to clauses/reservation stations closer to the bottom of the pipeline. It will not execute an alu clause until the texture fetches initiated by the previous texture clause have completed. There are two separate sets of reservation stations, one for pixel vectors and one for vertices vectors. This way a pixel can pass a vertex and a vertex can pass a pixel.

To support the shader pipe the raster engine also contains the shader instruction cache and constant store. There are only one constant store for the whole chip and one instruction store. These will be shared among the four shader pipes. The four shader pipes also execute the same instuction thus there is only one sequencer for the whole chip.

There are two sets of the above figure, one for vertices and one for pixels.

The rasterizer always checks the vertices FIFO first and if allowed by the sequencer sends the data to the shader. If the vertex FIFO is empty then, the rasterizer takes the first entry of the pixel FIFO (a vector of ~~16~~ 64 pixels) and sends it to the interpolators. Then the sequencer takes control of the packet. The packet consists of ~~3~~ 20 bits of state, 6-7 bits for the base address of the Shader program and some information on the coverage to determine texture LOD. All other information (2x2 adresses) is put in a FIFO (one for the pixels and one for the vertices) and retrieved when the packet finishes its last clause.

{Issue: How many bits of state exactly?}

On receipt of a packet, the input state machine (not pictured but just before the first FIFO) allocated enough space in the registers to store the interpolated values and temporaries. Following this, the input state machine stacks the packet in the first FIFO.

On receipt of a command, the level 0 texture machine issues a texure request and corresponding register address for the texture address (ta). A small command (tcmd) is passed to the texture system identifying the current level number (0) as well as the register write address for the texture return data. One texture request is sent every 4 clocks causing the texturing of ~~four~~ sixteen 2x2s worth of data (or ~~16~~ 64 vertices). Once all the requests are sent the packet is put in FIFO 1.

Upon recept of the return data, the texture unit writes the data to the register file using the write address that was provided by the level 0 texture machine and sends the clause number (0) to the level 0 texture state machine to signify that the write is done and thus the data is ready. Then, the level 0 texture machine increments the counter of FIFO 1 to signify to the ALU 1 that the data is ready to be processed.

On receipt of a command, the level 0 ALU machine first decrements the input FIFO counter and then issues a complete set of level 0 shader instructions. For each instruction, the state machine generates 3 source addresses, one destination address (3 cycles later) and an instruction. Once the last instruction as been issued, the packet is put into FIFO 2.

There will always be two active ALU clauses at any given time (and two arbitrers). One arbitrer will arbitrate over the odd clock cycles and the other one will arbitrate over the even clock cycles. The only constraints between the two arbitrers is that they are not allowed to pick the same clause number as they other one is currently working on if the packet os of the same type.

If the packet is a vertex packet, upon reaching ALU clause 4, it can export the position if the position is ready. So the arbitrer must prevent ALU clause 4 to be selected if the positional buffer is full (or can't be accessed). Along with the positional data, the location where the vertex data is to be put is also sent (parameter data pointers).

All other level process in the same way until the packet finally reaches the last ALU machine (8). On completion of the level 8 ALU clause, a valid bit is sent to the Render Backend which picks up the color data. This requires that the last instruction writes to the output register – a condition that is almost always true. If the packet was a vertex packet, instead of sending the valid bit to the RB, it is sent to the PA so it can know that the data present in the parameter store is valid.

Only two ALU state machine may have access to the register file address bus or the instruction decode bus at one time. Similarly, only one texture state machine may have access to the register file address bus at one time. Arbitration is performed by three arbitrer blocks (two for the ALU state machines and one for the texture state machines). The arbitrers always favor the higher number state machines, preventing a bunch of half finished jobs from clogging up the register files.

~~Each state machine maintains an address pointer specifying where the 16 entries vector is located in the register file (the texture machine has two pointers one for the read address and one for the write). Upon completion of its job, the address pointer is incremented by a predefined amount equal to the total number of registers required by the shading code. A comparison of the address pointer for the first state machine in the chain (the input state machine), and the last machine in the chain (the level 8 ALU machine), gives an indication of how much unallocated register file memory is available~~

P0

P1

Above is an example of a tile we might receive. The IJ information is packed in the IJ buffer 2 quads at a time. The sequencer allows at any given time as many as four quads to interpolate a parameter. They all have to come from the same primitive. Then the sequencer controls the write mask to the register to write the valid data in.~~Since each of the register file is actually physically divided (one 128x128 per MAC) and we don't have the place to hold a maximum size vector of vertices in the parameter buffer, we need to interpolate on a parameter basis rather than on a quad basis. So the order to the register file will be:~~

~~Q0P0 Q1P0 Q2P0 Q3P0 Q0P1 Q1P1 Q2P1 Q3P1 Q0P2 Q1P2 …~~

3. Instruction Store

There is going to be only one instruction store for the whole chip. It ~~may~~ will contain ~~up to 200~~40960 instructions of 96 bits each. There is also going to be a control instruction store of 256x32.

{ISSUE : The instruction store is loaded by the sequencer using the memory hub ?}.

The read bandwith from this store is ~~24~~ 96*2 bits/ 4 clocks (48 bits/clock)~~/pipe~~. ~~To achieve this this instruction store is likely to be broken up into 4 blocks. An ALU instruction section (1R/1W) split in two and a texture section (1R/1W) also split in two.~~ The bandwith out of those memories is ~~96~~ 48 bits/clock. It is likely to be a 1R/1W port memory; we use 2 clocks to load the ALU instruction and 2 clocks to load the Texture instruction.

Formatted: Bullets and Numbering

4. Sequencer Instructions

All control flow instructions and move instructions are handled by the sequencer only. The ALUs will perform NOPs during this time (MOV PV,PV, PS,PS).

Formatted: Bullets and Numbering

~~4.~~5. Constant Store

The constant store is managed by the CP. The sequencer is aware of where the constants are using a remaping table also managed by the CP. A likely size for the constant store is 512x128 bits. The constant store is also planned to be shared. The read BW from the constant store is 128~~512/4~~ bits/clock~~/pipe~~ and the write bandwith is 32/4 bits/clock.

In order to do constant store indexing, the sequencer must be loaded first with the indexes (that come from the GPRs). There are 144 wires from the exit of the SP to the sequencer (9 bits pointers x 16 vertexes/clock). Since the data must pass thru the Shader pipe for the float to fixed convertion, there is a latency of 4 clocks (1 instruction) between the time the sequencer is loaded and the time one can index into the constant store. The assembly will look like this

```
MOVA  R1.X,R2.X        // Loads the sequencer with the content of R2.X, also copies the content of R2.X into R1.X
NOP                    // latency of the float to fixed conversion
ADD   R3,R4,C0[R2.X]// Uses the state from the sequencer to add R4 to C0[R2.X] into R3
```

Note that we don't really care about what is in the brackets because we use the state from the MOVA instruction. R2.X is just written again for the sake of simplicity.

The storage needed in the sequencer in order to support this feature is 2*64*9 bits = 1152 bits.

Formatted: Bullets and Numbering

~~5.~~6. Looping and Branches

Loops and branches are planned to be supported and will have to be dealt with at the sequencer level. We plan on supporting constant loops and branches using a control program. The control program has 4 instructions:

Formatted: Bullets and Numbering

6.1 The controlling state.

As per Dx9 the following state is available for control flow:

Boolean[15:0]

loop_count[7:0][7:0]
In addition:
loop_start [7:0] [7:0]
loop_step [7:0] [7:0]
Exist to give more control to the controlling program.

We will extend that in the R400 to:
Boolean[31:0]
Loop_count[7:0][15:0]
Loop_Start[7:0] [15:0]
Loop_End[7:0] [15:0]

6.2 The Control Flow Program

Formatted: Bullets and Numbering

The R300 uses a match method for control flow: The shader is executed, and at every instruction its address is compared with addresses (or address?) in a control table. The "event" in the control table can redirect operations in the program. I believe that this method has increased area and complexity when the program size is increased.

The Method I prefer is a "control program"
The control program has four basic instructions:
Execute
Conditional_execute
Loop_start
Loop_end

Execute, causes the specified number of instructions in instruction store to be executed.
Conditional_execute checks a condition first, and if true, causes the specified number of instructions in instruction store to be executed.
Loop_start resets the corresponding loop counter to the start value.
Loop_end increments (decrements?) the loop counter and jumps back the specified number of instructions if the loop end condition is not met.

if we try and fit the control flow instructions into 32 bit words, the following instructions are possible choices:

Execute																															
31	30	29	28	27	26	25	24	23	22	21	20	19	18	17	16	15	14	13	12	11	10	9	8	7	6	5	4	3	2	1	0
0	0	0	0	instruction_count												Reserved			Address												

Execute up to 4K instructions at the specified address in the instruction memory.

Conditional Execute																															
31	30	29	28	27	26	25	24	23	22	21	20	19	18	17	16	15	14	13	12	11	10	9	8	7	6	5	4	3	2	1	0
0	0	0	1	Boolean						0: = 0 1: = 1 2,3:NA		Instruction_count							Address												

if the specified boolean (6 bits can address 64 booleans) meets the specified condition then execute the specified instructions (up to 64 instructions)

Conditional Execute Predicates																															
31	30	29	28	27	26	25	24	23	22	21	20	19	18	17	16	15	14	13	12	11	10	9	8	7	6	5	4	3	2	1	0
0	1	0	1	Reserved =0						0: = 0 1: = 1 2,3:NA		Instruction_count							Address												

Check the OR of all current predicate bits. If OR matches the condition execute the specified number of instructions.

Loop_Start																															
31	30	29	28	27	26	25	24	23	22	21	20	19	18	17	16	15	14	13	12	11	10	9	8	7	6	5	4	3	2	1	0

0	0	1	0																								Loop ID				

Initialize the specified loop

Loop_End																															
31	30	29	28	27	26	25	24	23	22	21	20	19	18	17	16	15	14	13	12	11	10	9	8	7	6	5	4	3	2	1	0
0	0	1	1	Reserved (must = 0)												Start Address								Reserved (must = 0)			Loop ID				

if the loop condition of the current loop is not met, then branch back to the specified address in the control flow program. Note that jumping back to the loop_start results in an infinite loop, the jump should be to loop_start+1.

the way this is described does not prevent nested loops, and the inclusion of the loop id make this easy to do.

The basic model is as follows:

The render state defined the clause boundaries:
Vertex_shader_fetch[7:0][7:0]   // eight 8 bit pointers to the location where each clauses control program is located
Vertex_shader_alu[7:0][7:0]   // eight 8 bit pointers to the location where each clauses control program is located
Pixel_shader_fetch[7:0][7:0]   // eight 8 bit pointers to the location where each clauses control program is located
Pixel_shader_alu[7:0][7:0]   // eight 8 bit pointers to the location where each clauses control program is located

The control program can be up to 256 instructions in size. (There is an offset added to the address from the render state before accessing the control flow program memory to allow for multiple programs resident at the same time)

The control program for a given clause is executed to completion before moving to another clause, (with the exception of the pick two nature of the alu execution)

The addresses from the control program are added to another offset to allow for multiple programs resident at the same time.

Under this model, all subroutine calls must be inlined into the control program.

6.3 Data dependant predicate instructions

Formatted: Bullets and Numbering

Data dependant conditionals will be supported in the R400. The only way we plan to support those is by supporting three vector/scalar predicate operations of the form:

PRED_SETE - similar to SETE except that the result is 'exported' to the sequencer.
PRED_SETGT - similar to SETGT except that the result is 'exported' to the sequencer
PRED_SETGTE - similar to SETGTE except that the result is 'exported' to the sequencer

For the scalar operations only we will also support the two following instructions:
PRED_SETE0 – SETE0
PRED_SETE1 – SETE1

The export is a single bit - 1 or 0 that is sent using the same data path as the MOVA instruction. The sequencer will maintain the 64 bit predicate vector and use it to control the write masking (two sets for interleaved operation). This predicate is not maintained across clause boundaries.

Then we have two conditional execute bits. The first bit is a conditional execute “on” bit and the second bit tells us if we execute on 1 or 0. For exemple, the instruction :

P0_ADD R0,R1,R2

Is only going to write the result of the ADD into those GPRs whose predicate bit is 0. Alternatively, P1_ADD would only write the results to the GPRs whose predicate bit is set. The use of the P0 or P1 without precharging the sequencer with a PRED instruction is undefined.

{Issue: do we have to have a NOP between PRED and the first instruction that uses a predicate?}

6.4 Register file indexing

Formatted: Bullets and Numbering

Because we can have loops in texture clause, we need to be able to index into the register file in order to retrieve the data created in a texture clause loop and use it into an ALU clause. The instruction will include the base address for register indexing and the instruction will contain these controls :

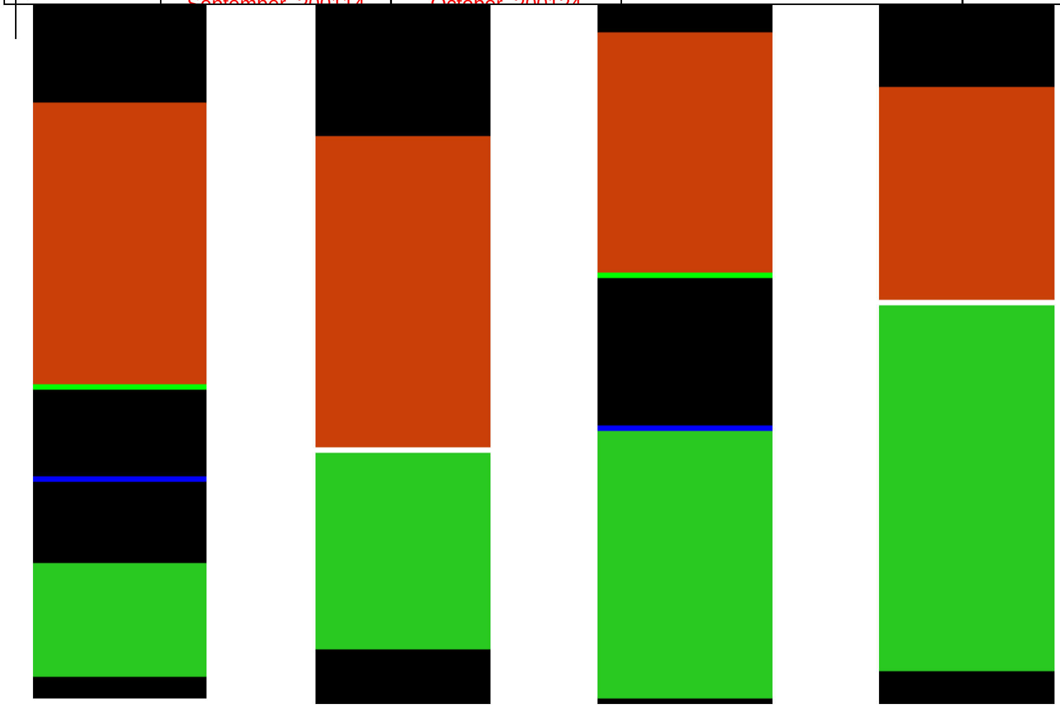
Bit7	Bit 6	
0	0	'absolute register'
0	1	'relative register'
1	0	'previous vector'
1	1	'previous scalar'

In the case of an absolute register we just take the address as is. In the case of a relative register read we take the base address and we add to it the loop_counter and this becomes our new address that we give to the shader pipe.~~However, it is still unclear if we plan on supporting data dependent branches or not.~~

~~6.~~7. Register file allocation

Formatted: Bullets and Numbering

The register file allocation for vertices and pixels can either be static or dynamic. In both cases, the register file in managed using two round robins (one for pixels and one for vertices). In the dynamic case the boundary between pixels and vertices is allowed to move, in the static case it is fixed to VERTEX_REG_SIZE for vertices and 256-VERTEX_REG_SIZE for pixels.



Above is an example of how the algorithm works. Vertices come in from top to bottom; pixels come in from bottom to top. Vertices are in orange and pixels in green. The blue line is the tail of the vertices and the green line is the tail of the pixels. Thus anything between the two lines is shared. When pixels meets vertices the line turns white and the boundary is static until both vertices and pixels share the same "unallocated bubble". Then the boundary ~~as~~ is allowed to moving~~e~~ again.

Formatted: Bullets and Numbering

~~7.~~8. Texture Arbitration

The texture arbitration logic chooses one of the 8 potentially pending texture clauses to be executed. The choice is made by looking at the fifos from 7 to 0 and picking the first one ready to execute. Once chosen, the clause state machine will send one 2x2 texture fetch per clock (or 4 fetches in one clock every 4 clocks) until all the texture fetch instructions of the clause are sent. This means that there cannot be any dependencies between two texture fetches of the same clause.

The arbitrator will not wait for the texture fetches to return prior to selecting another clause for execution. The texture pipe will be able to handle up to X(?) in flight texture fetches and thus there can be a fair number of active clauses waiting for their texture return data.

Formatted: Bullets and Numbering

~~8.~~9. ALU Arbitration

ALU arbitration proceeds in almost the same way than texture arbitration. The ALU arbitration logic chooses one of the 8 potentially pending ALU clauses to be executed. The choice is made by looking at the fifos from 7 to 0 and picking the first one ready to execute. There are two ALU arbitrers, one for the even clocks and one for the odd clocks. For exemple, here is the sequencing of two interleaved ALU clauses (E and O stands for Even and Odd):

Einst0 Oinst0 Einst1 Oinst1 Einst2 Oinst2 Einst0 Oinst3 Einst1 Oinst4 Einst2 Oinst0…
Proceeding this way hides the latency of 8 clocks of the ALUs.

~~9.~~10. Handling Stalls

Formatted: Bullets and Numbering

When the output file is full, the sequencer prevents the ALU arbitration logic to select the last clause (this way nothing can exit the shader pipe until there is place in the output file. If the packet is a vertex packet and the position buffer is full (POS_FULL) then the sequencer also prevents a thread to enter the exporting clause (4?). The sequencer will set the OUT_FILE_FULL signal n clocks before the output file is actually full and thus the ALU arbitrer will be able read this signal and act accordingly by not preventing exporting clauses to proceed.

~~10.~~11. Content of the reservation station FIFOs

Formatted: Bullets and Numbering

3 bits of Render State 6-7 bits for the base address of the instruction store, ~~and~~ some bits for LOD correction and coverage mask information in order to fetch texture for only valid pixels. Every other information (such as the coverage mask, quad address, etc.) is put in a FIFO and is retrieved when the quad exits the shader pipe to enter in the output file buffer. Since pixels and vertices are kept in order in the shader pipe, we only need two fifos (one for vertices and one for pixels) deep enough to cover the shader pipe latency. This size will be determined later when we will know the size of the small fifos between the reservation stations.

~~11.~~12. The Output File (RB FIFO and Parameter Cache)

Formatted: Bullets and Numbering

The output file is where program results are exported when the pixel/vertex shader finishes. It constists of a 512x128 memory cell that is statically divided between pixels and vertices. The output file has 1 write port and 1 read port. The sequencer is responsible for managing the addresses of this output file and for stalling the shader pipe should this output file fill up. The management is done by keeping the tail and head pointers of each sections (pixels and vertices) and incrementing them using a simple RoundRobin allocation policy. The sequencer must also arbitrate between the PA and the RB for the use of the read port. This arbitration will either be priority based or just interleaved evenly (1 read every 2 clocks for each of the blocks).

13. Registers

Formatted: Bullets and Numbering

DYNAMIC_REG	Dynamic allocation (pixel/vertex) of the register file on or off.
VERTEX_REG_SIZE	What portion of the register file is reserved for vertices (static allocation only)
PIXEL_MIN_SIZE	Minimal size of the register file's pixel portion (dynamic only)
VERTEX_MIN_SIZE	Minimal size of the register file's vertex portion (dynamic only)
Vshader_fetch[7:0][7:0]	eight 8 bit pointers to the location where each clauses control program is located
Vshader_alu[7:0][7:0]	eight 8 bit pointers to the location where each clauses control program is located
Pshader_fetch[7:0][7:0]	eight 8 bit pointers to the location where each clauses control program is located
Pshader_alu[7:0][7:0]	eight 8 bit pointers to the location where each clauses control program is located
PSHADER	base pointer for the pixel shader
VSHADER	base pointer for the vertex shader
PCNTLSHADER	base pointer for the pixel control program
VCNTLSHADER	base pointer for the vertex control program
VWRAP	wrap point for the vertex shader instruction store
PWRAP	wrap point for the pixel shader instruction store
REG_ALLOC_PIX	number of registers to allocate for pixel shader programs
REG_ALLOC_VERT	number of registers to allocate for vertex shader programs
PARAM_MASK[0…16]	parameter mask to specify wich parameters the pixel shader
FLAT_GOUR[0…16]	wich parameters are to be gouraud shaded
GEN_TEX[0….16]	for wich parameters do we need to generate tex coords.
CYL_WRAP[0…64]	for wich vertices do we do the cyl wrapping.
P_EXPORT	number of exports for pixel shader
V_EXPORT	number of exports for vertex shader (also the number of interpolated parameters)
V_EXPORT_LOC	Vertex shader exporting to RB or the PCACHE

~~12.~~14. Interfaces

Formatted: Bullets and Numbering

~~12.1~~14.1 External Interfaces

~~12.1.1~~14.1.1 *~~Sequencer to Shader Engine Bus~~PA/SC to RE : IJ bus*

~~This is a bus that sends the instruction and constant data to all 4 Sub-Engines of the Shader. Because a new instruction is needed only every 4 clocks, the width of the bus is divided by 4 and both constants and instruction are sent over those 4 clocks.~~ This is a bus that sends the IJ information to the IJ fifos on the top of each shader pipe. At the same time the control information goes to the sequencer

Name	Direction	Bits	Description
~~Instruction Start~~IJs	~~SEQ-> SP~~PA→RE	~~1~~64	~~High on first cycle of transfer~~IJ information sent over 2 clocks

Formatted: Bullets and Numbering

~~12.1.2~~

~~*12.1.2Shader Engine to Output File*~~

~~Every clock each Sub-Engine can output 128 bits of 'vector' data and 32 bits of 'scalar' data to an output file (?). This data will be compressed into 128 bits total prior to storage in output file.~~

14.1.2 *PA/SC to SEQ : IJ Control bus*

Formatted: Bullets and Numbering

This is the control information sent to the sequencer in order to control the IJ fifos and all other information needed to execute a shader program on the sent pixels.

Name	**Direction**	**Bits**	**Description**
Write Mask	PA→SEQ(RE)	4	Quad Write mask left to right
RB_ID	PA→SEQ(RE)	8	RB id for each quad sent 2 bits per quad
LOD_CORRECT	PA→SEQ(RE)	24	LOD correction per quad (6 bits per quad)
FVTX	PA→SEQ(RE)	2	Provoking vertex for flat shading
PPTR0	PA→SEQ(RE)	11	P Store pointer for vertex 0
PPRT1	PA→SEQ(RE)	11	P Store pointer for vertex 1
PPTR2	PA→SEQ(RE)	11	P Store pointer for vertex 2
E_OFF_VECTOR	PA→SEQ(RE)	1	End of the vector
DEALLOC	PA→SEQ(RE)	1	Deallocation token for the P Store
STATE	PA→SEQ(RE)	21	State/constant pointer (6*3+3)
SPRITE	PA→SEQ(RE)	1	Need to generate tex cords
VALID	PA→SEQ(RE)	16	Valid bits for all pixels
NULL	PA→SEQ(RE)	1	Null Primitive (for deallocation purposes)
E_OFF_PRIM	PA→SEQ(RE)	1	End Of the primitive
FBFACE	PA→SEQ(RE)	1	Front face = 1, back face = 0
STIPPLE_LINE	PA→SEQ(RE)	1	Stippled line need to load tex cords from alternate buffer
RTRn	SEQ→PA	1	Stalls the PA in n clocks
RTS	PA→SEQ(RE)	1	PA ready to send data

14.1.3 *PA/SC to RE : Vertex Bus*

Formatted: Bullets and Numbering

Name	**Direction**	**Bits**	**Description**

14.1.4 PA/SC to SEQ : Vertex Control Bus

Formatted: Bullets and Numbering

Name	**Direction**	**Bits**	**Description**
STATE	PA→SEQ	21	Render State (6*3+3 for constants)

14.1.5 CP to SEQ : Constant store load

Formatted: Bullets and Numbering

Name	**Direction**	**Bits**	**Description**
Constant Address	CP→SEQ	8	Address of the block of 4 constants
Constant Data	CP→SEQ	512	Data sent over X clocks
Remap Address	CP→SEQ	10	Remaping address write address
Remap Data pointer	CP→SEQ	8	Remaping pointer

14.1.6 CP to SEQ : Texture State store load

Formatted: Bullets and Numbering

Name	**Direction**	**Bits**	**Description**
Constant Address	CP→SEQ	8	Address of the block of 4 state constants
Constant Data	CP→SEQ	512	Data sent over X clocks
Remap Address	CP→SEQ	10	Remaping address write address
Remap Data pointer	CP→SEQ	8	Remaping pointer

14.1.7 CP to SEQ : Control State store load

Formatted: Bullets and Numbering

Name	**Direction**	**Bits**	**Description**

14.1.8 MH to SEQ: Instruction store Load

Formatted: Bullets and Numbering

Name	**Direction**	**Bits**	**Description**
Instruction address	MH→SEQ	12	Instruction address
Instruction	MH→SEQ	96	Instruction X times
Control Instruction address	MH→SEQ	8	Pointer to the instruction store
Control Instruction	MH→SEQ	32	Control Instruction X times

14.1.9 OB to RB : Pixel read from RBs

Formatted: Bullets and Numbering

Name	**Direction**	**Bits**	**Description**
Pixel Data	OB→RB	128	2 pixels (or ½ quad)
Quad Address	OB→RB	20	XY address 10 bits per

14.1.10 SP to PA/SC : Position return bus

Formatted: Bullets and Numbering

Name	**Direction**	**Bits**	**Description**
Position return	SP→PA	128	Position data or sprite size
Position Buffer pointer	SP→PA	7?	Pointer to the position cache
Parameter cache pointer	SP→PA	11	Pointer where the data will be in the parameter cache

~~12.1.3~~14.1.11 Shader Engine to Texture Unit Bus (Fast Bus)

Formatted: Bullets and Numbering

~~One~~ Four quad's worth of addresses is transferred to Texture Unit every clock. These are sourced from a different pixel within each of the sub-engines repeating every 4 clocks. The register file index to read must precede the data by 2 clocks. The Read address associated with Quad 0 must be sent 1 clock after the Instruction Start signal is sent, so that data is read 3 clocks after the Instruction Start.

~~One~~Four Quad's worth of Texture Data may be written to the Register file every clock. These are directed to a different pixel of the sub-engines repeating every 4 clocks. The register file index to write must accompany the data. Data and Index associated with the Quad 0 must be sent 3 clocks after the Instruction Start signal is sent.

Name	Direction	Bits	Description
Tex_Read_Register_Index	SEQ->SP	8	Index into Register files for reading Texture Address
Tex_RegFile_Read_Data	SP->TEX	~~512~~2048	~~4~~ 16 Texture Addresses read from the Register file
Tex_Write_Register_Index	SEQ->TEX	8	Index into Register file for write of returned Texture Data

~~12.1.4~~14.1.12 *Sequencer to Texture Unit bus (Slow Bus)*

Formatted: Bullets and Numbering

Once every four clock, the texture unit sends to the sequencer on wich clause it is now working and if the data in the registers is ready or not. This way the sequencer can update the texture counters for the reservation station fifos. The sequencer also provides the intruction and constants for the texture fetch to execute and the address in the register file where to write the texture return data.

Name	Direction	Bits	Description
Tex_Ready	TEX→ SEQ	1	Data ready
Tex_Clause_Num	TEX→ SEQ	3	Clause number
Tex_cst	SEQ→TEX	~~?~~10	Texture ~~constants X~~state address 10 bits sent over 4 clocks
Tex_Inst	SEQ→TEX	~~?~~12	Texture fetch instruction ~~X~~address 12 bits sent over 4 clocks

~~12.1.5 *Shader Engine to RE/PA Bus*~~

Formatted: Bullets and Numbering

~~12.1.6 *PA? to sequencer*~~

~~13.~~15. Examples of program executions

~~13.1.1~~15.1.1 *Sequencer Control of a Vector of Vertices*

1. PA sends a vector of ~~16~~ 64 vertices (actually vertex indices – 32 bits/index for ~~512~~ 2048 bit total) to the RE's Vertex FIFO
   - state pointer as well as tag into position cache is sent along with vertices
   - space was allocated in the position cache for transformed position before the vector was sent
   - **also before the vector is sent to the RE, the CP has loaded the global instruction store with the vertex shader program (using the MH?)**
   - The vertex program is assumed to be loaded when we receive the vertex vector.
     - the SEQ then accesses the IS base for this shader using the local state pointer (provided to all sequencers by the RBBM when the CP is done loading the program)
2. SEQ arbitrates between the Pixel FIFO and the Vertex FIFO – basically the Vertex FIFO always has priority
   - at this point the vector is removed from the Vertex FIFO
   - the arbitrer is not going to select a vector to be transformed if the parameter cache is full unless the pipe as nothing else to do (ie no pixels are in the pixel fifo).
3. SEQ allocates space in the SP register file for index data plus GPRs used by the program
   - the number of GPRs required by the program is stored in a local state register, which is accessed using the state pointer that came down with the vertices
   - SEQ will not send vertex data until space in the register file has been allocated
4. SEQ sends the vector to the SP register file over the RE_SP interface (which has a bandwidth of ~~512~~ 2048 bits/cycle)
   - the ~~16~~ 64 vertex indices are sent to the ~~16~~ 64 register files over 4 cycles
     - RF0 of SU0, SU1, SU2, and SU3 is written the first cycle
     - RF1 of SU0, SU1, SU2, and SU3 is written the second cycle
     - RF2 of SU0, SU1, SU2, and SU3 is written the third cycle

    - RF3 of SU0, SU1, SU2, and SU3 is written the fourth cycle
  - the index is written to the least significant 32 bits **(floating point format?) (what about compound indices)** of the 128-bit location within the register file (w); the remaining data bits are set to zero (x, y, z)

5. SEQ constructs a control packet for the vector and sends it to the first reservation station (the FIFO in front of texture state machine 0, or TSM0 FIFO)
   - the control packet contains the state pointer, the tag to the position cache and a register file base pointer.
6. TSM0 accepts the control packet and fetches the instructions for texture clause 0 from the global instruction store
   - TSM0 was first selected by the TSM arbiter before it could start
7. all instructions of texture clause 0 are issued by TSM0
8. the control packet is passed to the next reservation station (the FIFO in front of ALU state machine 0, or ASM0 FIFO)
   - TSM0 does not wait for requests made to the Texture Unit to complete; it passes the register file write index for the texture data to the TU, which will write the data to the RF as it is received
   - once the TU has written all the data to the register files, it increments a counter that is associated with ASM0 FIFO; a count greater than zero indicates that the ALU state machine can go ahead start to execute the ALU clause
9. ASM0 accepts the control packet (after being selected by the ASM arbiter) and gets the instructions for ALU clause 0 from the global instruction store
10. all instructions of ALU clause 0 are issued by ASM0, then the control packet is passed to the next reservation station (the FIFO in front of texture state machine 1, or TSM1 FIFO)
11. the control packet continues to travel down the path of reservation stations until all clauses have been executed
    - position can be exported in ALU clause 3 (or 4?); the data (and the tag) is sent over a position bus (which is shared with all four shader pipes) back to the PA's position cache
    - A parameter cache pointer is also sent along with the position data. This tells to the PA where the data is going to be in the parameter cache.
      - there is a position export FIFO in the SP that buffers position data before it gets sent back to the PA
      - the ASM arbiter will prevent a packet from starting an exporting clause if the position export FIFO is full
    - parameter data is exported in clause 7 (as well as position data if it was not exported earlier)
      - parameter data is sent to the Parameter Cache over a dedicated bus
      - the SEQ allocates storage in the Parameter Cache, and the SEQ deallocates that space when there is no longer a need for the parameters (it is told by the PA when using a token).
      - the ASM arbiter will prevent a packet from starting on ASM7 if the parameter cache (or the position buffer if position is being exported) is full
12. after the shader program has completed, the SEQ will free up the GPRs so that they can be used by another shader program

~~13.1.2~~15.1.2 *Sequencer Control of a Vector of Pixels*

Formatted: Bullets and Numbering

1. **As with vertex shader programs, pixel shaders are loaded into the global instruction store by the CP**
   - At this point it is assumed that the pixel program is loaded into the instruction store and thus ready to be read.

~~2.the RE's Parameter Buffer is loaded from the Parameter Cache before the SEQ takes control of the vector~~

- ~~after the HZ culling stage a request is made by the RE to send parameter data to the Parameter buffer~~
- ~~the Parameter buffer is wide enough to source 3 vertices worth of a particular parameter in one cycle~~
- ~~**at this moment the right sequencer will free up the parameter store locations not used anymore using the token provided by the PA**.~~

Formatted: Bullets and Numbering

~~3.~~2. the RE's Pixel FIFO is loaded with the barycentric coordinates for pixel quads by the detailed walker
   - the state pointer and the LOD correction bits are also placed in the Pixel FIF0
   - the Pixel FIFO is wide enough to source ~~one~~ four quad's worth of barycentrics per cycle

Formatted: Bullets and Numbering

~~4.~~3. SEQ arbitrates between Pixel FIFO and Vertex FIFO – when there are no vertices pending OR there is no space left in the register files for vertices, the Pixel FIFO is selected

~~5.~~4. SEQ allocates space in the SP register file for all the GPRs used by the program

- the number of GPRs required by the program is stored in a local state register, which is accessed using the state pointer
- SEQ will not allow interpolated data to be sent to the shader until space in the register file has been allocated

~~6.SEQ control starts with the interpolation of parameters (up to 16 per thread) by sending the barycentric coordinates from the Pixel FIFO and the parameters from the Parameter Buffer to the interpolator~~

Formatted: Bullets and Numbering

- ~~P0i, P0j, and P0k (the value of P0 at each vertex) are loaded into the interpolator from the Parameter buffer~~
- ~~Q0 i, j, and k are loaded into the interpolator from the Pixel FIFO~~
- ~~The interpolator then generates the parameter value for each pixel in Q0 (Q0P0)~~
- ~~**P0i, P0j, and P0k are sent to the interpolator for Q1 only if Q1 is from a different primitive; if Q1 is from the same primitive as Q0, then the P0i, P0j, and P0k values loaded for Q0 are held by the interpolator and reused for Q1**~~
  - ~~**a "different_prim" control bit is passed with the barycentric data for each quad in the Pixel FIFO that indicates whether new parameter data needs to be loaded into the interpolator**~~
- ~~Q1 i, j, and k are then loaded into the interpolator from the Pixel FIFO~~
- ~~The interpolator then generates the parameter value for each pixel in Q1 (Q1P0)~~
- ~~Q2P0 and Q3P0 are generated in a similar manner~~
- ~~The next set of parameter data - P1i, P1j, and P1k - is then loaded into the interpolator~~
- ~~Q0 i, j, and k now must be re-read from the Pixel FIFO – this means that the output of the Pixel FIFO loops through the top four entries on each read command until at the end a final "block_pop" signal is asserted, causing the top four sets of barycentric coordinates to finally be removed~~
- ~~so the order of parameter info generated is Q0P0, Q1P0, Q2P0, Q3P0, Q0P1, Q1P1, etc.~~

~~7.~~5. SEQ controls the transfer of interpolated data to the SP register file over the RE_SP interface (which has a bandwidth of ~~512~~ 2048 bits/cycle). See interpolated data bus diagrams for details.

- ~~16 pixels worth of interpolated parameter data is sent to the 16 register files over 4 cycles~~
  - ~~RF0 of SU0, SU1, SU2, and SU3 is written with Q0P0 the first cycle~~
  - ~~RF1 of SU0, SU1, SU2, and SU3 is written with Q1P0 second cycle~~
  - ~~RF2 of SU0, SU1, SU2, and SU3 is written with Q2P0 third cycle~~
  - ~~RF3 of SU0, SU1, SU2, and SU3 is written with Q3P0 fourth cycle~~

~~8.~~6. SEQ constructs a control packet for the vector and sends it to the first reservation station (the FIFO in front of texture state machine 0, or TSM0 FIFO)

- note that there is a separate set of reservation stations/arbiters/state machines for vertices and for pixels
- the control packet contains the state pointer, the register file base pointer, and the LOD correction bits
- all other informations (such as quad address for example) travels in a separate FIFO

~~9.~~7. TSM0 accepts the control packet and fetches the instructions for texture clause 0 from the global instruction store

Formatted: Bullets and Numbering

- TSM0 was first selected by the TSM arbiter before it could start

~~10.~~8. all instructions of texture clause 0 are issued by TSM0

Formatted: Bullets and Numbering

~~11.~~9. the control packet is passed to the next reservation station (the FIFO in front of ALU state machine 0, or ASM0 FIFO)

- TSM0 does not wait for texture requests made to the Texture Unit to complete; it passes the register file write index for the texture data to the TU, which will write the data to the RF as it is received
- once the TU has written all the data for a particular clause to the register files, it increments a counter that is associated with the ASM0 FIFO; a count greater than zero indicates that the ALU state machine can go ahead and pop the FIFO and start to execute the ALU clause

~~12.~~10. ASM0 accepts the control packet (after being selected by the ASM arbiter) and gets the instructions for ALU clause 0 from the global instruction store

Formatted: Bullets and Numbering

~~13.~~11. all instructions of ALU clause 0 are issued by ASM0, then the control packet is passed to the next reservation station (the FIFO in front of texture state machine 1, or TSM1 FIFO)

~~14.~~12. the control packet continues to travel down the path of reservation stations until all clauses have been executed

- pixel data is exported in the last ALU clause (clause 7)
  - it is sent to an output FIFO where it will be picked up by the render backend
  - the ASM arbiter will prevent a packet from starting on ASM7 if the output FIFO is full

~~15.~~13. after the shader program has completed, the SEQ will free up the GPRs so that they can be used by another shader program

Formatted: Bullets and Numbering

~~13.1.3~~15.1.3 *Notes*

Formatted: Bullets and Numbering

~~16.~~14. the state machines and arbitrers will operate ahead of time so that they will be able to immediately start the real threads or stall.

~~17.~~15. the register file base pointer for a vector needs to travel with the vector through the reservation stations, but the instruction store base pointer does not – this is because the RF pointer is different for all threads, but the IS pointer is only different for each state and thus can be accessed via the state pointer

16. Waterfalling, parameter buffer allocation, loops and branches and parameter cache de-allocation still needs to be specked out.

Timing Diagram 3: Sequencer - Texture Unit Interface and Texture Unit - Shader Pipe Data Transfer

~~14.4 Timing diagrams explanations~~

Formatted: Bullets and Numbering

~~The numbering of the four shader pipes, the four shader units, and the four MACs is from left to right and from 0 to 3. So for example the most significant 512 bits of a SP goes to SU0 and the least significant 512 bits go to SU3; within SU0, the most significant 128 bits go to MAC0 and the least significant 128 bits go to MAC3.~~
~~The following assumptions are made:~~

~~1.all block to block signals are register to register~~

Formatted: Bullets and Numbering

~~2.for register file reads, the RF read data is available in the MAC one clock after a RF read address is registered into the MAC (this is the same as saying the read data is valid out of the RF two clocks after the address is asserted on the SEQ to SP interface)~~

~~14.4.1 *Timing Diagram 1: Sequencer to Shader Pipe 0, Shader Unit 0, MAC 0*~~

~~This diagram shows the basics of the Sequencer to Shader Pipe interface. For simplicity only the timing relative to MAC0 is shown. The timing for MAC1 is one clock later than MAC0, MAC2 one clock later than MAC1, etc. This means that most of the signals need to be delayed in the SP by one cycle for MAC1, two cycles for MAC2, and three cycles for MAC3.~~
~~**SEQ_SP_constant0**: Constant 0 (128 bits over 4 cycles). Pipelined in SP for other MACs.~~
~~**SEQ_SP_constant1**: Constant 1 (128 bits over 4 cycles). Pipelined in SP for other MACs.~~
~~**SEQ_SP_read_addr**: Register File Read Address (8 bits). Pipelined in SP for other MACs.~~
~~**SEQ_SP_phase**: This signal syncs the data transfer to the RF from the RE, as well as defining the order of all writes into the RF. It is asserted during the cycle that interpolated data (ID) is valid on the RE_SP_ID bus. Pipelined in SP for other MACs.~~
~~**RE_SP_ID[511:384]**: This is the most significant 128 bits of the RE_SP_data interface (meaning that this MAC0 is in SU0).~~
~~**SEQ_SP_instruction**: 96 bits of instruction are sent over 4 cycles. Pipelined in SP for other MACs.~~
~~**SEQ_SP_instr_start**: control bit that signals the first cycle of the instruction transfer. Pipelined in SP for other MACs.~~
~~**mac0_phase**: registered version of SEQ_SP_phase used in MAC0 (this may not be he actual signal name).~~
~~**mac0_cycle_count**: a counter inside the MAC that keeps track of the RF write cycles; 0 here corresponds to the cycle RE interpolated data is written (this may not be he actual signal name).~~
~~**RF0_read_data**: data that is read out of MAC0's register file (this may not be he actual signal name).~~
~~**mac0_vector_result**: the 32-bit output of the vector ALU (PV is built up over 4 cycles) (this may not be he actual signal name).~~
~~**SEQ_SP_write_addr**: Register File Write Address (8 bits). Note that the SEQ does not send the Texture Data write address over this bus. Pipelined in SP for other MACs.~~
~~**RF0 write cycle**: the cycles allocated to the different write sources (ID = Interpolated Data, TD = Texture Data, PV = Previous Vector, PS = Previous Scalar) (not a signal – just a reference point on the diagram).~~

~~14.4.2 *Timing Diagram 2: RE Interpolator to Shader Pipe Data Transfer*~~

Formatted: Bullets and Numbering

~~This diagram shows how pixel data (barycentric coordinates i, j, and k) is sent from the Pixel FIFO to the interpolator under SEQ control, and how parameter data (for each vertex) is also sent to the interpolator under SEQ control. The output of the Interpolator is then shown being sent over the RE_SP interface.~~
~~**PXF_SEQ_rts**: Indicates that the output of the pixel FIFO is valid.~~
~~**PXF_SEQ_new_prim**: The current output of the Pixel FIFO is from a different primitive that the previous output. Tells the SEQ that new parameter info must be fetched (if its not from a new prim, then new parameter data is not needed).~~
~~**PXF_INT_data**: Data output of the Pixel FIFO – goes to the Interpolator.~~
~~**SEQ_PXF_rtr**: Indicates that the current Pixel FIFO output will be taken by the Interpolator (driven by SEQ). Then next quad of data will be driven the next cycle.~~
~~**SEQ_PXF_vector_pop**: SEQ tells the Pixel FIFO to pop a vector of pixels (otherwise RTRs cause the data to be cycled between the four quads).~~

~~**PMB_INT_data**: Data from the Parameter Buffer to the Interpolator. (Note that the control of the parameter buffer is TBD).~~

~~**SEQ_INT_pm_load**: controls the loading of parameter data into the Interpolator.~~

~~**INT_param_reg**: register in the Interpolator that holds the per-vertex parameter data while the per-pixel parameters are generated for one or more quads (may not be the actual signal name).~~
~~**SEQ_INT_px_load**: controls the loading of pixel data into the Interpolator.~~
~~**INT_quad_reg**: : register in the Interpolator that holds one quad's worth of pixel data(may not be the actual signal name).~~

~~**SEQ_SP_phase**: see above under TD1.~~
~~**SEQ_SP_write_addr**: see above under TD1.~~
~~**RE_SP_valid**: Interpolator Data Valid – indicates that the SP should write the ID on the appropriate cycle.~~
~~**RE_SP_data**: Data from the RE interpolator to the SP.~~
~~**RF0 write cycle**: see above under TD1.~~
~~**mac*_phase**: see above under TD1. These phase signals help to show the timing offset between the MACs. Note also that each Shader Unit has a set of these signals (all with the same timing).~~

~~14.4.3 *Timing Diagram 3: Sequencer - Texture Unit Interface and Texture Unit - Transfer*~~

Formatted: Bullets and Numbering

~~This diagram starts with the texture coordinate read from the register file and its transfer to the TX.   The instruction transfer is then shown, followed by the texture data transfer to the shader pipe.~~
~~**SEQ_SP_read_addr**: see above. Here shows the cycle that the texture coordinate read address is asserted.~~
~~**RF0_read_addr**: see above.~~
~~**SP_TX_tc**: Texture coordinate data sent from the shader pipe to the texture unit.~~
~~**SEQ_TX_instr_start**: Asserted on the first cycle of a SEQ to TX instruction transfer.~~
~~**SEQ_TX_instruction**: 96 bits of texture instruction transferred over 4 cycles.~~
~~**SEQ_TX_clause**: the clause number associated with this instruction.~~
~~**SEQ_TX_write_addr**: RF write index used by TX for returned texture data.~~
~~**SEQ_TX_last**: indicates that this is the last texture instruction of a clause.~~
~~**SEQ_TX_phase**: syncs the texture data write. Note that it is asserted early enough to be registered into TX and still allow TX to source the texture data to the SP on the correct cycle.~~

~~**tx_phase**: the phase signal after being registered into TX.~~
~~**TX_SP_write_addr**: RF write index for texture data.~~
~~**TX_SP_valid**: indicates that valid texture data is being driven to the SP.~~
~~**TX_SP_data**: the texture data.~~
~~**TX_SEQ_clause**: the clause number associated with the texture data.~~
~~**TX_SEQ_done**: indicates to the SEQ that the texture data transfer is complete for the clause number that is on the TX_SEQ_clause bus.~~

~~**SEQ_SP_phase**: see above under TD1 - shown here for reference.~~
~~**SEQ_SP_write_addr**: see above under TD1- shown here for reference.~~
~~**RF0 write cycle**: see above under TD1- shown here for reference.~~

~~15.~~16. Open issues

Formatted: Bullets and Numbering

There is currently an issue with constants. If the constants are not the same for the whole vector of vertices, we don't have the bandwith from the texture store to feed the ALUs. Two solutions exists for this problem:

1) Let the compiler handle the case and put those instructions in a texture clause so we can use the bandwith there to operate. This requires a significant amount of temporary storage in the register store.
2) Waterfall down the pipe allowing only at a given time the vertices having the same constants to operate in parrallel. This might in the worst case slow us down by a factor of 16.

Need to do some testing on the size of the register file as well as on the register file allocation method (dynamic VS static).

Saving power?

Size of the fifo containing the information of a vector of pixels/vertices. And size of the fifos before the reservation stations.

Sequencer Instruction memory, and constant memory.

Arbitration policy for the output file.

Loops and branches.

The parameter cache may end up in the PA rather than in the RS. Parameter cache management thus may change.

R400 Sequencer Specification

SEQ

Version 0.7~~5~~

Overview: This is an architectural specification for the R400 Sequencer block (SEQ). It provides an overview of the required capabilities and expected uses of the block. It also describes the block interfaces, internal sub-blocks, and provides internal state diagrams.

Revision Changes:

Rev 0.1 (Laurent Lefebvre) Date: May 7, 2001	First draft.
Rev 0.2 (Laurent Lefebvre) Date : July 9, 2001	Changed the interfaces to reflect the changes in the SP. Added some details in the arbitration section.
Rev 0.3 (Laurent Lefebvre) Date : August 6, 2001	Reviewed the Sequencer spec after the meeting on August 3, 2001.
Rev 0.4 (Laurent Lefebvre) Date : August 24, 2001	Added the dynamic allocation method for register file and an example (written in part by Vic) of the flow of pixels/vertices in the sequencer.
Rev 0.~~4~~ 5 (Laurent Lefebvre) Date : September 7, 2001	Added timing diagrams (Vic)
Rev 0.6 (Laurent Lefebvre) Date : September 24, 2001	Changed the spec to reflect the new R400 architecture. Added interfaces.
Rev 0.7 (Laurent Lefebvre) Date : October 5, 2001	Added constant store management, instruction store management, control flow management and data dependant predication.

1. Overview

The sequencer first arbitrates between vectors of ~~16~~ 64 vertices that arrive directly from primitive assembly and vectors of ~~4~~ 16 quads (~~16~~ 64 pixels) that are generated in the raster engine.

The vertex or pixel program specifies how many GPR's it needs to execute. The sequencer will not start the next vector until the needed space is available.

The sequencer is based on the R300 design. It chooses two ALU clauses and a texture clause to execute, and executes all of the instructions in a clause before looking for a new clause of the same type. Two ALU clauses are executed interleaved to hide the ALU latency. Each vector will have eight texture and eight ALU clauses, but clauses do not need to contain instructions. A vector of pixels or vertices ping-pongs along the sequencer FIFO, bouncing from texture reservation station to alu reservation station. A FIFO exists between each reservation stage, holding up vectors until the vector currently occupying a reservation station has left. A vector at a reservation station can be chosen to execute. The sequencer looks at all eight alu reservation stations to choose an alu clause to execute and all eight texture stations to choose a texture clause to execute. The arbitrator will give priority to clauses/reservation stations closer to the bottom of the pipeline. It will not execute an alu clause until the texture fetches initiated by the previous texture clause have completed. There are two separate sets of reservation stations, one for pixel vectors and one for vertices vectors. This way a pixel can pass a vertex and a vertex can pass a pixel.

To support the shader pipe the raster engine also contains the shader instruction cache and constant store. There are only one constant store for the whole chip and one instruction store. These will be shared among the four shader pipes. The four shader pipes also execute the same instuction thus there is only one sequencer for the whole chip.

There are two sets of the above figure, one for vertices and one for pixels.

The rasterizer always checks the vertices FIFO first and if allowed by the sequencer sends the data to the shader. If the vertex FIFO is empty then, the rasterizer takes the first entry of the pixel FIFO (a vector of ~~16~~ 64 pixels) and sends it to the interpolators. Then the sequencer takes control of the packet. The packet consists of ~~3~~ 21 bits of state, 6-7 bits for the base address of the Shader program and some information on the coverage to determine texture LOD. All other information (2x2 adresses) is put in a FIFO (one for the pixels and one for the vertices) and retrieved when the packet finishes its last clause.

On receipt of a packet, the input state machine (not pictured but just before the first FIFO) allocated enough space in the registers to store the interpolated values and temporaries. Following this, the input state machine stacks the packet in the first FIFO.

On receipt of a command, the level 0 texture machine issues a texure request and corresponding register address for the texture address (ta). A small command (tcmd) is passed to the texture system identifying the current level number (0) as well as the register write address for the texture return data. One texture request is sent every 4 clocks causing the texturing of ~~four~~ sixteen 2x2s worth of data (or ~~16~~ 64 vertices). Once all the requests are sent the packet is put in FIFO 1.

Upon recept of the return data, the texture unit writes the data to the register file using the write address that was provided by the level 0 texture machine and sends the clause number (0) to the level 0 texture state machine to signify that the write is done and thus the data is ready. Then, the level 0 texture machine increments the counter of FIFO 1 to signify to the ALU 1 that the data is ready to be processed.

On receipt of a command, the level 0 ALU machine first decrements the input FIFO counter and then issues a complete set of level 0 shader instructions. For each instruction, the state machine generates 3 source addresses, one destination address (3 cycles later) and an instruction. Once the last instruction as been issued, the packet is put into FIFO 2.

There will always be two active ALU clauses at any given time (and two arbitrers). One arbitrer will arbitrate over the odd clock cycles and the other one will arbitrate over the even clock cycles. The only constraints between the two arbitrers is that they are not allowed to pick the same clause number as they other one is currently working on if the packet os of the same type.

If the packet is a vertex packet, upon reaching ALU clause 4, it can export the position if the position is ready. So the arbitrer must prevent ALU clause 4 to be selected if the positional buffer is full (or can't be accessed). Along with the positional data, the location where the vertex data is to be put is also sent (parameter data pointers).

All other level process in the same way until the packet finally reaches the last ALU machine (8). On completion of the level 8 ALU clause, a valid bit is sent to the Render Backend which picks up the color data. This requires that the last instruction writes to the output register – a condition that is almost always true. If the packet was a vertex packet, instead of sending the valid bit to the RB, it is sent to the PA so it can know that the data present in the parameter store is valid.

Only two ALU state machine may have access to the register file address bus or the instruction decode bus at one time. Similarly, only one texture state machine may have access to the register file address bus at one time. Arbitration is performed by three arbitrer blocks (two for the ALU state machines and one for the texture state machines). The arbitrers always favor the higher number state machines, preventing a bunch of half finished jobs from clogging up the register files.

~~Each state machine maintains an address pointer specifying where the 16 entries vector is located in the register file (the texture machine has two pointers one for the read address and one for the write). Upon completion of its job, the address pointer is incremented by a predefined amount equal to the total number of registers required by the shading code. A comparison of the address pointer for the first state machine in the chain (the input state machine), and the last machine in the chain (the level 8 ALU machine), gives an indication of how much unallocated register file memory is available~~

				P0								P1								

Above is an example of a tile we might receive. The IJ information is packed in the IJ buffer 2 quads at a time. The sequencer allows at any given time as many as four quads to interpolate a parameter. They all have to come from the same primitive. Then the sequencer controls the write mask to the register to write the valid data in.~~Since each of the register file is actually physically divided (one 128x128 per MAC) and we don't have the place to hold a maximum size vector of vertices in the parameter buffer, we need to interpolate on a parameter basis rather than on a quad basis. So the order to the register file will be:~~

~~Q0P0 Q1P0 Q2P0 Q3P0 Q0P1 Q1P1 Q2P1 Q3P1 Q0P2 Q1P2 …~~

3. Instruction Store

There is going to be only one instruction store for the whole chip. It ~~may~~ will contain ~~up to 200~~4096~~0~~ instructions of 96 bits each. There is also going to be a control instruction store of size 256(512?)x32.

{ISSUE : The instruction store is loaded by the sequencer using the memory hub ?}.

The read bandwith from this store is ~~24~~ 96*2 bits/ 4 clocks (48 bits/clock)~~/pipe~~. ~~To achieve this this instruction store is likely to be broken up into 4 blocks. An ALU instruction section (1R/1W) split in two and a texture section (1R/1W) also split in two. The bandwith out of those memories is 96 bits/clock.~~It is likely to be a 1R/1W port memory; we use 2 clocks to load the ALU instruction and 2 clocks to load the Texture instruction.

Formatted: Bullets and Numbering

4. Sequencer Instructions

All control flow instructions and move instructions are handled by the sequencer only. The ALUs will perform NOPs during this time (MOV PV,PV, PS,PS).

Formatted: Bullets and Numbering

~~4.~~5. Constant Store

The constant store is managed by the CP. The sequencer is aware of where the constants are using a remaping table also managed by the CP. A likely size for the constant store is 512x128 bits. The constant store is also planned to be shared. The read BW from the constant store is 128~~512/4~~ bits/clock~~/pipe~~ and the write bandwith is 32/4 bits/clock.

In order to do constant store indexing, the sequencer must be loaded first with the indexes (that come from the GPRs). There are 144 wires from the exit of the SP to the sequencer (9 bits pointers x 16 vertexes/clock). Since the data must pass thru the Shader pipe for the float to fixed convertion, there is a latency of 4 clocks (1 instruction) between the time the sequencer is loaded and the time one can index into the constant store. The assembly will look like this

```
MOVA  R1.X,R2.X        // Loads the sequencer with the content of R2.X, also copies the content of R2.X into R1.X
NOP                    // latency of the float to fixed conversion
ADD   R3,R4,C0[R2.X]// Uses the state from the sequencer to add R4 to C0[R2.X] into R3
```

Note that we don't really care about what is in the brackets because we use the state from the MOVA instruction. R2.X is just written again for the sake of simplicity.

The storage needed in the sequencer in order to support this feature is 2*64*9 bits = 1152 bits.

Formatted: Bullets and Numbering

~~5.~~6. Looping and Branches

Loops and branches are planned to be supported and will have to be dealt with at the sequencer level. We plan on supporting constant loops and branches using a control program. The control program has 4(5) instructions:

Formatted: Bullets and Numbering

6.1 The controlling state.

As per Dx9 the following state is available for control flow:

Boolean[15:0]

loop_count[7:0][7:0]
In addition:
loop_start [7:0] [7:0]
loop_step [7:0] [7:0]
Exist to give more control to the controlling program.

We will extend that in the R400 to:
Boolean[31:0]
Loop_count[7:0][15:0]
Loop_Start[7:0] [15:0]
Loop_End[7:0] [15:0]

{ISSUE: How is the controlling state loaded and how many contexts do we have?}

Formatted: Bullets and Numbering

6.2 The Control Flow Program

The R300 uses a match method for control flow: The shader is executed, and at every instruction its address is compared with addresses (or address?) in a control table. The "event" in the control table can redirect operations in the program.

The Method chosen for the R400 is a "control program". The control program has four basic instructions:

Execute
Conditional_execute (Conditional Execute Predicates)
Loop_start
Loop_end

Execute, causes the specified number of instructions in instruction store to be executed.
Conditional_execute checks a condition first, and if true, causes the specified number of instructions in instruction store to be executed.
Loop_start resets the corresponding loop counter to the start value.
Loop_end increments (decrements?) the loop counter and jumps back the specified number of instructions if the loop end condition is not met.

if we try and fit the control flow instructions into 32 bit words, the following instructions are possible choices:

Execute																															
31	30	29	28	27	26	25	24	23	22	21	20	19	18	17	16	15	14	13	12	11	10	9	8	7	6	5	4	3	2	1	0
0	0	0	0	instruction_count												Reserved			Address												

Execute up to 4K instructions at the specified address in the instruction memory.

Conditional Execute																															
31	30	29	28	27	26	25	24	23	22	21	20	19	18	17	16	15	14	13	12	11	10	9	8	7	6	5	4	3	2	1	0
0	0	0	1	Boolean						0: = 0 1: = 1 2,3:NA			Instruction_count						Address												

if the specified boolean (6 bits can address 64 booleans) meets the specified condition then execute the specified instructions (up to 64 instructions)

Conditional Execute Predicates																															
31	30	29	28	27	26	25	24	23	22	21	20	19	18	17	16	15	14	13	12	11	10	9	8	7	6	5	4	3	2	1	0
0	1	0	1	Reserved =0						0: = 0 1: = 1 2,3:NA			Instruction_count						Address												

Check the OR of all current predicate bits. If OR matches the condition execute the specified number of instructions.

Loop_Start

31	30	29	28	27	26	25	24	23	22	21	20	19	18	17	16	15	14	13	12	11	10	9	8	7	6	5	4	3	2	1	0
0	0	1	0																								Loop ID				

Initialize the specified loop

Loop_End

31	30	29	28	27	26	25	24	23	22	21	20	19	18	17	16	15	14	13	12	11	10	9	8	7	6	5	4	3	2	1	0
0	0	1	1	Reserved (must = 0)												Start Address								Reserved (must = 0)			Loop ID				

If the loop condition of the current loop is not met, then branch back to the specified address in the control flow program. Note that jumping back to the loop_start results in an infinite loop, the jump should be to loop_start+1.

The way this is described does not prevent nested loops, and the inclusion of the loop id make this easy to do.

The basic model is as follows:

The render state defined the clause boundaries:
Vertex_shader_fetch[7:0][7:0] // eight 8 bit pointers to the location where each clauses control program is located
Vertex_shader_alu[7:0][7:0] // eight 8 bit pointers to the location where each clauses control program is located
Pixel_shader_fetch[7:0][7:0] // eight 8 bit pointers to the location where each clauses control program is located
Pixel_shader_alu[7:0][7:0] // eight 8 bit pointers to the location where each clauses control program is located

The control program can be up to 256 instructions in size. (There is an offset added to the address from the render state before accessing the control flow program memory to allow for multiple programs resident at the same time)

The control program for a given clause is executed to completion before moving to another clause, (with the exception of the pick two nature of the alu execution). The control program is the only program aware of the clause boundaries.

The addresses from the control program are added to another offset to allow for multiple programs resident at the same time.

Under this model, all subroutine calls must be inlined into the control program.

6.3 Data dependant predicate instructions

Formatted: Bullets and Numbering

Data dependant conditionals will be supported in the R400. The only way we plan to support those is by supporting three vector/scalar predicate operations of the form:

PRED_SETE - similar to SETE except that the result is 'exported' to the sequencer.
PRED_SETGT - similar to SETGT except that the result is 'exported' to the sequencer
PRED_SETGTE - similar to SETGTE except that the result is 'exported' to the sequencer

For the scalar operations only we will also support the two following instructions:
PRED_SETE0 – SETE0
PRED_SETE1 – SETE1

The export is a single bit - 1 or 0 that is sent using the same data path as the MOVA instruction. The sequencer will maintain the 64 bit predicate vector and use it to control the write masking (two sets for interleaved operation). This predicate is not maintained across clause boundaries.

Then we have two conditional execute bits. The first bit is a conditional execute "on" bit and the second bit tells us if we execute on 1 or 0. For exemple, the instruction :

P0_ADD R0,R1,R2

Is only going to write the result of the ADD into those GPRs whose predicate bit is 0. Alternatively, P1_ADD would only write the results to the GPRs whose predicate bit is set. The use of the P0 or P1 without precharging the sequencer with a PRED instruction is undefined.

{Issue: do we have to have a NOP between PRED and the first instruction that uses a predicate?}

Formatted: Bullets and Numbering

6.4 Register file indexing

Because we can have loops in texture clause, we need to be able to index into the register file in order to retrieve the data created in a texture clause loop and use it into an ALU clause. The instruction will include the base address for register indexing and the instruction will contain these controls :

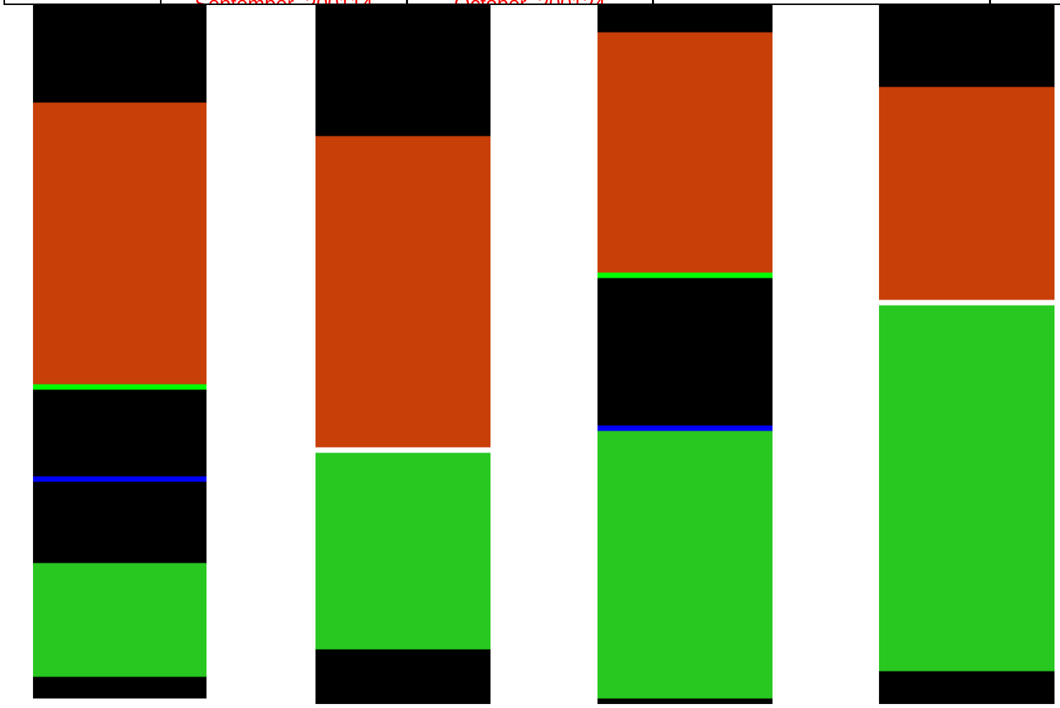
Bit7	Bit 6	
0	0	'absolute register'
0	1	'relative register'
1	0	'previous vector'
1	1	'previous scalar'

In the case of an absolute register we just take the address as is. In the case of a relative register read we take the base address and we add to it the loop counter and this becomes our new address that we give to the shader pipe.~~However, it is still unclear if we plan on supporting data dependent branches or not.~~

Formatted: Bullets and Numbering

~~6.~~7. Register file allocation

The register file allocation for vertices and pixels can either be static or dynamic. In both cases, the register file in managed using two round robins (one for pixels and one for vertices). In the dynamic case the boundary between pixels and vertices is allowed to move, in the static case it is fixed to VERTEX_REG_SIZE for vertices and 256-VERTEX_REG_SIZE for pixels.



Above is an example of how the algorithm works. Vertices come in from top to bottom; pixels come in from bottom to top. Vertices are in orange and pixels in green. The blue line is the tail of the vertices and the green line is the tail of the pixels. Thus anything between the two lines is shared. When pixels meets vertices the line turns white and the boundary is static until both vertices and pixels share the same "unallocated bubble". Then the boundary ~~as~~ is allowed to movi~~nge~~ again.

Formatted: Bullets and Numbering

~~7.~~8. Texture Arbitration

The texture arbitration logic chooses one of the 8 potentially pending texture clauses to be executed. The choice is made by looking at the fifos from 7 to 0 and picking the first one ready to execute. Once chosen, the clause state machine will send one 2x2 texture fetch per clock (or 4 fetches in one clock every 4 clocks) until all the texture fetch instructions of the clause are sent. This means that there cannot be any dependencies between two texture fetches of the same clause.

The arbitrator will not wait for the texture fetches to return prior to selecting another clause for execution. The texture pipe will be able to handle up to X(?) in flight texture fetches and thus there can be a fair number of active clauses waiting for their texture return data.

Formatted: Bullets and Numbering

~~8.~~9. ALU Arbitration

ALU arbitration proceeds in almost the same way than texture arbitration. The ALU arbitration logic chooses one of the 8 potentially pending ALU clauses to be executed. The choice is made by looking at the fifos from 7 to 0 and picking the first one ready to execute. There are two ALU arbitrers, one for the even clocks and one for the odd clocks. For exemple, here is the sequencing of two interleaved ALU clauses (E and O stands for Even and Odd):

Einst0 Oinst0 Einst1 Oinst1 Einst2 Oinst2 Einst0 Oinst3 Einst1 Oinst4 Einst2 Oinst0…
Proceeding this way hides the latency of 8 clocks of the ALUs.

~~9.~~10. Handling Stalls

Formatted: Bullets and Numbering

When the output file is full, the sequencer prevents the ALU arbitration logic to select the last clause (this way nothing can exit the shader pipe until there is place in the output file. If the packet is a vertex packet and the position buffer is full (POS_FULL) then the sequencer also prevents a thread to enter the exporting clause (4?). The sequencer will set the OUT_FILE_FULL signal n clocks before the output file is actually full and thus the ALU arbitrer will be able read this signal and act accordingly by not preventing exporting clauses to proceed.

~~10.~~11. Content of the reservation station FIFOs

Formatted: Bullets and Numbering

3 bits of Render State 6-7 bits for the base address of the instruction store, ~~and~~ some bits for LOD correction and coverage mask information in order to fetch texture for only valid pixels. Every other information (such as the coverage mask, quad address, etc.) is put in a FIFO and is retrieved when the quad exits the shader pipe to enter in the output file buffer. Since pixels and vertices are kept in order in the shader pipe, we only need two fifos (one for vertices and one for pixels) deep enough to cover the shader pipe latency. This size will be determined later when we will know the size of the small fifos between the reservation stations.

~~11.~~12. The Output File

Formatted: Bullets and Numbering

The output file is where pixels are put before they go to the RBs. The write BW to this store is 256 bits/clock. Just before this output file are staging registers with write BW 512 bits/clock and read BW 256 bits/clock. For this reason only ONE concurrent program can be of clause 8 (exporting clause) the other program MUST not. The staging registers are 4x128 (and there are 16 of those on the whole chip).

13. IJ Format

Formatted: Bullets and Numbering

The IJ information sent by the PA is of this format on a per quad basis:

We have a vector of IJ's (one IJ per pixel at the centroid of the fragment or at the center of the pixel depending on the mode bit). The interpolation is done at a different precision across the 2x2. The upper left pixel's parameters are always interpolated at full 24x24 mantissa precision. Then the result of the interpolation along with the difference in IJ in reduced precision is used to interpolate the parameter for the other three pixels of the 2x2. Here is how we do it:

Assuming P0 is the interpolated parameter at Pixel 0 having the barycentric coordinates I(0), J(0) and so on for P1,P2 and P3. Also assuming that A is the parameter value at V0 (interpolated with I), B is the parameter value at V1 (interpolated with J) and C is the parameter value at V2 (interpolated with (1-I-J).

$$\begin{aligned}
\Delta 01I &= I(1) - I(0) \\
\Delta 01J &= J(1) - J(0) \\
\Delta 02I &= I(2) - I(0) \\
\Delta 02J &= J(2) - J(0) \\
\Delta 03I &= I(3) - I(0) \\
\Delta 03J &= J(3) - J(0)
\end{aligned}$$

P0	P1
P2	P3

$$\begin{aligned}
P0 &= C + I(0)*(A - C) + J(0)*(B - C) \\
P1 &= P0 + \Delta 01I*(A - C) + \Delta 01J*(B - C) \\
P2 &= P0 + \Delta 02I*(A - C) + \Delta 02J*(B - C) \\
P3 &= P0 + \Delta 03I*(A - C) + \Delta 03J*(B - C)
\end{aligned}$$

P0 is computed at full 24x24 mantissa precision and P1 to P3 are computed at 8X24 mantissa precision. So far no visual degradation of the image was seen using this scheme.

Multiplies (Full Precision): 2
Multiplies (Reduced precision): 6
Subtracts 24x24 yielding 8 bits (IJs): 6
Subtracts 24x24 (Parameters): 2
Adds: 8

FORMAT OF P0's IJ : Mantissa 23 Exp 4 for I
Mantissa 23 Exp 4 for J

FORMAT of Deltas (x3): Mantissa 8 Exp 4 for I
Mantissa 8 Exp 4 for J

Total number of bits : 23*2 + 8*6 + 4*8 = 126 (rounded up on the bus to 128)

Formatted: Bullets and Numbering

14. The parameter cache

The parameter cache is where the vertex shaders export their data. It consists of 16 128x128 memories (1R/1W). The reuse engine will make it so that all vertexes of a given primitive will hit different memories.~~(RB FIFO and Parameter Cache)~~

Formatted: Bullets and Numbering

15. ~~The output file is where program results are exported when the pixel/vertex shader finishes. It constists of a 512x128 memory cell that is statically divided between pixels and vertices. The output file has 1 write port and 1 read port. The sequencer is responsible for managing the addresses of this output file and for stalling the shader pipe should this output file fill up. The management is done by keeping the tail and head pointers of each sections (pixels and vertices) and incrementing them using a simple RoundRobin allocation policy. The sequencer must also arbitrate between the PA and the RB for the use of the read port. This arbitration will either be priority based or just interleaved evenly (1 read every 2 clocks for each of the blocks).~~Vertex position exporting

On clause 4 (or 5) the vertex shader can export to the PA both the vertex position and the point sprite. It can also do so at clause 8 if not done at clause 4. The export is done by putting the exported position back into the GPRs. Then using the texture port in an opportunistic manner, 16 positions are put into a FIFO (16x128) in order (left to right). This fifo drains 128 bits per clock to the PA and once empty is filled up again with sprite sizes (if any). The process is repeated 4 times. The sequencer must make sure that the program doesn't enter ALU clause 5 (it can enter texture clause 5) because the registers can be reused at this point. The sequencer must also make sure not to dealocate an exporting program before it is done exporting data. Along with the position is exported a pointer to the parameter cache where the data will be once the vertex shader exports.

Formatted: Bullets and Numbering

16. Registers

DYNAMIC_REG	Dynamic allocation (pixel/vertex) of the register file on or off.
VERTEX_REG_SIZE	What portion of the register file is reserved for vertices (static allocation only)
PIXEL_MIN_SIZE	Minimal size of the register file's pixel portion (dynamic only)
VERTEX_MIN_SIZE	Minimal size of the register file's vertex portion (dynamic only)
Vshader_fetch[7:0][7:0]	eight 8 bit pointers to the location where each clauses control program is located
Vshader_alu[7:0][7:0]	eight 8 bit pointers to the location where each clauses control program is located
Pshader_fetch[7:0][7:0]	eight 8 bit pointers to the location where each clauses control program is located

Pshader_alu[7:0][7:0]	eight 8 bit pointers to the location where each clauses control program is located
PSHADER	base pointer for the pixel shader
VSHADER	base pointer for the vertex shader
PCNTLSHADER	base pointer for the pixel control program
VCNTLSHADER	base pointer for the vertex control program
VWRAP	wrap point for the vertex shader instruction store
PWRAP	wrap point for the pixel shader instruction store
REG_ALLOC_PIX	number of registers to allocate for pixel shader programs
REG_ALLOC_VERT	number of registers to allocate for vertex shader programs
PARAM_MASK[0…16]	parameter mask to specify wich parameters the pixel shader
FLAT_GOUR[0…16]	wich parameters are to be gouraud shaded
GEN_TEX[0….16]	for wich parameters do we need to generate tex coords.
CYL_WRAP[0…64]	for wich vertices do we do the cyl wrapping.
P_EXPORT	number of exports for pixel shader
V_EXPORT	number of exports for vertex shader (also the number of interpolated parameters for pixel shaders)
V_EXPORT_LOC	Vertex shader exporting to RB or the PCACHE

Formatted: Bullets and Numbering

~~12.~~17. Interfaces

~~12.1~~17.1 External Interfaces

~~12.1.1~~17.1.1 *~~Sequencer to Shader Engine Bus~~PA/SC to RE : IJ bus*

~~This is a bus that sends the instruction and constant data to all 4 Sub-Engines of the Shader. Because a new instruction is needed only every 4 clocks, the width of the bus is divided by 4 and both constants and instruction are sent over those 4 clocks.~~ This is a bus that sends the IJ information to the IJ fifos on the top of each shader pipe. At the same time the control information goes to the sequencer

Name	Direction	Bits	Description
~~Instruction Start~~IJs	~~SEQ->SP~~PA→RE	~~1~~64	~~High on first cycle of transfer~~IJ information sent over 2 clocks

Formatted: Bullets and Numbering

~~12.1.2~~

~~12.1.2Shader Engine to Output File~~

~~Every clock each Sub-Engine can output 128 bits of 'vector' data and 32 bits of 'scalar' data to an output file (?). This data will be compressed into 128 bits total prior to storage in output file.~~

Formatted: Bullets and Numbering

17.1.2 *PA/SC to SEQ : IJ Control bus*

This is the control information sent to the sequencer in order to control the IJ fifos and all other information needed to execute a shader program on the sent pixels.

Name	Direction	Bits	Description
Write Mask	PA→SEQ(RE)	4	Quad Write mask left to right
RB_ID	PA→SEQ(RE)	8	RB id for each quad sent 2 bits per quad
LOD_CORRECT	PA→SEQ(RE)	24	LOD correction per quad (6 bits per quad)
FVTX	PA→SEQ(RE)	2	Provoking vertex for flat shading
PPTR0	PA→SEQ(RE)	11	P Store pointer for vertex 0
PPRT1	PA→SEQ(RE)	11	P Store pointer for vertex 1
PPTR2	PA→SEQ(RE)	11	P Store pointer for vertex 2
E_OFF_VECTOR	PA→SEQ(RE)	1	End of the vector

DEALLOC	PA→SEQ(RE)	1	Deallocation token for the P Store
STATE	PA→SEQ(RE)	21	State/constant pointer (6*3+3)
SPRITE	PA→SEQ(RE)	1	Need to generate tex cords
VALID	PA→SEQ(RE)	16	Valid bits for all pixels
NULL	PA→SEQ(RE)	1	Null Primitive (for PC deallocation purposes)
E_OFF_PRIM	PA→SEQ(RE)	1	End Of the primitive
FBFACE	PA→SEQ(RE)	1	Front face = 1, back face = 0
STIPPLE_LINE	PA→SEQ(RE)	1	Stippled line need to load tex cords from alternate buffer
RTRn	SEQ→PA	1	Stalls the PA in n clocks
RTS	PA→SEQ(RE)	1	PA ready to send data
QuadX	PA→SEQ(RE)	40	Quad X address 10 bits per quad
QuadY	PA→SEQ(RE)	40	Quad Y address 10 bits per quad

17.1.3 *PA/SC to RE : Vertex Bus*

Formatted: Bullets and Numbering

Name	**Direction**	**Bits**	**Description**
Vertex indexes	PA→RE	32	Pointers of indexes

17.1.4 *PA/SC to SEQ : Vertex Control Bus*

Formatted: Bullets and Numbering

Name	**Direction**	**Bits**	**Description**
STATE	PA→SEQ	21	Render State (6*3+3 for constants)
Position Cache Pointer	PA→SEQ	7	Pointer to the position cache
Write Mask	PA→SEQ	64?	Which vertices are valid
E_OFF_VECTOR	PA→SEQ	1	End of the vector

17.1.5 *CP to SEQ : Constant store load*

Formatted: Bullets and Numbering

Name	**Direction**	**Bits**	**Description**
Constant Address	CP→SEQ	8	Address of the block of 4 constants
Constant Data	CP→SEQ	512	Data sent over 4 clocks
Remap Address	CP→SEQ	10	Remaping address write address
Remap Data pointer	CP→SEQ	8	Remaping pointer

17.1.6 *CP to SEQ : Texture State store load*

Formatted: Bullets and Numbering

Name	**Direction**	**Bits**	**Description**
Constant Address	CP→SEQ	8	Address of the block of 4 state constants
Constant Data	CP→SEQ	512	Data sent over 4 clocks
Remap Address	CP→SEQ	10	Remaping address write address
Remap Data pointer	CP→SEQ	8	Remaping pointer

17.1.7 *CP to SEQ : Control State store load*

Formatted: Bullets and Numbering

Name	**Direction**	**Bits**	**Description**

{ISSUE: How,Who and what is the size of this bus?}

17.1.8 *MH to SEQ: Instruction store Load*

Formatted: Bullets and Numbering

Name	**Direction**	**Bits**	**Description**
Instruction address	MH→SEQ	12	Instruction address
Instruction	MH→SEQ	96	Instruction X times
Control Instruction address	MH→SEQ	9	Pointer to the control instruction store
Control Instruction	MH→SEQ	32	Control Instruction X times

17.1.9 SP to RB : Pixel read from RBs

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
Pixel Data	SP→RB	256	2 pixels (or ½ quad)
Quad Address	SP→RB	20	XY address 10 bits per

Only one exporting clause (7) can be selected at any given time.

17.1.10 SP to PA/SC : Position return bus

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
Position return	SP→PA	128	Position data or sprite size
Position Buffer pointer	SP→PA	7	Pointer to the position cache
Parameter cache pointer	SP→PA	11	Pointer where the data will be in the parameter cache

For point sprites and position exports the size and position are interleaved on a 16 x 16 basis. We export 16 positions then 16 point sprite sizes. The registers are taken until the next ALU clause where they are going to be available again. Thus the sequencer has to make sure that we finished exporting data before allowing the program in the next ALU clause.

~~12.1.3~~17.1.11 Shader Engine to Texture Unit Bus (Fast Bus)

Formatted: Bullets and Numbering

~~One~~ Four quad's worth of addresses is transferred to Texture Unit every clock. These are sourced from a different pixel within each of the sub-engines repeating every 4 clocks. The register file index to read must precede the data by 2 clocks. The Read address associated with Quad 0 must be sent 1 clock after the Instruction Start signal is sent, so that data is read 3 clocks after the Instruction Start.

~~One~~Four Quad's worth of Texture Data may be written to the Register file every clock. These are directed to a different pixel of the sub-engines repeating every 4 clocks. The register file index to write must accompany the data. Data and Index associated with the Quad 0 must be sent 3 clocks after the Instruction Start signal is sent.

Name	Direction	Bits	Description
Tex_Read_Register_Index	SEQ->SP	~~8~~7	Index into Register files for reading Texture Address
Tex_RegFile_Read_Data	SP->TEX	~~512~~2048	~~4~~ 16 Texture Addresses read from the Register file
Tex_Write_Register_Index	SEQ->TEX	~~8~~7	Index into Register file for write of returned Texture Data

~~12.1.4~~17.1.12 Sequencer to Texture Unit bus (Slow Bus)

Formatted: Bullets and Numbering

Once every four clock, the texture unit sends to the sequencer on wich clause it is now working and if the data in the registers is ready or not. This way the sequencer can update the texture counters for the reservation station fifos. The sequencer also provides the intruction and constants for the texture fetch to execute and the address in the register file where to write the texture return data.

Name	Direction	Bits	Description
Tex_Ready	TEX→ SEQ	1	Data ready
Tex_Clause_Num	TEX→ SEQ	3	Clause number
Tex_cst	SEQ→TEX	~~?~~10	Texture ~~constants X~~state address 10 bits sent over 4 clocks
Tex_Inst	SEQ→TEX	~~?~~12	Texture fetch instruction ~~X~~address 12 bits sent over 4 clocks
EO_CLAUSE	SEQ→TEX	1	Last instruction of the clause
PHASE	SEQ→TEX	1	Write phase signal

Formatted: Bullets and Numbering

18. Internal interfaces

~~12.1.5 *Shader Engine to RE/PA Bus*~~

~~12.1.6 *PA? to sequencer*~~

~~13.~~19. Examples of program executions

~~13.1.1~~19.1.1 *Sequencer Control of a Vector of Vertices*

1. PA sends a vector of ~~16~~ 64 vertices (actually vertex indices – 32 bits/index for ~~512~~ 2048 bit total) to the RE's Vertex FIFO
   - state pointer as well as tag into position cache is sent along with vertices
   - space was allocated in the position cache for transformed position before the vector was sent
   - **also before the vector is sent to the RE, the CP has loaded the global instruction store with the vertex shader program (using the MH?)**
   - The vertex program is assumed to be loaded when we receive the vertex vector.
     - the SEQ then accesses the IS base for this shader using the local state pointer (provided to all sequencers by the RBBM when the CP is done loading the program)
2. SEQ arbitrates between the Pixel FIFO and the Vertex FIFO – basically the Vertex FIFO always has priority
   - at this point the vector is removed from the Vertex FIFO
   - the arbitrer is not going to select a vector to be transformed if the parameter cache is full unless the pipe as nothing else to do (ie no pixels are in the pixel fifo).
3. SEQ allocates space in the SP register file for index data plus GPRs used by the program
   - the number of GPRs required by the program is stored in a local state register, which is accessed using the state pointer that came down with the vertices
   - SEQ will not send vertex data until space in the register file has been allocated
4. SEQ sends the vector to the SP register file over the RE_SP interface (which has a bandwidth of ~~512~~ 2048 bits/cycle)
   - the ~~16~~ 64 vertex indices are sent to the ~~16~~ 64 register files over 4 cycles
     - RF0 of SU0, SU1, SU2, and SU3 is written the first cycle
     - RF1 of SU0, SU1, SU2, and SU3 is written the second cycle
     - RF2 of SU0, SU1, SU2, and SU3 is written the third cycle
     - RF3 of SU0, SU1, SU2, and SU3 is written the fourth cycle
   - the index is written to the least significant 32 bits **(floating point format?) (what about compound indices)** of the 128-bit location within the register file (w); the remaining data bits are set to zero (x, y, z)
5. SEQ constructs a control packet for the vector and sends it to the first reservation station (the FIFO in front of texture state machine 0, or TSM0 FIFO)
   - the control packet contains the state pointer, the tag to the position cache and a register file base pointer.
6. TSM0 accepts the control packet and fetches the instructions for texture clause 0 from the global instruction store
   - TSM0 was first selected by the TSM arbiter before it could start
7. all instructions of texture clause 0 are issued by TSM0
8. the control packet is passed to the next reservation station (the FIFO in front of ALU state machine 0, or ASM0 FIFO)
   - TSM0 does not wait for requests made to the Texture Unit to complete; it passes the register file write index for the texture data to the TU, which will write the data to the RF as it is received
   - once the TU has written all the data to the register files, it increments a counter that is associated with ASM0 FIFO; a count greater than zero indicates that the ALU state machine can go ahead start to execute the ALU clause

9. ASM0 accepts the control packet (after being selected by the ASM arbiter) and gets the instructions for ALU clause 0 from the global instruction store

10. all instructions of ALU clause 0 are issued by ASM0, then the control packet is passed to the next reservation station (the FIFO in front of texture state machine 1, or TSM1 FIFO)

11. the control packet continues to travel down the path of reservation stations until all clauses have been executed
    - position can be exported in ALU clause 3 (or 4?); the data (and the tag) is sent over a position bus (which is shared with all four shader pipes) back to the PA's position cache
    - A parameter cache pointer is also sent along with the position data. This tells to the PA where the data is going to be in the parameter cache.
        - there is a position export FIFO in the SP that buffers position data before it gets sent back to the PA
        - the ASM arbiter will prevent a packet from starting an exporting clause if the position export FIFO is full
    - parameter data is exported in clause 7 (as well as position data if it was not exported earlier)
        - parameter data is sent to the Parameter Cache over a dedicated bus
        - the SEQ allocates storage in the Parameter Cache, and the SEQ deallocates that space when there is no longer a need for the parameters (it is told by the PA when using a token).
        - the ASM arbiter will prevent a packet from starting on ASM7 if the parameter cache (or the position buffer if position is being exported) is full

12. after the shader program has completed, the SEQ will free up the GPRs so that they can be used by another shader program

~~13.1.2~~19.1.2 *Sequencer Control of a Vector of Pixels*

Formatted: Bullets and Numbering

1. **As with vertex shader programs, pixel shaders are loaded into the global instruction store by the CP**
    - At this point it is assumed that the pixel program is loaded into the instruction store and thus ready to be read.

~~2.the RE's Parameter Buffer is loaded from the Parameter Cache before the SEQ takes control of the vector~~

Formatted: Bullets and Numbering

- ~~after the HZ culling stage a request is made by the RE to send parameter data to the Parameter buffer~~
- ~~the Parameter buffer is wide enough to source 3 vertices worth of a particular parameter in one cycle~~
- ~~**at this moment the right sequencer will free up the parameter store locations not used anymore using the token provided by the PA**.~~

~~3.~~2. the RE's Pixel FIFO is loaded with the barycentric coordinates for pixel quads by the detailed walker
- the state pointer and the LOD correction bits are also placed in the Pixel FIF0
- the Pixel FIFO is wide enough to source ~~one~~ four quad's worth of barycentrics per cycle

~~4.~~3. SEQ arbitrates between Pixel FIFO and Vertex FIFO – when there are no vertices pending OR there is no space left in the register files for vertices, the Pixel FIFO is selected

Formatted: Bullets and Numbering

~~5.~~4. SEQ allocates space in the SP register file for all the GPRs used by the program
- the number of GPRs required by the program is stored in a local state register, which is accessed using the state pointer
- SEQ will not allow interpolated data to be sent to the shader until space in the register file has been allocated

~~6.SEQ control starts with the interpolation of parameters (up to 16 per thread) by sending the barycentric coordinates from the Pixel FIFO and the parameters from the Parameter Buffer to the interpolator~~

Formatted: Bullets and Numbering

- ~~P0i, P0j, and P0k (the value of P0 at each vertex) are loaded into the interpolator from the Parameter buffer~~
- ~~Q0 i, j, and k are loaded into the interpolator from the Pixel FIFO~~
- ~~The interpolator then generates the parameter value for each pixel in Q0 (Q0P0)~~
- ~~**P0i, P0j, and P0k are sent to the interpolator for Q1 only if Q1 is from a different primitive; if Q1 is from the same primitive as Q0, then the P0i, P0j, and P0k values loaded for Q0 are held by the interpolator and reused for Q1**~~
    - ~~**a "different_prim" control bit is passed with the barycentric data for each quad in the Pixel FIFO that indicates whether new parameter data needs to be loaded into the interpolator**~~
- ~~Q1 i, j, and k are then loaded into the interpolator from the Pixel FIFO~~
- ~~The interpolator then generates the parameter value for each pixel in Q1 (Q1P0)~~
- ~~Q2P0 and Q3P0 are generated in a similar manner~~
- ~~The next set of parameter data - P1i, P1j, and P1k - is then loaded into the interpolator~~

- ~~Q0 i, j, and k now must be re-read from the Pixel FIFO – this means that the output of the Pixel FIFO loops through the top four entries on each read command until at the end a final “block_pop” signal is asserted, causing the top four sets of barycentric coordinates to finally be removed~~
- ~~so the order of parameter info generated is Q0P0, Q1P0, Q2P0, Q3P0, Q0P1, Q1P1, etc.~~

~~7.~~5. SEQ controls the transfer of interpolated data to the SP register file over the RE_SP interface (which has a bandwidth of ~~512~~ 2048 bits/cycle). See interpolated data bus diagrams for details.

- ~~16 pixels worth of interpolated parameter data is sent to the 16 register files over 4 cycles~~
    - ~~RF0 of SU0, SU1, SU2, and SU3 is written with Q0P0 the first cycle~~
    - ~~RF1 of SU0, SU1, SU2, and SU3 is written with Q1P0 second cycle~~
    - ~~RF2 of SU0, SU1, SU2, and SU3 is written with Q2P0 third cycle~~
    - ~~RF3 of SU0, SU1, SU2, and SU3 is written with Q3P0 fourth cycle~~

~~8.~~6. SEQ constructs a control packet for the vector and sends it to the first reservation station (the FIFO in front of texture state machine 0, or TSM0 FIFO)

- note that there is a separate set of reservation stations/arbiters/state machines for vertices and for pixels
- the control packet contains the state pointer, the register file base pointer, and the LOD correction bits
- all other informations (such as quad address for example) travels in a separate FIFO

~~9.~~7. TSM0 accepts the control packet and fetches the instructions for texture clause 0 from the global instruction store

Formatted: Bullets and Numbering

- TSM0 was first selected by the TSM arbiter before it could start

~~10.~~8. all instructions of texture clause 0 are issued by TSM0

Formatted: Bullets and Numbering

~~11.~~9. the control packet is passed to the next reservation station (the FIFO in front of ALU state machine 0, or ASM0 FIFO)

- TSM0 does not wait for texture requests made to the Texture Unit to complete; it passes the register file write index for the texture data to the TU, which will write the data to the RF as it is received
- once the TU has written all the data for a particular clause to the register files, it increments a counter that is associated with the ASM0 FIFO; a count greater than zero indicates that the ALU state machine can go ahead and pop the FIFO and start to execute the ALU clause

~~12.~~10. ASM0 accepts the control packet (after being selected by the ASM arbiter) and gets the instructions for ALU clause 0 from the global instruction store

Formatted: Bullets and Numbering

~~13.~~11. all instructions of ALU clause 0 are issued by ASM0, then the control packet is passed to the next reservation station (the FIFO in front of texture state machine 1, or TSM1 FIFO)

~~14.~~12. the control packet continues to travel down the path of reservation stations until all clauses have been executed

- pixel data is exported in the last ALU clause (clause 7)
    - it is sent to an output FIFO where it will be picked up by the render backend
    - the ASM arbiter will prevent a packet from starting on ASM7 if the output FIFO is full

~~15.~~13. after the shader program has completed, the SEQ will free up the GPRs so that they can be used by another shader program

Formatted: Bullets and Numbering

~~13.1.3~~19.1.3 *Notes*

Formatted: Bullets and Numbering

~~16.~~14. the state machines and arbitrers will operate ahead of time so that they will be able to immediately start the real threads or stall.

~~17.~~15. the register file base pointer for a vector needs to travel with the vector through the reservation stations, but the instruction store base pointer does not – this is because the RF pointer is different for all threads, but the IS pointer is only different for each state and thus can be accessed via the state pointer

16. Waterfalling, parameter buffer allocation, loops and branches and parameter cache de-allocation still needs to be specked out.

~~14. Timing Diagrams~~

Timing Diagram 3: Sequencer - Texture Unit Interface and Texture Unit - Shader Pipe Data Transfer

~~14.4 Timing diagrams explanations~~

Formatted: Bullets and Numbering

~~The numbering of the four shader pipes, the four shader units, and the four MACs is from left to right and from 0 to 3. So for example the most significant 512 bits of a SP goes to SU0 and the least significant 512 bits go to SU3; within SU0, the most significant 128 bits go to MAC0 and the least significant 128 bits go to MAC3.~~

~~The following assumptions are made:~~

Formatted: Bullets and Numbering

1. ~~all block to block signals are register to register~~
2. ~~for register file reads, the RF read data is available in the MAC one clock after a RF read address is registered into the MAC (this is the same as saying the read data is valid out of the RF two clocks after the address is asserted on the SEQ to SP interface)~~

~~14.4.1 *Timing Diagram 1: Sequencer to Shader Pipe 0, Shader Unit 0, MAC 0*~~

~~This diagram shows the basics of the Sequencer to Shader Pipe interface. For simplicity only the timing relative to MAC0 is shown. The timing for MAC1 is one clock later than MAC0, MAC2 one clock later than MAC1, etc. This means that most of the signals need to be delayed in the SP by one cycle for MAC1, two cycles for MAC2, and three cycles for MAC3.~~

~~**SEQ_SP_constant0**: Constant 0 (128 bits over 4 cycles). Pipelined in SP for other MACs.~~

~~**SEQ_SP_constant1**: Constant 1 (128 bits over 4 cycles). Pipelined in SP for other MACs.~~

~~**SEQ_SP_read_addr**: Register File Read Address (8 bits). Pipelined in SP for other MACs.~~

~~**SEQ_SP_phase**: This signal syncs the data transfer to the RF from the RE, as well as defining the order of all writes into the RF. It is asserted during the cycle that interpolated data (ID) is valid on the RE_SP_ID bus. Pipelined in SP for other MACs.~~

~~**RE_SP_ID[511:384]**: This is the most significant 128 bits of the RE_SP_data interface (meaning that this MAC0 is in SU0).~~

~~**SEQ_SP_instruction**: 96 bits of instruction are sent over 4 cycles. Pipelined in SP for other MACs.~~

~~**SEQ_SP_instr_start**: control bit that signals the first cycle of the instruction transfer. Pipelined in SP for other MACs.~~

~~**mac0_phase**: registered version of SEQ_SP_phase used in MAC0 (this may not be he actual signal name).~~

~~**mac0_cycle_count**: a counter inside the MAC that keeps track of the RF write cycles; 0 here corresponds to the cycle RE interpolated data is written (this may not be he actual signal name).~~

~~**RF0_read_data**: data that is read out of MAC0's register file (this may not be he actual signal name).~~

~~**mac0_vector_result**: the 32-bit output of the vector ALU (PV is built up over 4 cycles) (this may not be he actual signal name).~~

~~**SEQ_SP_write_addr**: Register File Write Address (8 bits). Note that the SEQ does not send the Texture Data write address over this bus. Pipelined in SP for other MACs.~~

~~**RF0 write cycle**: the cycles allocated to the different write sources (ID = Interpolated Data, TD = Texture Data, PV = Previous Vector, PS = Previous Scalar) (not a signal – just a reference point on the diagram).~~

~~14.4.2 *Timing Diagram 2: RE Interpolator to Shader Pipe Data Transfer*~~

Formatted: Bullets and Numbering

~~This diagram shows how pixel data (barycentric coordinates i, j, and k) is sent from the Pixel FIFO to the interpolator under SEQ control, and how parameter data (for each vertex) is also sent to the interpolator under SEQ control. The output of the Interpolator is then shown being sent over the RE_SP interface.~~

~~**PXF_SEQ_rts**: Indicates that the output of the pixel FIFO is valid.~~

~~**PXF_SEQ_new_prim**: The current output of the Pixel FIFO is from a different primitive that the previous output. Tells the SEQ that new parameter info must be fetched (if its not from a new prim, then new parameter data is not needed).~~

~~**PXF_INT_data**: Data output of the Pixel FIFO – goes to the Interpolator.~~

~~**SEQ_PXF_rtr**: Indicates that the current Pixel FIFO output will be taken by the Interpolator (driven by SEQ). Then next quad of data will be driven the next cycle.~~

~~**SEQ_PXF_vector_pop**: SEQ tells the Pixel FIFO to pop a vector of pixels (otherwise RTRs cause the data to be cycled between the four quads).~~

~~**PMB_INT_data**: Data from the Parameter Buffer to the Interpolator. (Note that the control of the parameter buffer is TBD).~~

~~**SEQ_INT_pm_load**: controls the loading of parameter data into the Interpolator.~~

~~**INT_param_reg**: register in the Interpolator that holds the per-vertex parameter data while the per-pixel parameters are generated for one or more quads (may not be the actual signal name).~~
~~**SEQ_INT_px_load**: controls the loading of pixel data into the Interpolator.~~
~~**INT_quad_reg**: : register in the Interpolator that holds one quad's worth of pixel data(may not be the actual signal name).~~

~~**SEQ_SP_phase**: see above under TD1.~~
~~**SEQ_SP_write_addr**: see above under TD1.~~
~~**RE_SP_valid**: Interpolator Data Valid – indicates that the SP should write the ID on the appropriate cycle.~~
~~**RE_SP_data**: Data from the RE interpolator to the SP.~~
~~**RF0 write cycle**: see above under TD1.~~
~~**mac*_phase**: see above under TD1. These phase signals help to show the timing offset between the MACs. Note also that each Shader Unit has a set of these signals (all with the same timing).~~

~~14.4.3 *Timing Diagram 3: Sequencer - Texture Unit Interface and Texture Unit - Shader Pipe Data Transfer*~~

Formatted: Bullets and Numbering

~~This diagram starts with the texture coordinate read from the register file and its transfer to the TX. The instruction transfer is then shown, followed by the texture data transfer to the shader pipe.~~
~~**SEQ_SP_read_addr**: see above. Here shows the cycle that the texture coordinate read address is asserted.~~
~~**RF0_read_addr**: see above.~~
~~**SP_TX_tc**: Texture coordinate data sent from the shader pipe to the texture unit.~~
~~**SEQ_TX_instr_start**: Asserted on the first cycle of a SEQ to TX instruction transfer.~~
~~**SEQ_TX_instruction**: 96 bits of texture instruction transferred over 4 cycles.~~
~~**SEQ_TX_clause**: the clause number associated with this instruction.~~
~~**SEQ_TX_write_addr**: RF write index used by TX for returned texture data.~~
~~**SEQ_TX_last**: indicates that this is the last texture instruction of a clause.~~
~~**SEQ_TX_phase**: syncs the texture data write. Note that it is asserted early enough to be registered into TX and still allow TX to source the texture data to the SP on the correct cycle.~~

~~**tx_phase**: the phase signal after being registered into TX.~~
~~**TX_SP_write_addr**: RF write index for texture data.~~
~~**TX_SP_valid**: indicates that valid texture data is being driven to the SP.~~
~~**TX_SP_data**: the texture data.~~
~~**TX_SEQ_clause**: the clause number associated with the texture data.~~
~~**TX_SEQ_done**: indicates to the SEQ that the texture data transfer is complete for the clause number that is on the TX_SEQ_clause bus.~~

~~**SEQ_SP_phase**: see above under TD1 - shown here for reference.~~
~~**SEQ_SP_write_addr**: see above under TD1- shown here for reference.~~
~~**RF0 write cycle**: see above under TD1- shown here for reference.~~

~~15.~~20. Open issues

Formatted: Bullets and Numbering

There is currently an issue with constants. If the constants are not the same for the whole vector of vertices, we don't have the bandwith from the texture store to feed the ALUs. Two solutions exists for this problem:

1) Let the compiler handle the case and put those instructions in a texture clause so we can use the bandwith there to operate. This requires a significant amount of temporary storage in the register store.
2) Waterfall down the pipe allowing only at a given time the vertices having the same constants to operate in parrallel. This might in the worst case slow us down by a factor of 16.

Need to do some testing on the size of the register file as well as on the register file allocation method (dynamic VS static).

Saving power?

Size of the fifo containing the information of a vector of pixels/vertices. And size of the fifos before the reservation stations.

~~Sequencer Instruction memory, and constant memory.~~

~~Arbitration policy for the output file.~~

Loops and branches.

~~The parameter cache may end up in the PA rather than in the RS. Parameter cache management thus may change.~~

R400 Sequencer Specification

SEQ

Version 0.8~~7~~

Overview: This is an architectural specification for the R400 Sequencer block (SEQ). It provides an overview of the required capabilities and expected uses of the block. It also describes the block interfaces, internal sub-blocks, and provides internal state diagrams.

First draft.

Changed the interfaces to reflect the changes in the SP. Added some details in the arbitration section.
Reviewed the Sequencer spec after the meeting on August 3, 2001.
Added the dynamic allocation method for register file and an example (written in part by Vic) of the flow of pixels/vertices in the sequencer.
Added timing diagrams (Vic)

Changed the spec to reflect the new R400 architecture. Added interfaces.
Added constant store management, instruction store management, control flow management and data dependant predication.
Changed the control flow method to be more flexible. Also updated the external interfaces.

1. Overview

The sequencer first arbitrates between vectors of 64 vertices that arrive directly from primitive assembly and vectors of 16 quads (64 pixels) that are generated in the raster engine.

The vertex or pixel program specifies how many GPR's it needs to execute. The sequencer will not start the next vector until the needed space is available.

The sequencer is based on the R300 design. It chooses two ALU clauses and a ~~texture~~fetch clause to execute, and executes all of the instructions in a clause before looking for a new clause of the same type. Two ALU clauses are executed interleaved to hide the ALU latency. Each vector will have eight ~~texture~~fetch and eight ALU clauses, but clauses do not need to contain instructions. A vector of pixels or vertices ping-pongs along the sequencer FIFO, bouncing from ~~texture~~fetch reservation station to alu reservation station. A FIFO exists between each reservation stage, holding up vectors until the vector currently occupying a reservation station has left. A vector at a reservation station can be chosen to execute. The sequencer looks at all eight alu reservation stations to choose an alu clause to execute and all eight ~~texture~~fetch stations to choose a ~~texture~~fetch clause to execute. The arbitrator will give priority to clauses/reservation stations closer to the bottom of the pipeline. It will not execute an alu clause until the ~~texture~~fetch fetches initiated by the previous ~~texture~~fetch clause have completed. There are two separate sets of reservation stations, one for pixel vectors and one for vertices vectors. This way a pixel can pass a vertex and a vertex can pass a pixel.

To support the shader pipe the raster engine also contains the shader instruction cache and constant store. There are only one constant store for the whole chip and one instruction store. These will be shared among the four shader pipes. The four shader pipes also execute the same instuction thus there is only one sequencer for the whole chip.

There are two sets of the above figure, one for vertices and one for pixels.

The rasterizer always checks the vertices FIFO first and if allowed by the sequencer sends the data to the shader. If the vertex FIFO is empty then, the rasterizer takes the first entry of the pixel FIFO (a vector of 64 pixels) and sends it to the interpolators. Then the sequencer takes control of the packet. The packet consists of 21 bits of state, 6-7 bits for the base address of the Shader program and some information on the coverage to determine ~~texture~~fetch LOD. All other information (2x2 adresses) is put in a FIFO (one for the pixels and one for the vertices) and retrieved when the packet finishes its last clause.

On receipt of a packet, the input state machine (not pictured but just before the first FIFO) allocated enough space in the registers to store the interpolated values and temporaries. Following this, the input state machine stacks the packet in the first FIFO.

On receipt of a command, the level 0 ~~texture~~fetch machine issues a texure request and corresponding register address for the ~~texture~~fetch address (ta). A small command (tcmd) is passed to the ~~texture~~fetch system identifying the current level number (0) as well as the register write address for the ~~texture~~fetch return data. One ~~texture~~fetch request is sent every 4 clocks causing the texturing of sixteen 2x2s worth of data (or 64 vertices). Once all the requests are sent the packet is put in FIFO 1.

Upon recept of the return data, the ~~texture~~fetch unit writes the data to the register file using the write address that was provided by the level 0 ~~texture~~fetch machine and sends the clause number (0) to the level 0 ~~texture~~fetch state machine to signify that the write is done and thus the data is ready. Then, the level 0 ~~texture~~fetch machine increments the counter of FIFO 1 to signify to the ALU 1 that the data is ready to be processed.

On receipt of a command, the level 0 ALU machine first decrements the input FIFO counter and then issues a complete set of level 0 shader instructions. For each instruction, the state machine generates 3 source addresses, one destination address (3 cycles later) and an instruction. Once the last instruction as been issued, the packet is put into FIFO 2.

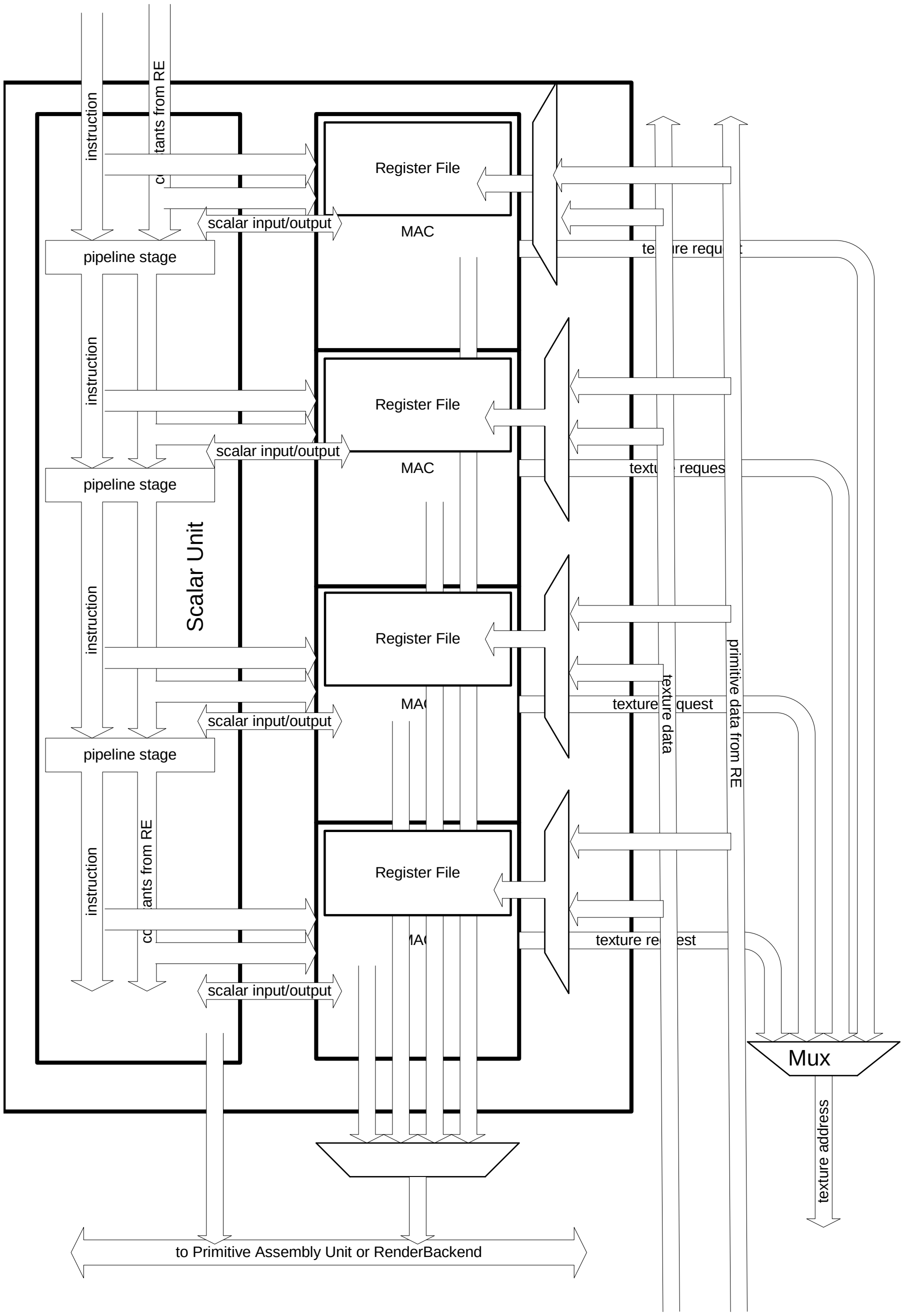
There will always be two active ALU clauses at any given time (and two arbitrers). One arbitrer will arbitrate over the odd clock cycles and the other one will arbitrate over the even clock cycles. The only constraints between the two arbitrers is that they are not allowed to pick the same clause number as they other one is currently working on if the packet os of the same type.

If the packet is a vertex packet, upon reaching ALU clause 4, it can export the position if the position is ready. So the arbitrer must prevent ALU clause 4 to be selected if the positional buffer is full (or can't be accessed). Along with the positional data, the location where the vertex data is to be put is also sent (parameter data pointers).

All other level process in the same way until the packet finally reaches the last ALU machine (8). On completion of the level 8 ALU clause, a valid bit is sent to the Render Backend which picks up the color data. This requires that the last instruction writes to the output register – a condition that is almost always true. If the packet was a vertex packet, instead of sending the valid bit to the RB, it is sent to the PA so it can know that the data present in the parameter store is valid.

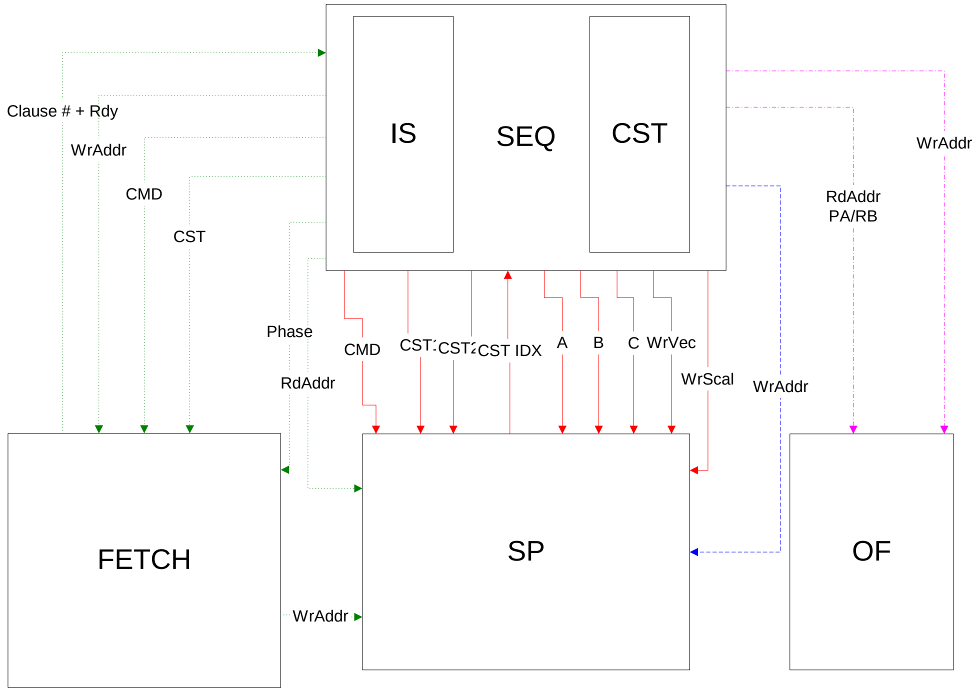
Only two ALU state machine may have access to the register file address bus or the instruction decode bus at one time. Similarly, only one ~~texture~~fetch state machine may have access to the register file address bus at one time. Arbitration is performed by three arbitrer blocks (two for the ALU state machines and one for the ~~texture~~fetch state machines). The arbitrers always favor the higher number state machines, preventing a bunch of half finished jobs from clogging up the register files.

1.2 Data Flow graph



The gray area represents blocks that are replicated 4 times per shader pipe (16 times on the overall chip).

1.3 Control Graph



In green is represented the ~~Texture~~Fetch control interface, in red the ALU control interface, in blue the Interpolated/Vector control interface and in purple is the output file control interface.

2. Interpolated data bus

The interpolators contain an IJ buffer to pack the information as much as possible before writing it to the register file.

	P0								P1											

Above is an example of a tile we might receive. The IJ information is packed in the IJ buffer 2 quads at a time. The sequencer allows at any given time as many as four quads to interpolate a parameter. They all have to come from the same primitive. Then the sequencer controls the write mask to the register to write the valid data in.

3. Instruction Store

There is going to be only one instruction store for the whole chip. It will contain 4096 instructions of 96 bits each. There is also going to be a control instruction store of size 256(512?)x32.

{ISSUE : The instruction store is loaded by the sequencer using the memory hub ?}.

The read bandwith from this store is 96*2 bits/ 4 clocks (48 bits/clock). It is likely to be a 1~~R/1W~~ port memory; we use ~~2~~ 1 clock~~s~~ to load the ALU instruction, ~~and~~ 1~~2~~ clocks to load the ~~Texture~~Fetch instruction, 1 clock to load 2 control flow instructions and 1 clock to write instructions.

4. Sequencer Instructions

All control flow instructions and move instructions are handled by the sequencer only. The ALUs will perform NOPs during this time (MOV PV,PV, PS,PS).

5. Constant Store

The constant store is managed by the CP. The sequencer is aware of where the constants are using a remaping table also managed by the CP. A likely size for the constant store is 512x128 bits. The constant store is also planned to be shared. The read BW from the constant store is 128 bits/clock and the write bandwith is 32/4 bits/clock.

In order to do constant store indexing, the sequencer must be loaded first with the indexes (that come from the GPRs). There are 144 wires from the exit of the SP to the sequencer (9 bits pointers x 16 vertexes/clock). Since the data must pass thru the Shader pipe for the float to fixed convertion, there is a latency of 4 clocks (1 instruction) between the time the sequencer is loaded and the time one can index into the constant store. The assembly will look like this

```
MOVA  R1.X,R2.X        // Loads the sequencer with the content of R2.X, also copies the content of R2.X into R1.X
NOP                    // latency of the float to fixed conversion
ADD   R3,R4,C0[R2.X]// Uses the state from the sequencer to add R4 to C0[R2.X] into R3
```

Note that we don't really care about what is in the brackets because we use the state from the MOVA instruction. R2.X is just written again for the sake of simplicity.

The storage needed in the sequencer in order to support this feature is 2*64*9 bits = 1152 bits.

6. Looping and Branches

Loops and branches are planned to be supported and will have to be dealt with at the sequencer level. We plan on supporting constant loops and branches using a control program. The control program has 4(5) instructions:

6.1 The controlling state.

As per Dx9 the following state is available for control flow:

Boolean[15:0]
loop_count[7:0][7:0]
In addition:
loop_start [7:0] [7:0]
loop_step [7:0] [7:0]
Exist to give more control to the controlling program.

We will extend that in the R400 to:

Boolean[255~~31~~:0]
Loop_count[7:0][15:0]
Loop_Start[7:0] [15:0]
Loop_End[7:0] [15:0]

{ISSUE: How is the controlling state loaded and how many contexts do we have?}

6.2 The Control Flow Program

The R300 uses a match method for control flow: The shader is executed, and at every instruction its address is compared with addresses (or address?) in a control table. The "event" in the control table can redirect operations in the program.

The Method chosen for the R400 is a "control program". The control program has ~~four~~ ten basic instructions:

Execute
Conditional_execute
~~(~~Conditional_~~-~~Execut~~e~~e_~~-~~Predicates~~)~~
Conditional_execute_or_Jump
Conditional_jump
Call
Return
Loop_start
Loop_end
End_of_clause

Execute, causes the specified number of instructions in instruction store to be executed.
Conditional_execute checks a condition first, and if true, causes the specified number of instructions in instruction store to be executed.
Loop_start resets the corresponding loop counter to the start value on the first pass after it checks for the end condition and if met jumps over to a specified address.
Loop_end increments (decrements?) the loop counter and jumps back the specified number of instructions.
Call jumps to an address and pushes the IP counter on the stack. On the return instruction, the IP is poped from the stack.
Conditional_execute_or_Jump executes a block of instructions or jumps to an address is the condition is not met.
Conditional_execute_Predicates executes a block of instructions if all bits in the predicate vectors meet the condition.
End_of_clause marks the end of a clause.
Conditional_jumps jumps to an address if the condition is met. ~~if the loop end condition is not met.~~

~~if we try and fit the control flow instructions into 32 bit words, the following instructions are possible choices:~~We have to fit instructions into 48 bits in order to be able to put two control flow instruction per line in the instruction store.

Execute				
47	46… 42	41 … 24	23 … 12	11 … 0
Addressing	00001	RESERVED	Instruction_count	Exec Address

Execute up to ~~4K~~ 4k instructions at the specified address in the instruction memory.

Conditionnal_Execute_or_Jump						
47	46 … 42	41 … 34	33	32 … 21	20 … 12	11 … 0
Addressing	00010	Booleans	Condition	Jump address	Instruction_count	Exec Address

I~~i~~f the specified boolean (~~6~~8 bits can address ~~64~~256 booleans) meets the specified condition then execute the specified instructions (up to ~~64~~ 512 instructions) or if the condition is not met jump to the jump address in the control flow program. This MUST be a forward jump.

Conditionnal_Execute						
47	46 … 42	41 … 34	33	32 … 21	20 … 12	11 … 0
Addressing	00011	Boolean address	Condition	RESERVED	Instruction_count	Exec Address

If the specified boolean (8 bits can address 256 booleans) meets the specified condition then execute the specified instructions (up to 512 instructions)

Conditionnal_Execute_Predicates						
47	46 … 42	41 … 38	37	36 … 21	20 … 12	11 … 0
Addressing	00100	Predicate vector	Condition	RESERVED	Instruction_count	Exec Address

Check the OR of all current predicate bits. If OR matches the condition execute the specified number of instructions.

~~Initialize the specified loop~~

~~If the loop condition of the current loop is not met, then branch back to the specified address in the control flow program. Note that jumping back to the loop_start results in an infinite loop, the jump should be to loop_start+1.~~

Loop_Start				
47	46 … 42	41 … 16	15 … 4	3 … 0
Addressing	00101	RESERVED	Jump address	Loop ID

Loop Start. Compares the loop count with the end value. If loop condition not met jump to the address. Forward jump only. Also computes the index value.

Loop_End				
47	46 … 42	41 … 16	15 … 4	3 … 0
Addressing	00111	RESERVED	Start address	Loop ID

Loop end. Increments the counter by one and jumps BACK only to the start of the loop.

The way this is described does not prevent nested loops, and the inclusion of the loop id make this easy to do.

Call			
47	46 … 42	41…12	11 … 0
Addressing	01000	RESERVED	Address

Jumps to the specified address and pushes the IP counter on the stack.

Return		
47	46 … 42	41 … 0

Addressing	01001	RESERVED

Pops the topmost address from the stack and jumps to that address.

Conditionnal_Jump					
47	46 … 42	41 … 34	33	32 … 12	11 … 0
Addressing	01010	Boolean address	Condition	RESERVED	Address

If condition met, jumps to the address. FORWARD jump only allowed.

End_of_Clause		
47	46 … 42	41 … 0
Addressing	01011	RESERVED

Marks the end of a clause.

To prevent infinite loops, we will keep 9 bits loop counters instead of 8 (we are only able to loop 256 times). If the counter goes higher than 255 then the loop_end or the loop_start is going to break the loop. The sequencer will keep a loop index value of 17 bits. This will be updated everytime we loop and can only be used to index the constant store and the register file. The way to compute this value is:

Index = Loop_counter*Loop_iterator + Loop_init.

The basic model is as follows:

The render state defined the clause boundaries:

```
Vertex_shader_fetch[7:0][7:0]    // eight 8 bit pointers to the location where each clauses control program is located
Vertex_shader_alu[7:0][7:0]      // eight 8 bit pointers to the location where each clauses control program is located
Pixel_shader_fetch[7:0][7:0]     // eight 8 bit pointers to the location where each clauses control program is located
Pixel_shader_alu[7:0][7:0]       // eight 8 bit pointers to the location where each clauses control program is located
```

~~The control program can be up to 256 instructions in size. (There is an offset added to the address from the render state before accessing the control flow program memory to allow for multiple programs resident at the same time)~~

The control program for a given clause is executed to completion before moving to another clause, (with the exception of the pick two nature of the alu execution). The control program is the only program aware of the clause boundaries.

~~The addresses from the control program are added to another offset to allow for multiple programs resident at the same time.~~

~~Under this model, all subroutine calls must be inlined into the control program.~~

6.3 Data dependant predicate instructions

Data dependant conditionals will be supported in the R400. The only way we plan to support those is by supporting three vector/scalar predicate operations of the form:

PRED_SETE_# - similar to SETE except that the result is 'exported' to the sequencer.

PRED_SETGT_# - similar to SETGT except that the result is 'exported' to the sequencer
PRED_SETGTE_# - similar to SETGTE except that the result is 'exported' to the sequencer

For the scalar operations only we will also support the two following instructions:
PRED_SETE0_# – SETE0
PRED_SETE1_# – SETE1

The export is a single bit - 1 or 0 that is sent using the same data path as the MOVA instruction. The sequencer will maintain ~~the~~4 sets of 64 bit predicate vectors (in fact 8 sets because we interleave two programs but only 4 will be exposed) and use it to control the write masking~~ (two sets for interleaved operation)~~. This predicate is not maintained across clause boundaries. The # sign is used to specify wich predicate set you want to use 0 thru 3.

Then we have two conditional execute bits. The first bit is a conditional execute “on” bit and the second bit tells us if we execute on 1 or 0. For exemple, the instruction :

P0_ADD_# R0,R1,R2

Is only going to write the result of the ADD into those GPRs whose predicate bit is 0. Alternatively, P1_ADD_# would only write the results to the GPRs whose predicate bit is set. The use of the P0 or P1 without precharging the sequencer with a PRED instruction is undefined.

{Issue: do we have to have a NOP between PRED and the first instruction that uses a predicate?}

6.4 Register file indexing

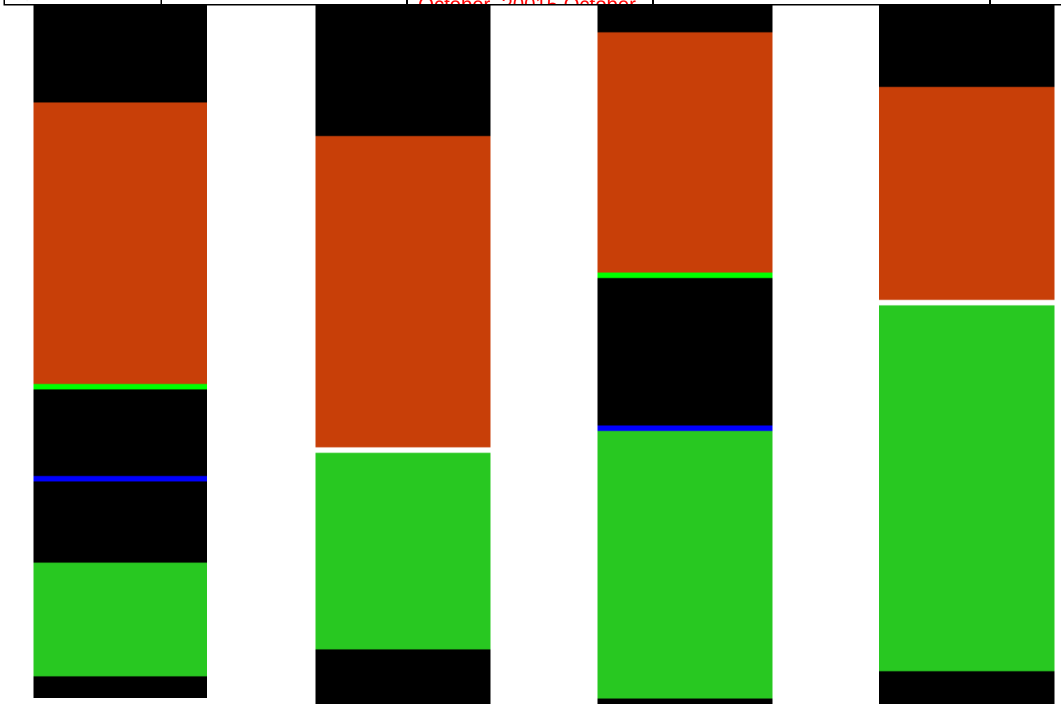
Because we can have loops in ~~texture~~fetch clause, we need to be able to index into the register file in order to retrieve the data created in a ~~texture~~fetch clause loop and use it into an ALU clause. The instruction will include the base address for register indexing and the instruction will contain these controls :

Bit7	Bit 6	
0	0	'absolute register'
0	1	'relative register'
1	0	'previous vector'
1	1	'previous scalar'

In the case of an absolute register we just take the address as is. In the case of a relative register read we take the base address and we add to it the ~~loop_counter~~loop_index and this becomes our new address that we give to the shader pipe.

7. Register file allocation

The register file allocation for vertices and pixels can either be static or dynamic. In both cases, the register file in managed using two round robins (one for pixels and one for vertices). In the dynamic case the boundary between pixels and vertices is allowed to move, in the static case it is fixed to VERTEX_REG_SIZE for vertices and 256-VERTEX_REG_SIZE for pixels.



Above is an example of how the algorithm works. Vertices come in from top to bottom; pixels come in from bottom to top. Vertices are in orange and pixels in green. The blue line is the tail of the vertices and the green line is the tail of the pixels. Thus anything between the two lines is shared. When pixels meets vertices the line turns white and the boundary is static until both vertices and pixels share the same “unallocated bubble”. Then the boundary is allowed to move again.

8. ~~Texture~~Fetch Arbitration

The ~~texture~~fetch arbitration logic chooses one of the 8 potentially pending ~~texture~~fetch clauses to be executed. The choice is made by looking at the fifos from 7 to 0 and picking the first one ready to execute. Once chosen, the clause state machine will send one 2x2 ~~texture~~ fetch per clock (or 4 fetches in one clock every 4 clocks) until all the ~~texture~~ fetch instructions of the clause are sent. This means that there cannot be any dependencies between two ~~texture~~ fetches of the same clause.

The arbitrator will not wait for the ~~texture~~ fetches to return prior to selecting another clause for execution. The ~~texture~~fetch pipe will be able to handle up to X(?) in flight ~~texture~~ fetches and thus there can be a fair number of active clauses waiting for their ~~texture~~fetch return data.

9. ALU Arbitration

ALU arbitration proceeds in almost the same way than ~~texture~~fetch arbitration. The ALU arbitration logic chooses one of the 8 potentially pending ALU clauses to be executed. The choice is made by looking at the fifos from 7 to 0 and picking the first one ready to execute. There are two ALU arbitrers, one for the even clocks and one for the odd clocks. For exemple, here is the sequencing of two interleaved ALU clauses (E and O stands for Even and Odd sets of 4 clocks):

Einst0 Oinst0 Einst1 Oinst1 Einst2 Oinst2 Einst0 Oinst3 Einst1 Oinst4 Einst2 Oinst0…
Proceeding this way hides the latency of 8 clocks of the ALUs.

10. Handling Stalls

When the output file is full, the sequencer prevents the ALU arbitration logic to select the last clause (this way nothing can exit the shader pipe until there is place in the output file. If the packet is a vertex packet and the position buffer is full (POS_FULL) then the sequencer also prevents a thread to enter the exporting clause (4?). The sequencer will set the OUT_FILE_FULL signal n clocks before the output file is actually full and thus the ALU arbitrer will be able read this signal and act accordingly by not preventing exporting clauses to proceed.

11. Content of the reservation station FIFOs

3 bits of Render State 6-7 bits for the base address of the instruction store, some bits for LOD correction and coverage mask information in order to fetch ~~texture~~fetch for only valid pixels. Every other information (such as the coverage mask, quad address, etc.) is put in a FIFO and is retrieved when the quad exits the shader pipe to enter in the output file buffer. Since pixels and vertices are kept in order in the shader pipe, we only need two fifos (one for vertices and one for pixels) deep enough to cover the shader pipe latency. This size will be determined later when we will know the size of the small fifos between the reservation stations.

12. The Output File

The output file is where pixels are put before they go to the RBs. The write BW to this store is 256 bits/clock. Just before this output file are staging registers with write BW 512 bits/clock and read BW 256 bits/clock. For this reason only ONE concurrent program can be of clause 8 (exporting clause) the other program MUST not. The staging registers are 4x128 (and there are 16 of those on the whole chip).

13. IJ Format

The IJ information sent by the PA is of this format on a per quad basis:

We have a vector of IJ's (one IJ per pixel at the centroid of the fragment or at the center of the pixel depending on the mode bit). The interpolation is done at a different precision across the 2x2. The upper left pixel's parameters are always interpolated at full 19~~24~~x24 mantissa precision. Then the result of the interpolation along with the difference in IJ in reduced precision is used to interpolate the parameter for the other three pixels of the 2x2. Here is how we do it:

Assuming P0 is the interpolated parameter at Pixel 0 having the barycentric coordinates I(0), J(0) and so on for P1,P2 and P3. Also assuming that A is the parameter value at V0 (interpolated with I), B is the parameter value at V1 (interpolated with J) and C is the parameter value at V2 (interpolated with (1-I-J).

$$\Delta 01I = I(1) - I(0)$$
$$\Delta 01J = J(1) - J(0)$$
$$\Delta 02I = I(2) - I(0)$$
$$\Delta 02J = J(2) - J(0)$$
$$\Delta 03I = I(3) - I(0)$$
$$\Delta 03J = J(3) - J(0)$$

P0	P1
P2	P3

$$P0 = C + I(0)*(A-C) + J(0)*(B-C)$$
$$P1 = P0 + \Delta 01I*(A-C) + \Delta 01J*(B-C)$$
$$P2 = P0 + \Delta 02I*(A-C) + \Delta 02J*(B-C)$$
$$P3 = P0 + \Delta 03I*(A-C) + \Delta 03J*(B-C)$$

P0 is computed at ~~full~~ 19~~24~~x24 mantissa precision and P1 to P3 are computed at 8X24 mantissa precision. So far no visual degradation of the image was seen using this scheme.

Multiplies (Full Precision): 2
Multiplies (Reduced precision): 6
~~Subtracts 24x24 yielding 8 bits (IJs): 6~~
Subtracts ~~24x24~~ 19x24 (Parameters): 2
Adds: 8

FORMAT OF P0's IJ : Mantissa ~~23~~19 Exp 4 for I + Sign
Mantissa ~~23~~19 Exp 4 for J + Sign

FORMAT of Deltas (x3): Mantissa 8 Exp 4 for I + Sign
Mantissa 8 Exp 4 for J + Sign

Total number of bits : 19~~23~~*2 + 8*6 + 4*8 + 4*2 = 126 ~~(rounded up on the bus to 128)~~

14. The parameter cache

The parameter cache is where the vertex shaders export their data. It consists of 16 128x128 memories (1R/1W). The reuse engine will make it so that all vertexes of a given primitive will hit different memories.

15. Vertex position exporting

On clause 4 (or 5) the vertex shader can export to the PA both the vertex position and the point sprite. It can also do so at clause 8 if not done at clause 4. ~~The export is done by putting the exported position back into the GPRs. Then using the texture port in an opportunistic manner, 16 positions are put into a FIFO (16x128) in order (left to right). This fifo drains 128 bits per clock to the PA and once empty is filled up again with sprite sizes (if any). The process is~~

~~repeated 4 times. The sequencer must make sure that the program doesn't enter ALU clause 5 (it can enter texture clause 5) because the registers can be reused at this point. The sequencer must also make sure not to dealocate an exporting program before it is done exporting data.~~ Along with the position is exported a pointer to the parameter cache where the data will be once the vertex shader exports. The storage needed to perform the position export is at least 64x128 memories for the position and 64x32 memories for the sprite size. It is going to be taken in the pixel output fifo.

Formatted: Bullets and Numbering

16. Real time commands

We are unable to use the parameter memory since there is no way for a command stream to write into it. Instead we need to add three 16x128 memories (one for each of three vertices x 16 interpolants). These will be mapped onto the register bus and written by type 0 packets, and output to the the parameter busses (the sequencer and/or PA need to be able to address the realtime parameter memory as well as the regular parameter store. For higher performance we should be able able to view them as two banks of 16 and do double buffering allowing one to be loaded, while the other is rasterized with. Most overlay shaders will need 2 or 4 scalar coordinates, one option might be to restrict the memory to 16x64 or 32x64 allowing only two interpolated scalars per cycle, the only problem I see with this is, if we view support for 16 vector-4 interpolants important (true only if we map microsoft's high priority stream to the realtime stream), then the PA/sequencer need to support a realtime-specific mode where we need to address 32 vectors of parameters instead of 16.

Formatted: Bullets and Numbering

~~16.~~17. Registers

DYNAMIC_REG	Dynamic allocation (pixel/vertex) of the register file on or off.
VERTEX_REG_SIZE	What portion of the register file is reserved for vertices (static allocation only)
PIXEL_MIN_SIZE	Minimal size of the register file's pixel portion (dynamic only)
VERTEX_MIN_SIZE	Minimal size of the register file's vertex portion (dynamic only)
Vshader_fetch[~~7~~11:0][7:0]	eight ~~8~~ 12 bit pointers to the location where each clauses control program is located
Vshader_alu[~~7~~11:0][7:0]	eight ~~8~~ 12 bit pointers to the location where each clauses control program is located
Pshader_fetch[~~7~~11:0][7:0]	eight ~~8~~ 12 bit pointers to the location where each clauses control program is located
Pshader_alu[~~7~~11:0][7:0]	eight ~~8~~ 12 bit pointers to the location where each clauses control program is located
PSHADER	base pointer for the pixel shader
VSHADER	base pointer for the vertex shader
~~PCNTLSHADER~~	~~base pointer for the pixel control program~~
~~VCNTLSHADER~~	~~base pointer for the vertex control program~~
VWRAP	wrap point for the vertex shader instruction store
PWRAP	wrap point for the pixel shader instruction store
REG_ALLOC_PIX	number of registers to allocate for pixel shader programs
REG_ALLOC_VERT	number of registers to allocate for vertex shader programs
PARAM_MASK[0…16]	parameter mask to specify ~~wich~~ how parameters maps in the pixel shader
FLAT_GOUR[0…16]	wich parameters are to be gouraud shaded
GEN_TEX[0….16]	for wich parameters do we need to generate tex coords.
CYL_WRAP[0…64]	for wich ~~vertices~~ parameters (and channels (xyzw)) do we do the cyl wrapping.
P_EXPORT	number of exports for pixel shader
V_EXPORT	number of exports for vertex shader (also the number of interpolated parameters for pixel shaders)
V_EXPORT_LOC	Vertex shader exporting to RB or the PCACHE
ARBITRATION_policy	policy of the arbitration between vetexes and pixels

Formatted: Bullets and Numbering

~~17.~~18. Interfaces

~~17.1~~18.1 External Interfaces

~~17.1.1~~18.1.1 *PA/SC to RE : IJ bus*

This is a bus that sends the IJ information to the IJ fifos on the top of each shader pipe. At the same time the control information goes to the sequencer

Name	Direction	Bits	Description

IJs	PA→RE	6~~3~~4	IJ information sent over 2 clocks
Mask	PA→RE	1	Write Mask

~~17.1.2~~18.1.2 *PA/SC to SEQ : IJ Control bus*

Formatted: Bullets and Numbering

This is the control information sent to the sequencer in order to control the IJ fifos and all other information needed to execute a shader program on the sent pixels.

Name	Direction	Bits	Description
Write Mask	PA→SEQ(RE)	4	Quad Write mask left to right
RB_ID	PA→SEQ(RE)	8	RB id for each quad sent 2 bits per quad
LOD_CORRECT	PA→SEQ(RE)	24	LOD correction per quad (6 bits per quad)
FVTX	PA→SEQ(RE)	2	Provoking vertex for flat shading
PPTR0	PA→SEQ(RE)	11	P Store pointer for vertex 0
PPRT1	PA→SEQ(RE)	11	P Store pointer for vertex 1
PPTR2	PA→SEQ(RE)	11	P Store pointer for vertex 2
E_OFF_VECTOR	PA→SEQ(RE)	1	End of the vector
DEALLOC	PA→SEQ(RE)	1	Deallocation token for the P Store
STATE	PA→SEQ(RE)	21	State/constant pointer (6*3+3)
VALID	PA→SEQ(RE)	16	Valid bits for all pixels
NULL	PA→SEQ(RE)	1	Null Primitive (for PC deallocation purposes)
E_OFF_PRIM	PA→SEQ(RE)	1	End Of the primitive
FBFACE	PA→SEQ(RE)	1	Front face = 1, back face = 0
~~STIPPLE_LINE~~TYPE	PA→SEQ(RE)	3~~1~~	Stippled line and Real time command need to load tex cords from alternate buffer 000 : Normal 001 : Stippled line 011 : Real Time 100 : Line AA 101 : Point AA 110 : Sprite
RTRn	SEQ→PA	1	Stalls the PA in n clocks
RTS	PA→SEQ(RE)	1	PA ready to send data
QuadX	PA→SEQ(RE)	~~40~~8	Quad X address ~~10~~ 2 bits per quad
QuadY	PA→SEQ(RE)	~~40~~8	Quad Y address ~~10~~ 2 bits per quad

~~17.1.3~~18.1.3 *~~PA/S~~VGT~~C~~ to RE : Vertex Bus*

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
Vertex indexes	VGT~~PA~~→RE	~~32~~128	Pointers of indexes or HOS surface information
EOF_vector	VGT→RE	1	End of the vector
Inputs_vert	VGT→RE	1	0: Normal 128 bits per vert 1: double 256 bits per vert

~~17.1.4~~18.1.4 *VGT~~PA/SC~~ to SEQ : Vertex Control Bus*

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
STATE	VGT~~PA~~→SEQ	21	Render State (6*3+3 for constants)
~~Write Mask~~Vert counter	VGT~~PA~~→SEQ	~~64~~?6	Which vertices are valid
Inputs_vert	VGT→SEQ	1	0: Normal 128 bits per vert 1: double 256 bits per vert

This information needs to be sent over 64 clocks.

~~17.1.5~~18.1.5 *CP to SEQ : Constant store load*

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
Constant Address	CP→SEQ	8	Address of the block of 4 constants

Constant Data	CP→SEQ	512	Data sent over 4 clocks
Remap Address	CP→SEQ	10	Remaping address write address
Remap Data pointer	CP→SEQ	8	Remaping pointer

~~17.1.6~~18.1.6 *CP to SEQ : ~~Texture~~Fetch State store load*

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
Constant Address	CP→SEQ	8	Address of the block of 4 state constants
Constant Data	CP→SEQ	512	Data sent over 4 clocks
Remap Address	CP→SEQ	10	Remaping address write address
Remap Data pointer	CP→SEQ	8	Remaping pointer

~~17.1.7~~18.1.7 *CP to SEQ : Control State store load*

Formatted: Bullets and Numbering

Name	Direction	Bits	Description

{ISSUE: How,Who and what is the size of this bus?}

~~17.1.8~~18.1.8 *MH to SEQ: Instruction store Load*

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
Instruction address	MH→SEQ	12	Instruction address
Instruction	MH→SEQ	96	Instruction X times
Control Instruction address	MH→SEQ	9	Pointer to the control instruction store
Control Instruction	MH→SEQ	32	Control Instruction X times

~~17.1.9~~18.1.9 *SP to RB : Pixel read from RBs*

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
~~Pixel Data~~Export_data	SP→RB	~~256~~64	~~2 pixels (or ½ quad)~~a pair of 32 bits channel values
ExportID	SP→RB	9	0cvvvvhqq: Vertex data vvvv 0-15 from first or second clause (c=0 or 1), XY or ZW components (h=0 or 1), quad 0-3 in the shader (qq= 0-3) 1cbbkttqq: Pixel data for buffer bb (0-3) from first or second clause (0-1) killed or not (k=1 or 0) quad 0-3 in the shader and data is RG (tt=0), BA (tt=1) or Z (tt=2)
ExportMask	SP→RB	2	Specifies whether to write low, high or both 32 bit words. If export mask is 00 data is invalid
ExportLast	SP→RB	1	Last export instruction of the clause

18.1.10 *SEQ to RB : Control bus*

Formatted: Bullets and Numbering

Name	**Direction**	**Bits**	**Description**
Type	SEQ→RB	1	0: Pixel 1: Vertex
Interleaving	SEQ→RB	1	0: first interleaved clause 1: second interleaved clause
Export_size	SEQ→RB	4	0 thru 16 parameters exported for vertexes (vvvv) OR (bbzs) 1-4 color buffers (bb), two component (s=0) or 4 component colors (s=1) with z (z=1) or without z (z=0)
Valid	SEQ→RB	1	Data valid

Only one exporting clause (7) can be selected at any given time.

18.1.11 *RB to SEQ : Output file control*

Formatted: Bullets and Numbering

Name	**Direction**	**Bits**	**Description**
Buff_Full	RB→SEQ	1	Set if full

Avail_size	RB→SEQ	6	Size available in output buffers (in 32bits increments)

~~17.1.10~~18.1.12 *SP to ~~PA/SC~~RB : Position return bus*

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
Position return	SP→~~PA~~RB	128	Position data or sprite size (per clock)
Parameter cache pointer	SP→~~PA~~RB	11	Pointer where the data will be in the parameter cache for each vertex

For point sprites and position exports the size and position are interleaved on a 16 x 16 basis. We export ~~16~~1 position~~s~~ then ~~16~~ 1 point sprite sizes. The storage used is of 64x128 bits for position and 64x32 bits for sprite size, it is taken from the output buffer. Additionnally,if needed the edge flags are packed into the bits of the sprite sizes.~~The registers are taken until the next ALU clause where they are going to be available again. Thus the sequencer has to make sure that we finished exporting data before allowing the program in the next ALU clause.~~

~~17.1.11~~18.1.13 *Shader Engine to ~~Texture~~Fetch Unit Bus (Fast Bus)*

Formatted: Bullets and Numbering

Four quad's worth of addresses is transferred to ~~Texture~~Fetch Unit every clock. These are sourced from a different pixel within each of the sub-engines repeating every 4 clocks. The register file index to read must precede the data by 2 clocks. The Read address associated with Quad 0 must be sent 1 clock after the Instruction Start signal is sent, so that data is read 3 clocks after the Instruction Start.

Four Quad's worth of ~~Texture~~Fetch Data may be written to the Register file every clock. These are directed to a different pixel of the sub-engines repeating every 4 clocks. The register file index to write must accompany the data. Data and Index associated with the Quad 0 must be sent 3 clocks after the Instruction Start signal is sent.

Name	Direction	Bits	Description
Tex_Read_Register_Index	SEQ->SP	7	Index into Register files for reading ~~Texture~~Fetch Address
Tex_RegFile_Read_Data	SP->TEX	2048	16 ~~Texture~~Fetch Addresses read from the Register file
Tex_Write_Register_Index	SEQ->TEX	7	Index into Register file for write of returned ~~Texture~~Fetch Data

~~17.1.12~~18.1.14 *Sequencer to ~~Texture~~Fetch Unit bus (Slow Bus)*

Formatted: Bullets and Numbering

Once every four clock, the ~~texture~~fetch unit sends to the sequencer on wich clause it is now working and if the data in the registers is ready or not. This way the sequencer can update the ~~texture~~fetch counters for the reservation station fifos. The sequencer also provides the intruction and constants for the~~ texture~~ fetch to execute and the address in the register file where to write the ~~texture~~fetch return data.

Name	Direction	Bits	Description
Tex_Ready	TEX→ SEQ	1	Data ready
Tex_Clause_Num	TEX→ SEQ	3	Clause number
Tex_cst	SEQ→TEX	10	~~Texture~~Fetch state address 10 bits sent over 4 clocks
Tex_Inst	SEQ→TEX	12	~~Texture f~~Fetch instruction address 12 bits sent over 4 clocks
EO_CLAUSE	SEQ→TEX	1	Last instruction of the clause
PHASE	SEQ→TEX	1	Write phase signal

Formatted: Bullets and Numbering

~~18.~~19. Internal interfaces

~~19.~~20. Examples of program executions

~~19.1.1~~20.1.1 *Sequencer Control of a Vector of Vertices*

1. PA sends a vector of 64 vertices (actually vertex indices – 32 bits/index for 2048 bit total) to the RE's Vertex FIFO
   - state pointer as well as tag into position cache is sent along with vertices
   - space was allocated in the position cache for transformed position before the vector was sent

- **also before the vector is sent to the RE, the CP has loaded the global instruction store with the vertex shader program (using the MH?)**
- The vertex program is assumed to be loaded when we receive the vertex vector.
    - the SEQ then accesses the IS base for this shader using the local state pointer (provided to all sequencers by the RBBM when the CP is done loading the program)

2. SEQ arbitrates between the Pixel FIFO and the Vertex FIFO – basically the Vertex FIFO always has priority
    - at this point the vector is removed from the Vertex FIFO
    - the arbitrer is not going to select a vector to be transformed if the parameter cache is full unless the pipe as nothing else to do (ie no pixels are in the pixel fifo).
3. SEQ allocates space in the SP register file for index data plus GPRs used by the program
    - the number of GPRs required by the program is stored in a local state register, which is accessed using the state pointer that came down with the vertices
    - SEQ will not send vertex data until space in the register file has been allocated
4. SEQ sends the vector to the SP register file over the RE_SP interface (which has a bandwidth of 2048 bits/cycle)
    - the 64 vertex indices are sent to the 64 register files over 4 cycles
        - RF0 of SU0, SU1, SU2, and SU3 is written the first cycle
        - RF1 of SU0, SU1, SU2, and SU3 is written the second cycle
        - RF2 of SU0, SU1, SU2, and SU3 is written the third cycle
        - RF3 of SU0, SU1, SU2, and SU3 is written the fourth cycle
    - the index is written to the least significant 32 bits **(floating point format?) (what about compound indices)** of the 128-bit location within the register file (w); the remaining data bits are set to zero (x, y, z)
5. SEQ constructs a control packet for the vector and sends it to the first reservation station (the FIFO in front of ~~texture~~fetch state machine 0, or TSM0 FIFO)
    - the control packet contains the state pointer, the tag to the position cache and a register file base pointer.
6. TSM0 accepts the control packet and fetches the instructions for ~~texture~~fetch clause 0 from the global instruction store
    - TSM0 was first selected by the TSM arbiter before it could start
7. all instructions of ~~texture~~fetch clause 0 are issued by TSM0
8. the control packet is passed to the next reservation station (the FIFO in front of ALU state machine 0, or ASM0 FIFO)
    - TSM0 does not wait for requests made to the ~~Texture~~Fetch Unit to complete; it passes the register file write index for the ~~texture~~fetch data to the TU, which will write the data to the RF as it is received
    - once the TU has written all the data to the register files, it increments a counter that is associated with ASM0 FIFO; a count greater than zero indicates that the ALU state machine can go ahead start to execute the ALU clause
9. ASM0 accepts the control packet (after being selected by the ASM arbiter) and gets the instructions for ALU clause 0 from the global instruction store
10. all instructions of ALU clause 0 are issued by ASM0, then the control packet is passed to the next reservation station (the FIFO in front of ~~texture~~fetch state machine 1, or TSM1 FIFO)
11. the control packet continues to travel down the path of reservation stations until all clauses have been executed
    - position can be exported in ALU clause 3 (or 4?); the data (and the tag) is sent over a position bus (which is shared with all four shader pipes) back to the PA's position cache
    - A parameter cache pointer is also sent along with the position data. This tells to the PA where the data is going to be in the parameter cache.
        - there is a position export FIFO in the SP that buffers position data before it gets sent back to the PA
        - the ASM arbiter will prevent a packet from starting an exporting clause if the position export FIFO is full
    - parameter data is exported in clause 7 (as well as position data if it was not exported earlier)
        - parameter data is sent to the Parameter Cache over a dedicated bus
        - the SEQ allocates storage in the Parameter Cache, and the SEQ deallocates that space when there is no longer a need for the parameters (it is told by the PA when using a token).
        - the ASM arbiter will prevent a packet from starting on ASM7 if the parameter cache (or the position buffer if position is being exported) is full

12. after the shader program has completed, the SEQ will free up the GPRs so that they can be used by another shader program

~~19.1.2~~20.1.2 *Sequencer Control of a Vector of Pixels*

Formatted: Bullets and Numbering

1. **As with vertex shader programs, pixel shaders are loaded into the global instruction store by the CP**
   - At this point it is assumed that the pixel program is loaded into the instruction store and thus ready to be read.
2. the RE's Pixel FIFO is loaded with the barycentric coordinates for pixel quads by the detailed walker
   - the state pointer and the LOD correction bits are also placed in the Pixel FIF0
   - the Pixel FIFO is wide enough to source four quad's worth of barycentrics per cycle
3. SEQ arbitrates between Pixel FIFO and Vertex FIFO – when there are no vertices pending OR there is no space left in the register files for vertices, the Pixel FIFO is selected
4. SEQ allocates space in the SP register file for all the GPRs used by the program
   - the number of GPRs required by the program is stored in a local state register, which is accessed using the state pointer
   - SEQ will not allow interpolated data to be sent to the shader until space in the register file has been allocated
5. SEQ controls the transfer of interpolated data to the SP register file over the RE_SP interface (which has a bandwidth of 2048 bits/cycle). See interpolated data bus diagrams for details.
6. SEQ constructs a control packet for the vector and sends it to the first reservation station (the FIFO in front of ~~texture~~fetch state machine 0, or TSM0 FIFO)
   - note that there is a separate set of reservation stations/arbiters/state machines for vertices and for pixels
   - the control packet contains the state pointer, the register file base pointer, and the LOD correction bits
   - all other informations (such as quad address for example) travels in a separate FIFO
7. TSM0 accepts the control packet and fetches the instructions for ~~texture~~fetch clause 0 from the global instruction store
   - TSM0 was first selected by the TSM arbiter before it could start
8. all instructions of ~~texture~~fetch clause 0 are issued by TSM0
9. the control packet is passed to the next reservation station (the FIFO in front of ALU state machine 0, or ASM0 FIFO)
   - TSM0 does not wait for ~~texture~~fetch requests made to the ~~Texture~~Fetch Unit to complete; it passes the register file write index for the ~~texture~~fetch data to the TU, which will write the data to the RF as it is received
   - once the TU has written all the data for a particular clause to the register files, it increments a counter that is associated with the ASM0 FIFO; a count greater than zero indicates that the ALU state machine can go ahead and pop the FIFO and start to execute the ALU clause
10. ASM0 accepts the control packet (after being selected by the ASM arbiter) and gets the instructions for ALU clause 0 from the global instruction store
11. all instructions of ALU clause 0 are issued by ASM0, then the control packet is passed to the next reservation station (the FIFO in front of ~~texture~~fetch state machine 1, or TSM1 FIFO)
12. the control packet continues to travel down the path of reservation stations until all clauses have been executed
    - pixel data is exported in the last ALU clause (clause 7)
      - it is sent to an output FIFO where it will be picked up by the render backend
      - the ASM arbiter will prevent a packet from starting on ASM7 if the output FIFO is full
13. after the shader program has completed, the SEQ will free up the GPRs so that they can be used by another shader program

~~19.1.3~~20.1.3 *Notes*

Formatted: Bullets and Numbering

14. the state machines and arbitrers will operate ahead of time so that they will be able to immediately start the real threads or stall.

15. the register file base pointer for a vector needs to travel with the vector through the reservation stations, but the instruction store base pointer does not – this is because the RF pointer is different for all threads, but the IS pointer is only different for each state and thus can be accessed via the state pointer

16. Waterfalling, parameter buffer allocation, loops and branches and parameter cache de-allocation still needs to be specked out.

~~20.~~21. Open issues

Formatted: Bullets and Numbering

There is currently an issue with constants. If the constants are not the same for the whole vector of vertices, we don't have the bandwith from the ~~texture~~fetch store to feed the ALUs. Two solutions exists for this problem:

1) Let the compiler handle the case and put those instructions in a ~~texture~~fetch clause so we can use the bandwith there to operate. This requires a significant amount of temporary storage in the register store.
2) Waterfall down the pipe allowing only at a given time the vertices having the same constants to operate in parrallel. This might in the worst case slow us down by a factor of 16.

Need to do some testing on the size of the register file as well as on the register file allocation method (dynamic VS static).

Saving power?

Size of the fifo containing the information of a vector of pixels/vertices. And size of the fifos before the reservation stations.

Loops and branches.

R400 Sequencer Specification

SEQ

Version 0.9~~8~~

Overview: This is an architectural specification for the R400 Sequencer block (SEQ). It provides an overview of the required capabilities and expected uses of the block. It also describes the block interfaces, internal sub-blocks, and provides internal state diagrams.

AUTOMATICALLY UPDATED FIELDS:

Document Location: C:\perforce\r400\arch\doc\gfx\RE\R400_Sequencer.doc

Revision Changes:

Rev 0.1 (Laurent Lefebvre) Date: May 7, 2001	First draft.
Rev 0.2 (Laurent Lefebvre) Date : July 9, 2001	Changed the interfaces to reflect the changes in the SP. Added some details in the arbitration section.
Rev 0.3 (Laurent Lefebvre) Date : August 6, 2001	Reviewed the Sequencer spec after the meeting on August 3, 2001.
Rev 0.4 (Laurent Lefebvre) Date : August 24, 2001	Added the dynamic allocation method for register file and an example (written in part by Vic) of the flow of pixels/vertices in the sequencer.
Rev 0.5 (Laurent Lefebvre) Date : September 7, 2001	Added timing diagrams (Vic)
Rev 0.6 (Laurent Lefebvre) Date : September 24, 2001	Changed the spec to reflect the new R400 architecture. Added interfaces.
Rev 0.7 (Laurent Lefebvre) Date : October 5, 2001	Added constant store management, instruction store management, control flow management and data dependant predication.
Rev 0.8 (Laurent Lefebvre) Date : October 8, 2001	Changed the control flow method to be more flexible. Also updated the external interfaces.
Rev 0.9 (Laurent Lefebvre) Date : October 17, 2001	Incorporated changes made in the 10/18/01 control flow meeting. Added a NOP instruction, removed

the conditional_execute_or_jump. Added debug registers.

1. Overview

The sequencer first arbitrates between vectors of 64 vertices that arrive directly from primitive assembly and vectors of 16 quads (64 pixels) that are generated in the raster engine.

The vertex or pixel program specifies how many GPR's it needs to execute. The sequencer will not start the next vector until the needed space is available.

The sequencer is based on the R300 design. It chooses two ALU clauses and a fetch clause to execute, and executes all of the instructions in a clause before looking for a new clause of the same type. Two ALU clauses are executed interleaved to hide the ALU latency. Each vector will have eight fetch and eight ALU clauses, but clauses do not need to contain instructions. A vector of pixels or vertices ping-pongs along the sequencer FIFO, bouncing from fetch reservation station to alu reservation station. A FIFO exists between each reservation stage, holding up vectors until the vector currently occupying a reservation station has left. A vector at a reservation station can be chosen to execute. The sequencer looks at all eight alu reservation stations to choose an alu clause to execute and all eight fetch stations to choose a fetch clause to execute. The arbitrator will give priority to clauses/reservation stations closer to the bottom of the pipeline. It will not execute an alu clause until the fetch fetches initiated by the previous fetch clause have completed. There are two separate sets of reservation stations, one for pixel vectors and one for vertices vectors. This way a pixel can pass a vertex and a vertex can pass a pixel.

To support the shader pipe the raster engine also contains the shader instruction cache and constant store. There are only one constant store for the whole chip and one instruction store. These will be shared among the four shader pipes. The four shader pipes also execute the same instuction thus there is only one sequencer for the whole chip.

There are two sets of the above figure, one for vertices and one for pixels.

The rasterizer always checks the vertices FIFO first and if allowed by the sequencer sends the data to the shader. If the vertex FIFO is empty then, the rasterizer takes the first entry of the pixel FIFO (a vector of 64 pixels) and sends it to the interpolators. Then the sequencer takes control of the packet. The packet consists of 21 bits of state, 6-7 bits for the base address of the Shader program and some information on the coverage to determine fetch LOD plus other various small state bits. ~~All other information (2x2 adresses) is put in a FIFO (one for the pixels and one for the vertices) and retrieved when the packet finishes its last clause.~~

On receipt of a packet, the input state machine (not pictured but just before the first FIFO) allocated enough space in the registers to store the interpolated values and temporaries. Following this, the input state machine stacks the packet in the first FIFO.

On receipt of a command, the level 0 fetch machine issues a texure request and corresponding register address for the fetch address (ta). A small command (tcmd) is passed to the fetch system identifying the current level number (0) as well as the register write address for the fetch return data. One fetch request is sent every 4 clocks causing the texturing of sixteen 2x2s worth of data (or 64 vertices). Once all the requests are sent the packet is put in FIFO 1.

Upon recept of the return data, the fetch unit writes the data to the register file using the write address that was provided by the level 0 fetch machine and sends the clause number (0) to the level 0 fetch state machine to signify that the write is done and thus the data is ready. Then, the level 0 fetch machine increments the counter of FIFO 1 to signify to the ALU 1 that the data is ready to be processed.

On receipt of a command, the level 0 ALU machine first decrements the input FIFO counter and then issues a complete set of level 0 shader instructions. For each instruction, the state machine generates 3 source addresses, one destination address (3 cycles later) and an instruction. Once the last instruction as been issued, the packet is put into FIFO 2.

There will always be two active ALU clauses at any given time (and two arbitrers). One arbitrer will arbitrate over the odd instructions (4 clocks cycles) and the other one will arbitrate over the even instructions (4 clocks cycles). The only constraints between the two arbitrers is that they are not allowed to pick the same clause number as they other one is currently working on if the packet os of the same type.

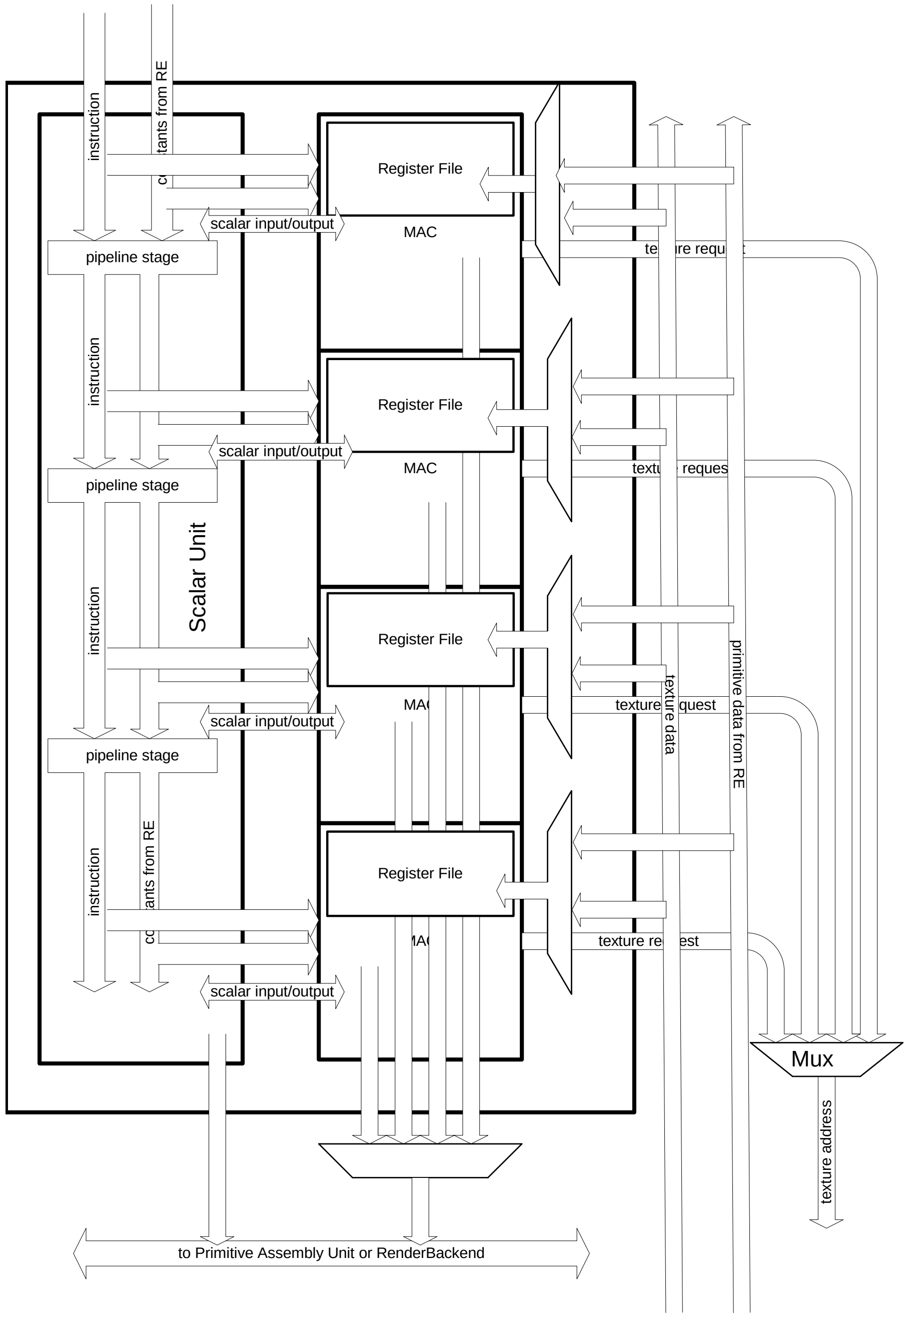
If the packet is a vertex packet, upon reaching ALU clause 3~~4~~, it can export the position if the position is ready. So the arbitrer must prevent ALU clause 3~~4~~ to be selected if the positional buffer is full (or can't be accessed). Along with the positional data, the location where the vertex data is to be put is also sent (parameter data pointers).

A special case is for HOS surfaces wich can export 12 parameters per clause to the output buffer. If the output buffer is full or doesn't have enough space the sequencer will prevent such a vertex group to enter an exporting clause.

All other level process in the same way until the packet finally reaches the last ALU machine (8). On completion of the level 8 ALU clause, a valid bit is sent to the Render Backend which picks up the color data. This requires that the last instruction writes to the output register – a condition that is almost always true. If the packet was a vertex packet, instead of sending the valid bit to the RB, it is sent to the PA so it can know that the data present in the parameter store is valid.

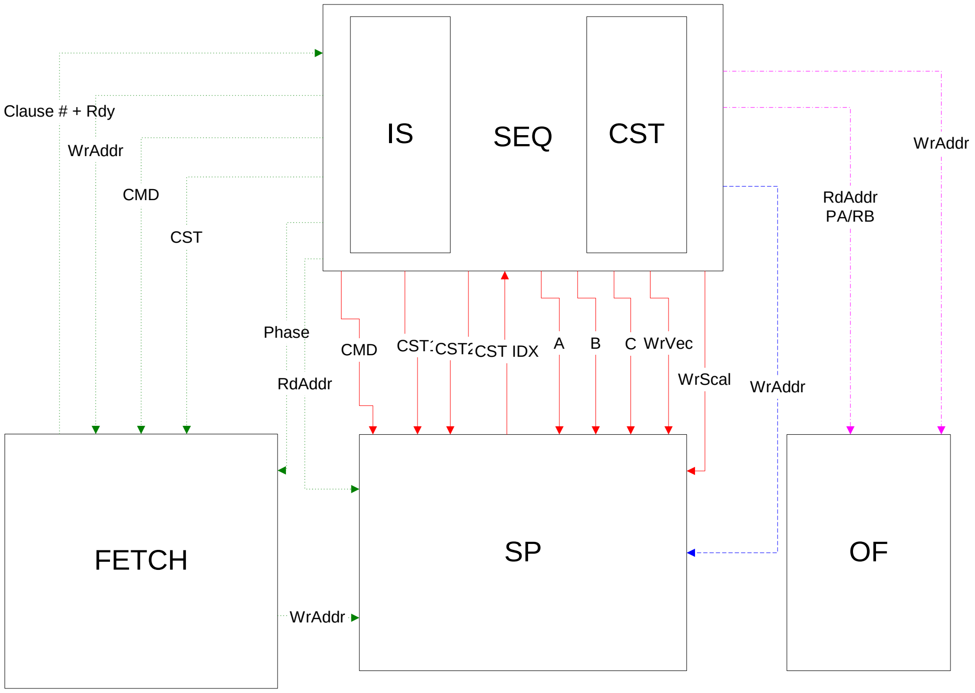
Only two ALU state machine may have access to the register file address bus or the instruction decode bus at one time. Similarly, only one fetch state machine may have access to the register file address bus at one time. Arbitration is performed by three arbitrer blocks (two for the ALU state machines and one for the fetch state machines). The arbitrers always favor the higher number state machines, preventing a bunch of half finished jobs from clogging up the register files.

1.2 Data Flow graph



The gray area represents blocks that are replicated 4 times per shader pipe (16 times on the overall chip).

1.3 Control Graph



In green is represented the Fetch control interface, in red the ALU control interface, in blue the Interpolated/Vector control interface and in purple is the output file control interface.

2. Interpolated data bus

The interpolators contain an IJ buffer to pack the information as much as possible before writing it to the register file.

P0

P1

Above is an example of a tile we might receive. The IJ information is packed in the IJ buffer 2 quads at a time. The sequencer allows at any given time as many as four quads to interpolate a parameter. They all have to come from the same primitive. Then the sequencer controls the write mask to the register to write the valid data in.

3. Instruction Store

There is going to be only one instruction store for the whole chip. It will contain 4096 instructions of 96 bits each. There is also going to be a control instruction store of size 256(512?)x32.

{ISSUE : The instruction store is loaded by the sequencer using the memory hub ?}.

The read bandwith from this store is 96*2 bits/ 4 clocks (48 bits/clock). It is likely to be a 1 port memory; we use 1 clock to load the ALU instruction, 1 clocks to load the Fetch instruction, 1 clock to load 2 control flow instructions and 1 clock to write instructions.

4. Sequencer Instructions

All control flow instructions and move instructions are handled by the sequencer only. The ALUs will perform NOPs during this time (MOV PV,PV, PS,PS).

5. Constant Store

The constant store is managed by the CP. The sequencer is aware of where the constants are using a remaping table also managed by the CP. A likely size for the constant store is 512x128 bits. The constant store is also planned to be shared. The read BW from the constant store is 128 bits/clock and the write bandwith is 32/4 bits/clock.

In order to do constant store indexing, the sequencer must be loaded first with the indexes (that come from the GPRs). There are 144 wires from the exit of the SP to the sequencer (9 bits pointers x 16 vertexes/clock). Since the data must pass thru the Shader pipe for the float to fixed convertion, there is a latency of 4 clocks (1 instruction) between the time the sequencer is loaded and the time one can index into the constant store. The assembly will look like this

```
MOVA  R1.X,R2.X       // Loads the sequencer with the content of R2.X, also copies the content of R2.X into R1.X
NOP                   // latency of the float to fixed conversion
ADD   R3,R4,C0[R2.X]// Uses the state from the sequencer to add R4 to C0[R2.X] into R3
```

Note that we don't really care about what is in the brackets because we use the state from the MOVA instruction. R2.X is just written again for the sake of simplicity.

The storage needed in the sequencer in order to support this feature is 2*64*9 bits = 1152 bits.

6. Looping and Branches

Loops and branches are planned to be supported and will have to be dealt with at the sequencer level. We plan on supporting constant loops and branches using a control program. ~~The control program has 4(5) instructions:~~

6.1 The controlling state.

As per Dx9 the following state is available for control flow:

Boolean[15:0]
loop_count[7:0][7:0]
In addition:
loop_start [7:0] [7:0]
loop_step [7:0] [7:0]
Exist to give more control to the controlling program.

We will extend that in the R400 to:

Boolean[255:0]
Loop_count[7:0][15:0]
Loop_Start[7:0] [15:0] times 2 (one for constant,registert)
Loop_Step[7:0] [15:0] times 2 (one for constant,register)
Loop_End[7:0] [15:0]

{ISSUE: How is the controlling state loaded and how many contexts do we have?}

We have a stack of 4 elements for calling subroutines and 4 loop counters to allow for nested loops.

We also keep 8 predicate vectors and 8 AND/OR sets of 3 bits. These bits can be 0: all 0s, 1: all ones and 11: mixed.

6.2 The Control Flow Program

The R300 uses a match method for control flow: The shader is executed, and at every instruction its address is compared with addresses (or address?) in a control table. The “event” in the control table can redirect operations in the program.

The Method chosen for the R400 is a “control program”. The control program has ten basic instructions:

Execute
Conditional_execute
Conditional_Execute_Predicates
Conditional_execute_or_Jump
Conditional_jump
Call
Return
Loop_start
Loop_end
End_of_clause

Execute, causes the specified number of instructions in instruction store to be executed.
Conditional_execute checks a condition first, and if true, causes the specified number of instructions in instruction store to be executed.
Loop_start resets the corresponding loop counter to the start value on the first pass after it checks for the end condition and if met jumps over to a specified address.
Loop_end increments (decrements?) the loop counter and jumps back the specified number of instructions.
Call jumps to an address and pushes the IP counter on the stack. On the return instruction, the IP is poped from the stack.
Conditional_execute_or_Jump executes a block of instructions or jumps to an address is the condition is not met.
Conditional_execute_Predicates executes a block of instructions if all bits in the predicate vectors meet the condition.
End_of_clause marks the end of a clause.
Conditional_jumps jumps to an address if the condition is met.
NOP is a regular NOP

NOTE THAT ALL JUMPS MUST JUMP TO EVEN CFP ADDRESSES. Thus the compiler must insert NOPs where needed to align the jumps on even CFP addresses.

Also if the jump is logically bigger than 4096 we break the program and set the debug registers.

We have to fit instructions into 48 bits in order to be able to put two control flow instruction per line in the instruction store.

Execute				
47	46… 42	41 … 24	23 … 12	11 … 0
Addressing	00001	RESERVED	Instruction _count	Exec Address

Execute up to 4k instructions at the specified address in the instruction memory.

~~Conditionnal_Execute_or_Jump~~NOP		
47	46 … 42	~~41 … 34~~ ~~33~~ ~~32 … 21~~ ~~20 … 12~~ ~~11 … 0~~41 … 0
Addressing	00010	~~Booleans~~ ~~Condition~~ ~~Jump address~~ ~~Instruction_count~~ ~~Exec Address~~RESERVED

If the specified boolean (8 bits can address 256 booleans) meets the specified condition then execute the specified instructions (up to 512 instructions) or if the condition is not met jump to the jump address in the control flow program. This MUST be a forward jump.

Conditionnal_Execute						
47	46 … 42	41 … 34	33	32 … 24~~1~~	2~~0~~3 … 12	11 … 0
Addressing	00011	Boolean address	Condition	RESERVED	Instruction_count	Exec Address

If the specified boolean (8 bits can address 256 booleans) meets the specified condition then execute the specified instructions (up to 4k~~512~~ instructions)

Conditionnal_Execute_Predicates						
47	46 … 42	41 … 38	37	36 … 24~~1~~	2~~0~~3 … 12	11 … 0
Addressing	00100	Predicate vector	Condition	RESERVED	Instruction_count	Exec Address

Check the AND/OR of all current predicate bits. If AND/OR matches the condition execute the specified number of instructions.

Loop_Start				
47	46 … 42	41 … 16	15 … 4	3 … 0
Addressing	00101	RESERVED	Jump address	Loop ID

Loop Start. Compares the loop count with the end value. If loop condition not met jump to the address. Forward jump only. Also computes the index value.

Loop_End				
47	46 … 42	41 … 16	15 … 4	3 … 0
Addressing	00111	RESERVED	Start address	Loop ID

Loop end. Increments the counter by one and jumps BACK only to the start of the loop.

The way this is described does not prevent nested loops, and the inclusion of the loop id make this easy to do.

Call			
47	46 … 42	41…12	11 … 0
Addressing	01000	RESERVED	Address

Jumps to the specified address and pushes the IP counter on the stack.

Return		
47	46 … 42	41 … 0
Addressing	01001	RESERVED

Pops the topmost address from the stack and jumps to that address. If nothing is on the stack, the program will just continue to the next instruction.

Conditionnal_Jump					
47	46 … 42	41 … 34	33	32 … 12	11 … 0
Addressing	01010	Boolean address	Condition	RESERVED	Address

If condition met, jumps to the address. FORWARD jump only allowed.

End_of_Clause		
47	46 … 42	41 … 0
Addressing	01011	RESERVED

Marks the end of a clause.

To prevent infinite loops, we will keep 9 bits loop counters instead of 8 (we are only able to loop 256 times). If the counter goes higher than 255 then the loop_end or the loop_start is going to break the loop and set de debug registers. The sequencer will keep ~~a~~ two loop indexes values~~ of 17 bits~~:

IC index for constant indexing (9 bits)

IR index for register file indexing (7 bits)

~~.~~ This will be updated everytime we loop and can only be used to index the constant store and the register file. The way to compute this value is:

Index = Loop_counter*Loop_iterator + Loop_init.

The IC for constant is going to return 0 if it is out of the constant range. The IR index is going to break the program if the index exeeds the number of requested registers.

The basic model is as follows:

The render state defined the clause boundaries:
Vertex_shader_fetch[7:0][7:0] // eight 8 bit pointers to the location where each clauses control program is located
Vertex_shader_alu[7:0][7:0] // eight 8 bit pointers to the location where each clauses control program is located
Pixel_shader_fetch[7:0][7:0] // eight 8 bit pointers to the location where each clauses control program is located
Pixel_shader_alu[7:0][7:0] // eight 8 bit pointers to the location where each clauses control program is located

The control program for a given clause is executed to completion before moving to another clause, (with the exception of the pick two nature of the alu execution). The control program is the only program aware of the clause boundaries.

6.3 Data dependant predicate instructions

Data dependant conditionals will be supported in the R400. The only way we plan to support those is by supporting three vector/scalar predicate operations of the form:

PRED_SETE_# - similar to SETE except that the result is 'exported' to the sequencer.
PRED_SETGT_# - similar to SETGT except that the result is 'exported' to the sequencer
PRED_SETGTE_# - similar to SETGTE except that the result is 'exported' to the sequencer

For the scalar operations only we will also support the two following instructions:
PRED_SETE0_# – SETE0
PRED_SETE1_# – SETE1

The export is a single bit - 1 or 0 that is sent using the same data path as the MOVA instruction. The sequencer will maintain 4 sets of 64 bit predicate vectors (in fact 8 sets because we interleave two programs but only 4 will be exposed) and use it to control the write masking. This predicate is not maintained across clause boundaries. The # sign is used to specify wich predicate set you want to use 0 thru 3.

Then we have two conditional execute bits. The first bit is a conditional execute “on” bit and the second bit tells us if we execute on 1 or 0. For exemple, the instruction :

P0_ADD_# R0,R1,R2

Is only going to write the result of the ADD into those GPRs whose predicate bit is 0. Alternatively, P1_ADD_# would only write the results to the GPRs whose predicate bit is set. The use of the P0 or P1 without precharging the sequencer with a PRED instruction is undefined.

{Issue: do we have to have a NOP between PRED and the first instruction that uses a predicate?}

6.4 Register file indexing

Because we can have loops in fetch clause, we need to be able to index into the register file in order to retrieve the data created in a fetch clause loop and use it into an ALU clause. The instruction will include the base address for register indexing and the instruction will contain these controls :

Bit7	Bit 6	
0	0	'absolute register'
0	1	'relative register'
1	0	'previous vector'
1	1	'previous scalar'

In the case of an absolute register we just take the address as is. In the case of a relative register read we take the base address and we add to it the loop_index and this becomes our new address that we give to the shader pipe.

Formatted: Bullets and Numbering

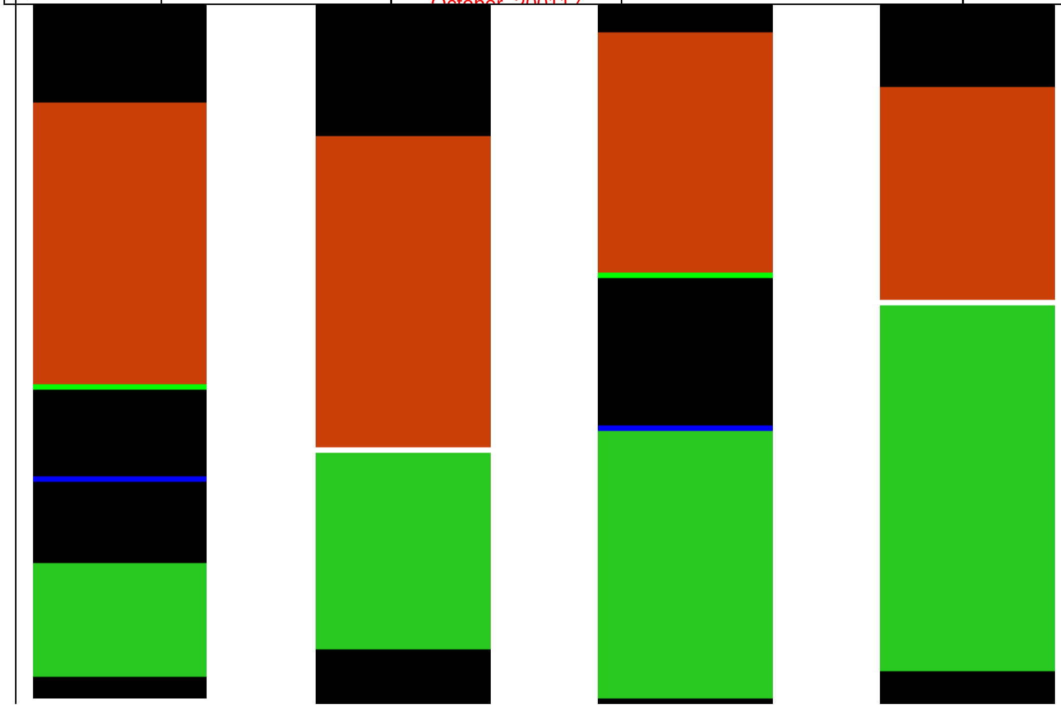
7. HOS surfaces

HOS surfaces are able to export from any clause but to memory ONLY. If they want to export to the parameter cache they have to do it in the last clause (7). They can also export position in clause 3. The buffer they want to export into must be specified in the "exports" field of the state registers.

Formatted: Bullets and Numbering

~~7.~~8. Register file allocation

The register file allocation for vertices and pixels can either be static or dynamic. In both cases, the register file in managed using two round robins (one for pixels and one for vertices). In the dynamic case the boundary between pixels and vertices is allowed to move, in the static case it is fixed to VERTEX_REG_SIZE for vertices and 256-VERTEX_REG_SIZE for pixels.



Above is an example of how the algorithm works. Vertices come in from top to bottom; pixels come in from bottom to top. Vertices are in orange and pixels in green. The blue line is the tail of the vertices and the green line is the tail of the pixels. Thus anything between the two lines is shared. When pixels meets vertices the line turns white and the boundary is static until both vertices and pixels share the same “unallocated bubble”. Then the boundary is allowed to move again.

~~8.~~9. Fetch Arbitration

Formatted: Bullets and Numbering

The fetch arbitration logic chooses one of the 8 potentially pending fetch clauses to be executed. The choice is made by looking at the fifos from 7 to 0 and picking the first one ready to execute. Once chosen, the clause state machine will send one 2x2 fetch per clock (or 4 fetches in one clock every 4 clocks) until all the fetch instructions of the clause are sent. This means that there cannot be any dependencies between two fetches of the same clause.

The arbitrator will not wait for the fetches to return prior to selecting another clause for execution. The fetch pipe will be able to handle up to X(?) in flight fetches and thus there can be a fair number of active clauses waiting for their fetch return data.

~~9.~~10. ALU Arbitration

Formatted: Bullets and Numbering

ALU arbitration proceeds in almost the same way than fetch arbitration. The ALU arbitration logic chooses one of the 8 potentially pending ALU clauses to be executed. The choice is made by looking at the fifos from 7 to 0 and picking the first one ready to execute. There are two ALU arbitrers, one for the even clocks and one for the odd clocks. For exemple, here is the sequencing of two interleaved ALU clauses (E and O stands for Even and Odd sets of 4 clocks):

Einst0 Oinst0 Einst1 Oinst1 Einst2 Oinst2 Einst0 Oinst3 Einst1 Oinst4 Einst2 Oinst0…
Proceeding this way hides the latency of 8 clocks of the ALUs.

Formatted: Bullets and Numbering

~~10.~~11. Handling Stalls

When the output file is full, the sequencer prevents the ALU arbitration logic to select the last clause (this way nothing can exit the shader pipe until there is place in the output file. If the packet is a vertex packet and the position buffer is full (POS_FULL) then the sequencer also prevents a thread to enter the exporting clause (4?). The sequencer will set the OUT_FILE_FULL signal n clocks before the output file is actually full and thus the ALU arbitrer will be able read this signal and act accordingly by not preventing exporting clauses to proceed.

Formatted: Bullets and Numbering

~~11.~~12. Content of the reservation station FIFOs

~~3~~21 bits of Render State ~~6~~77 bits for the base address of the ~~instruction~~ GPRs~~store~~, some bits for LOD correction and coverage mask information in order to fetch fetch for only valid pixels, quad address and 1 bit to specify if the vector is of pixels or vertices. ~~Every other information (such as the coverage mask, quad address, etc.) is put in a FIFO and is retrieved when the quad exits the shader pipe to enter in the output file buffer.~~ Since pixels and vertices are kept in order in the shader pipe, we only need two fifos (one for vertices and one for pixels) deep enough to cover the shader pipe latency. This size will be determined later when we will know the size of the small fifos between the reservation stations.

For texture clauses, 3 bits * 4 are going to be kept. These are the AND/OR of the predicate vectors. 0 for all 0s, 1 for all ones and MIXED.

Formatted: Bullets and Numbering

~~12.~~13. The Output File

The output file is where pixels are put before they go to the RBs. The write BW to this store is 256 bits/clock. Just before this output file are staging registers with write BW 512 bits/clock and read BW 256 bits/clock. For this reason only ONE concurrent program can be of clause 8 (exporting clause) the other program MUST not. The staging registers are 4x128 (and there are 16 of those on the whole chip).

Formatted: Bullets and Numbering

~~13.~~14. IJ Format

The IJ information sent by the PA is of this format on a per quad basis:

We have a vector of IJ's (one IJ per pixel at the centroid of the fragment or at the center of the pixel depending on the mode bit). The interpolation is done at a different precision across the 2x2. The upper left pixel's parameters are always interpolated at full 19x24 mantissa precision. Then the result of the interpolation along with the difference in IJ in reduced precision is used to interpolate the parameter for the other three pixels of the 2x2. Here is how we do it:

Assuming P0 is the interpolated parameter at Pixel 0 having the barycentric coordinates I(0), J(0) and so on for P1,P2 and P3. Also assuming that A is the parameter value at V0 (interpolated with I), B is the parameter value at V1 (interpolated with J) and C is the parameter value at V2 (interpolated with (1-I-J).

$$\Delta 01I = I(1) - I(0)$$
$$\Delta 01J = J(1) - J(0)$$
$$\Delta 02I = I(2) - I(0)$$
$$\Delta 02J = J(2) - J(0)$$
$$\Delta 03I = I(3) - I(0)$$
$$\Delta 03J = J(3) - J(0)$$

P0	P1
P2	P3

$$P0 = C + I(0) * (A - C) + J(0) * (B - C)$$
$$P1 = P0 + \Delta 01I * (A - C) + \Delta 01J * (B - C)$$
$$P2 = P0 + \Delta 02I * (A - C) + \Delta 02J * (B - C)$$
$$P3 = P0 + \Delta 03I * (A - C) + \Delta 03J * (B - C)$$

P0 is computed at 19x24 mantissa precision and P1 to P3 are computed at 8X24 mantissa precision. So far no visual degradation of the image was seen using this scheme.

Multiplies (Full Precision): 2
Multiplies (Reduced precision): 6
Subtracts 19x24 (Parameters): 2
Adds: 8

FORMAT OF P0's IJ : Mantissa 19 Exp 4 for I + Sign
Mantissa 19 Exp 4 for J + Sign

FORMAT of Deltas (x3):Mantissa 8 Exp 4 for I + Sign
Mantissa 8 Exp 4 for J + Sign

Total number of bits : 19*2 + 8*6 + 4*8 + 4*2 = 126

Formatted: Bullets and Numbering

~~14.~~15. The parameter cache

The parameter cache is where the vertex shaders export their data. It consists of 16 128x128 memories (1R/1W). The reuse engine will make it so that all vertexes of a given primitive will hit different memories.

Formatted: Bullets and Numbering

~~15.~~16. Vertex position exporting

On clause 4 (or 5) the vertex shader can export to the PA both the vertex position and the point sprite. It can also do so at clause 8 if not done at clause 4. Along with the position is exported a pointer to the parameter cache where the data will be once the vertex shader exports. The storage needed to perform the position export is at least 64x128 memories for the position and 64x32 memories for the sprite size. It is going to be taken in the pixel output fifo.

Formatted: Bullets and Numbering

~~16.~~17. Real time commands

We are unable to use the parameter memory since there is no way for a command stream to write into it. Instead we need to add three 16x128 memories (one for each of three vertices x 16 interpolants). These will be mapped onto the register bus and written by type 0 packets, and output to the the parameter busses (the sequencer and/or PA need to be able to address the realtime parameter memory as well as the regular parameter store. For higher performance we should be able able to view them as two banks of 16 and do double buffering allowing one to be loaded, while the other is rasterized with. Most overlay shaders will need 2 or 4 scalar coordinates, one option might be to restrict the memory to 16x64 or 32x64 allowing only two interpolated scalars per cycle, the only problem I see with this is, if we view support for 16 vector-4 interpolants important (true only if we map microsoft's high priority stream to the realtime stream), then the PA/sequencer need to support a realtime-specific mode where we need to address 32 vectors of parameters instead of 16.

~~17.~~18. Registers

Formatted: Bullets and Numbering

DYNAMIC_REG	Dynamic allocation (pixel/vertex) of the register file on or off.
VERTEX_REG_SIZE	What portion of the register file is reserved for vertices (static allocation only)
PIXEL_MIN_SIZE	Minimal size of the register file's pixel portion (dynamic only)
VERTEX_MIN_SIZE	Minimal size of the register file's vertex portion (dynamic only)
Vshader_fetch[11:0][7:0]	eight 12 bit pointers to the location where each clauses control program is located
Vshader_alu[11:0][7:0]	eight 12 bit pointers to the location where each clauses control program is located
Pshader_fetch[11:0][7:0]	eight 12 bit pointers to the location where each clauses control program is located
Pshader_alu[11:0][7:0]	eight 12 bit pointers to the location where each clauses control program is located
PSHADER	base pointer for the pixel shader
VSHADER	base pointer for the vertex shader
VWRAP	wrap point for the vertex shader instruction store
PWRAP	wrap point for the pixel shader instruction store
REG_ALLOC_PIX	number of registers to allocate for pixel shader programs
REG_ALLOC_VERT	number of registers to allocate for vertex shader programs
PARAM_MASK[0…16]	parameter mask to specify how parameters maps in the pixel shader
FLAT_GOUR[0…16]	wich parameters are to be gouraud shaded
GEN_TEX[0….16]	for wich parameters do we need to generate tex coords.
CYL_WRAP[0…64]	for wich parameters (and channels (xyzw)) do we do the cyl wrapping.
P_EXPORT[8]	number of exports for pixel shader
V_EXPORT[8]	number of exports for vertex shader for each clause. All numbers relate to the output buffer exports but for V_EXPORT[7] than can relate to the PC if Exports[7] is set to 00000.~~(also the number of interpolated parameters for pixel shaders)~~
~~V_EXPORT_LOC~~	~~Vertex shader exporting to RB or the PCACHE~~
ARBITRATION_policy	policy of the arbitration between vetexes and pixels
Exports[8][6]	Wich clause is exporting to the output buffer and what is it exporting.
	000000 : Not exporting (or exporting only to the PC)
	000001 : Exporting position (1)
	000010 : Exporting position (2)
	(1)00100 : Exporting RG
	(1)01000 : Exporting BA
	(1)10000 : Exporting Z
	If MSB set pixel shader exporting linear to memory not to Frame Buffer.
CST_SIZE_P	Size of the constant store for pixels
CST_SIZE_V	Size of the constant store for vertexes

19. DEBUG registers

Formatted: Bullets and Numbering

PROB_ADDR	instruction address where the first problem occurred
PROB_COUNT	number of problems encountered during the execution of the program

~~18.~~20. Interfaces

Formatted: Bullets and Numbering

~~18.1~~20.1 External Interfaces

~~18.1.1~~20.1.1 *PA/SC to RE : IJ bus*

This is a bus that sends the IJ information to the IJ fifos on the top of each shader pipe. At the same time the control information goes to the sequencer

Name	Direction	Bits	Description
IJs	PA→RE	63	IJ information sent over 2 clocks
Mask	PA→RE	1	Write Mask

~~18.1.2~~20.1.2 PA/SC to SEQ : IJ Control bus

Formatted: Bullets and Numbering

This is the control information sent to the sequencer in order to control the IJ fifos and all other information needed to execute a shader program on the sent pixels.

Name	Direction	Bits	Description
Write Mask	PA→SEQ(RE)	4	Quad Write mask left to right
RB_ID	PA→SEQ(RE)	8	RB id for each quad sent 2 bits per quad
LOD_CORRECT	PA→SEQ(RE)	24	LOD correction per quad (6 bits per quad)
FVTX	PA→SEQ(RE)	2	Provoking vertex for flat shading
PPTR0	PA→SEQ(RE)	11	P Store pointer for vertex 0
PPRT1	PA→SEQ(RE)	11	P Store pointer for vertex 1
PPTR2	PA→SEQ(RE)	11	P Store pointer for vertex 2
E_OFF_VECTOR	PA→SEQ(RE)	1	End of the vector
DEALLOC	PA→SEQ(RE)	1	Deallocation token for the P Store
STATE	PA→SEQ(RE)	21	State/constant pointer (6*3+3)
VALID	PA→SEQ(RE)	16	Valid bits for all pixels
NULL	PA→SEQ(RE)	1	Null Primitive (for PC deallocation purposes)
E_OFF_PRIM	PA→SEQ(RE)	1	End Of the primitive
FBFACE	PA→SEQ(RE)	1	Front face = 1, back face = 0
TYPE	PA→SEQ(RE)	3	Stippled line and Real time command need to load tex cords from alternate buffer 000 : Normal 001 : Stippled line 011 : Real Time 100 : Line AA 101 : Point AA 110 : Sprite
RTRn	SEQ→PA	1	Stalls the PA in n clocks
RTS	PA→SEQ(RE)	1	PA ready to send data
QuadX	PA→SEQ(RE)	8	Quad X address 2 bits per quad
QuadY	PA→SEQ(RE)	8	Quad Y address 2 bits per quad

~~18.1.3~~20.1.3 VGT to RE : Vertex Bus

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
Vertex indexes	VGT→RE	128	Pointers of indexes or HOS surface information
EOF_vector	VGT→RE	1	End of the vector
Inputs_vert	VGT→RE	1	0: Normal 128 bits per vert 1: double 256 bits per vert
STATE	VGT→SEQ	21	Render State (6*3+3 for constants)

~~18.1.4VGT to SEQ : Vertex Control Bus~~

Formatted: Bullets and Numbering

~~This information needs to be sent over 64 clocks.~~

~~18.1.5~~20.1.4 CP to SEQ : Constant store load

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
Constant Address	CP→SEQ	8	Address of the block of 4 constants
Constant Data	CP→SEQ	512	Data sent over 4 clocks
Remap Address	CP→SEQ	10	Remaping address write address
Remap Data pointer	CP→SEQ	8	Remaping pointer

~~18.1.6~~20.1.5 CP to SEQ : Fetch State store load

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
Constant Address	CP→SEQ	8	Address of the block of 4 state constants

Constant Data	CP→SEQ	512	Data sent over 4 clocks
Remap Address	CP→SEQ	10	Remaping address write address
Remap Data pointer	CP→SEQ	8	Remaping pointer

~~18.1.7~~20.1.6 CP to SEQ : Control State store load

Formatted: Bullets and Numbering

Name	Direction	Bits	Description

{ISSUE: How,Who and what is the size of this bus?}

~~18.1.8~~20.1.7 MH to SEQ: Instruction store Load

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
Instruction address	MH→SEQ	12	Instruction address
Instruction	MH→SEQ	96	Instruction X times
Control Instruction address	MH→SEQ	9	Pointer to the control instruction store
Control Instruction	MH→SEQ	32	Control Instruction X times

~~18.1.9~~20.1.8 SP to RB : Pixel read from RBs

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
Export_data	SP→RB	64	a pair of 32 bits channel values
ExportID	SP→RB	9	0cvvvvhqq: Vertex data vvvv 0-15 from first or second clause (c=0 or 1), XY or ZW components (h=0 or 1), quad 0-3 in the shader (qq= 0-3) 1cbbkttqq: Pixel data for buffer bb (0-3) from first or second clause (0-1) killed or not (k=1 or 0) quad 0-3 in the shader and data is RG (tt=0), BA (tt=1) or Z (tt=2)
ExportMask	SP→RB	2	Specifies whether to write low, high or both 32 bit words. If export mask is 00 data is invalid
ExportLast	SP→RB	1	Last export instruction of the clause

~~18.1.10~~20.1.9 SEQ to RB : Control bus

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
Type	SEQ→RB	1	0: Pixel 1: Vertex
Interleaving	SEQ→RB	1	0: first interleaved clause 1: second interleaved clause
Export_size	SEQ→RB	4	0 thru 16 parameters exported for vertexes (vvvv) OR (bbzs) 1-4 color buffers (bb), two component (s=0) or 4 component colors (s=1) with z (z=1) or without z (z=0)
Valid	SEQ→RB	1	Data valid

Only one exporting clause (7) can be selected at any given time.

~~18.1.11~~20.1.10 RB to SEQ : Output file control

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
Buff_Full	RB→SEQ	1	Set if full
Avail_size	RB→SEQ	6	Size available in output buffers (in 32bits increments)

~~18.1.12~~20.1.11 SP to RB : Position return bus

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
Position return	SP→RB	128	Position data or sprite size (per clock)
Parameter cache pointer	SP→RB	11	Pointer where the data will be in the parameter cache for each vertex

For point sprites and position exports the size and position are interleaved on a 16 x 16 basis. We export 1 position then 1 point sprite sizes. The storage used is of 64x128 bits for position and 64x32 bits for sprite size, it is taken from the output buffer. Additionnally,if needed the edge flags are packed into the bits of the sprite sizes.

~~18.1.13~~20.1.12 *Shader Engine to Fetch Unit Bus (Fast Bus)*

Formatted: Bullets and Numbering

Four quad's worth of addresses is transferred to Fetch Unit every clock. These are sourced from a different pixel within each of the sub-engines repeating every 4 clocks. The register file index to read must precede the data by 2 clocks. The Read address associated with Quad 0 must be sent 1 clock after the Instruction Start signal is sent, so that data is read 3 clocks after the Instruction Start.

Four Quad's worth of Fetch Data may be written to the Register file every clock. These are directed to a different pixel of the sub-engines repeating every 4 clocks. The register file index to write must accompany the data. Data and Index associated with the Quad 0 must be sent 3 clocks after the Instruction Start signal is sent.

Name	Direction	Bits	Description
Tex_Read_Register_Index	SEQ->SP	7	Index into Register files for reading Fetch Address
Tex_RegFile_Read_Data	SP->TEX	2048	16 Fetch Addresses read from the Register file
Tex_Write_Register_Index	SEQ->TEX	7	Index into Register file for write of returned Fetch Data

~~18.1.14~~20.1.13 *Sequencer to Fetch Unit bus (Slow Bus)*

Formatted: Bullets and Numbering

Once every four clock, the fetch unit sends to the sequencer on wich clause it is now working and if the data in the registers is ready or not. This way the sequencer can update the fetch counters for the reservation station fifos. The sequencer also provides the intruction and constants for the fetch to execute and the address in the register file where to write the fetch return data.

Name	Direction	Bits	Description
Tex_Ready	TEX→ SEQ	1	Data ready
Tex_Clause_Num	TEX→ SEQ	3	Clause number
Tex_cst	SEQ→TEX	10	Fetch state address 10 bits sent over 4 clocks
Tex_Inst	SEQ→TEX	12	Fetch instruction address 12 bits sent over 4 clocks
EO_CLAUSE	SEQ→TEX	1	Last instruction of the clause
PHASE	SEQ→TEX	1	Write phase signal

~~19.~~21. Internal interfaces

Formatted: Bullets and Numbering

21.1.1 *RE to SEQ : Vertex Control Bus*

Name	**Direction**	**Bits**	**Description**
STATE	VGT→SEQ	21	Render State (6*3+3 for constants)
Vert counter	VGT→SEQ	6	Which vertices are valid
Inputs_vert	VGT→SEQ	1	0: Normal 128 bits per vert 1: double 256 bits per vert

This information needs to be sent over 64 clocks.

~~20.~~22. Examples of program executions

Formatted: Bullets and Numbering

~~20.1.1~~22.1.1 *Sequencer Control of a Vector of Vertices*

1. PA sends a vector of 64 vertices (actually vertex indices – 32 bits/index for 2048 bit total) to the RE's Vertex FIFO
   - state pointer as well as tag into position cache is sent along with vertices
   - space was allocated in the position cache for transformed position before the vector was sent
   - **also before the vector is sent to the RE, the CP has loaded the global instruction store with the vertex shader program (using the MH?)**
   - The vertex program is assumed to be loaded when we receive the vertex vector.

- the SEQ then accesses the IS base for this shader using the local state pointer (provided to all sequencers by the RBBM when the CP is done loading the program)

2. SEQ arbitrates between the Pixel FIFO and the Vertex FIFO – basically the Vertex FIFO always has priority
   - at this point the vector is removed from the Vertex FIFO
   - the arbitrer is not going to select a vector to be transformed if the parameter cache is full unless the pipe as nothing else to do (ie no pixels are in the pixel fifo).
3. SEQ allocates space in the SP register file for index data plus GPRs used by the program
   - the number of GPRs required by the program is stored in a local state register, which is accessed using the state pointer that came down with the vertices
   - SEQ will not send vertex data until space in the register file has been allocated
4. SEQ sends the vector to the SP register file over the RE_SP interface (which has a bandwidth of 2048 bits/cycle)
   - the 64 vertex indices are sent to the 64 register files over 4 cycles
     - RF0 of SU0, SU1, SU2, and SU3 is written the first cycle
     - RF1 of SU0, SU1, SU2, and SU3 is written the second cycle
     - RF2 of SU0, SU1, SU2, and SU3 is written the third cycle
     - RF3 of SU0, SU1, SU2, and SU3 is written the fourth cycle
   - the index is written to the least significant 32 bits **(floating point format?) (what about compound indices)** of the 128-bit location within the register file (w); the remaining data bits are set to zero (x, y, z)
5. SEQ constructs a control packet for the vector and sends it to the first reservation station (the FIFO in front of fetch state machine 0, or TSM0 FIFO)
   - the control packet contains the state pointer, the tag to the position cache and a register file base pointer.
6. TSM0 accepts the control packet and fetches the instructions for fetch clause 0 from the global instruction store
   - TSM0 was first selected by the TSM arbiter before it could start
7. all instructions of fetch clause 0 are issued by TSM0
8. the control packet is passed to the next reservation station (the FIFO in front of ALU state machine 0, or ASM0 FIFO)
   - TSM0 does not wait for requests made to the Fetch Unit to complete; it passes the register file write index for the fetch data to the TU, which will write the data to the RF as it is received
   - once the TU has written all the data to the register files, it increments a counter that is associated with ASM0 FIFO; a count greater than zero indicates that the ALU state machine can go ahead start to execute the ALU clause
9. ASM0 accepts the control packet (after being selected by the ASM arbiter) and gets the instructions for ALU clause 0 from the global instruction store
10. all instructions of ALU clause 0 are issued by ASM0, then the control packet is passed to the next reservation station (the FIFO in front of fetch state machine 1, or TSM1 FIFO)
11. the control packet continues to travel down the path of reservation stations until all clauses have been executed
    - position can be exported in ALU clause 3 (or 4?); the data (and the tag) is sent over a position bus (which is shared with all four shader pipes) back to the PA's position cache
    - A parameter cache pointer is also sent along with the position data. This tells to the PA where the data is going to be in the parameter cache.
      - there is a position export FIFO in the SP that buffers position data before it gets sent back to the PA
      - the ASM arbiter will prevent a packet from starting an exporting clause if the position export FIFO is full
    - parameter data is exported in clause 7 (as well as position data if it was not exported earlier)
      - parameter data is sent to the Parameter Cache over a dedicated bus
      - the SEQ allocates storage in the Parameter Cache, and the SEQ deallocates that space when there is no longer a need for the parameters (it is told by the PA when using a token).
      - the ASM arbiter will prevent a packet from starting on ASM7 if the parameter cache (or the position buffer if position is being exported) is full
12. after the shader program has completed, the SEQ will free up the GPRs so that they can be used by another shader program

~~20.1.2~~22.1.2 *Sequencer Control of a Vector of Pixels*

Formatted: Bullets and Numbering

1. **As with vertex shader programs, pixel shaders are loaded into the global instruction store by the CP**
   - At this point it is assumed that the pixel program is loaded into the instruction store and thus ready to be read.
2. the RE's Pixel FIFO is loaded with the barycentric coordinates for pixel quads by the detailed walker
   - the state pointer and the LOD correction bits are also placed in the Pixel FIF0
   - the Pixel FIFO is wide enough to source four quad's worth of barycentrics per cycle
3. SEQ arbitrates between Pixel FIFO and Vertex FIFO – when there are no vertices pending OR there is no space left in the register files for vertices, the Pixel FIFO is selected
4. SEQ allocates space in the SP register file for all the GPRs used by the program
   - the number of GPRs required by the program is stored in a local state register, which is accessed using the state pointer
   - SEQ will not allow interpolated data to be sent to the shader until space in the register file has been allocated
5. SEQ controls the transfer of interpolated data to the SP register file over the RE_SP interface (which has a bandwidth of 2048 bits/cycle). See interpolated data bus diagrams for details.
6. SEQ constructs a control packet for the vector and sends it to the first reservation station (the FIFO in front of fetch state machine 0, or TSM0 FIFO)
   - note that there is a separate set of reservation stations/arbiters/state machines for vertices and for pixels
   - the control packet contains the state pointer, the register file base pointer, and the LOD correction bits
   - all other informations (such as quad address for example) travels in a separate FIFO
7. TSM0 accepts the control packet and fetches the instructions for fetch clause 0 from the global instruction store
   - TSM0 was first selected by the TSM arbiter before it could start
8. all instructions of fetch clause 0 are issued by TSM0
9. the control packet is passed to the next reservation station (the FIFO in front of ALU state machine 0, or ASM0 FIFO)
   - TSM0 does not wait for fetch requests made to the Fetch Unit to complete; it passes the register file write index for the fetch data to the TU, which will write the data to the RF as it is received
   - once the TU has written all the data for a particular clause to the register files, it increments a counter that is associated with the ASM0 FIFO; a count greater than zero indicates that the ALU state machine can go ahead and pop the FIFO and start to execute the ALU clause
10. ASM0 accepts the control packet (after being selected by the ASM arbiter) and gets the instructions for ALU clause 0 from the global instruction store
11. all instructions of ALU clause 0 are issued by ASM0, then the control packet is passed to the next reservation station (the FIFO in front of fetch state machine 1, or TSM1 FIFO)
12. the control packet continues to travel down the path of reservation stations until all clauses have been executed
   - pixel data is exported in the last ALU clause (clause 7)
     - it is sent to an output FIFO where it will be picked up by the render backend
     - the ASM arbiter will prevent a packet from starting on ASM7 if the output FIFO is full
13. after the shader program has completed, the SEQ will free up the GPRs so that they can be used by another shader program

~~20.1.3~~22.1.3 *Notes*

Formatted: Bullets and Numbering

14. the state machines and arbitrers will operate ahead of time so that they will be able to immediately start the real threads or stall.
15. the register file base pointer for a vector needs to travel with the vector through the reservation stations, but the instruction store base pointer does not – this is because the RF pointer is different for all threads, but the IS pointer is only different for each state and thus can be accessed via the state pointer

16. Waterfalling, parameter buffer allocation, loops and branches and parameter cache de-allocation still needs to be specked out.

Formatted: Bullets and Numbering

~~21.~~23. Open issues

There is currently an issue with constants. If the constants are not the same for the whole vector of vertices, we don't have the bandwith from the fetch store to feed the ALUs. Two solutions exists for this problem:

1) Let the compiler handle the case and put those instructions in a fetch clause so we can use the bandwith there to operate. This requires a significant amount of temporary storage in the register store.
2) Waterfall down the pipe allowing only at a given time the vertices having the same constants to operate in parrallel. This might in the worst case slow us down by a factor of 16.

Need to do some testing on the size of the register file as well as on the register file allocation method (dynamic VS static).

Saving power?

Size of the fifo containing the information of a vector of pixels/vertices. And size of the fifos before the reservation stations.

Loops and branches.

R400 Sequencer Specification

SEQ

Version ~~0.9~~1.0

Overview: This is an architectural specification for the R400 Sequencer block (SEQ). It provides an overview of the required capabilities and expected uses of the block. It also describes the block interfaces, internal sub-blocks, and provides internal state diagrams.

AUTOMATICALLY UPDATED FIELDS:

Revision Changes:

Rev 0.1 (Laurent Lefebvre) Date: May 7, 2001	First draft.
Rev 0.2 (Laurent Lefebvre) Date : July 9, 2001	Changed the interfaces to reflect the changes in the SP. Added some details in the arbitration section.
Rev 0.3 (Laurent Lefebvre) Date : August 6, 2001	Reviewed the Sequencer spec after the meeting on August 3, 2001.
Rev 0.4 (Laurent Lefebvre) Date : August 24, 2001	Added the dynamic allocation method for register file and an example (written in part by Vic) of the flow of pixels/vertices in the sequencer.
Rev 0.5 (Laurent Lefebvre) Date : September 7, 2001	Added timing diagrams (Vic)
Rev 0.6 (Laurent Lefebvre) Date : September 24, 2001	Changed the spec to reflect the new R400 architecture. Added interfaces.
Rev 0.7 (Laurent Lefebvre) Date : October 5, 2001	Added constant store management, instruction store management, control flow management and data dependant predication.
Rev 0.8 (Laurent Lefebvre) Date : October 8, 2001	Changed the control flow method to be more flexible. Also updated the external interfaces.
Rev 0.9 (Laurent Lefebvre) Date : October 17, 2001	Incorporated changes made in the 10/18/01 control flow meeting. Added a NOP instruction, removed the conditional_execute_or_jump. Added debug registers.
Rev 1.0 (Laurent Lefebvre) Date : October 19, 2001	Refined interfaces to RB. Added state registers.

1. Overview

The sequencer first arbitrates between vectors of 64 vertices that arrive directly from primitive assembly and vectors of 16 quads (64 pixels) that are generated in the raster engine.

The vertex or pixel program specifies how many GPR's it needs to execute. The sequencer will not start the next vector until the needed space is available.

The sequencer is based on the R300 design. It chooses two ALU clauses and a fetch clause to execute, and executes all of the instructions in a clause before looking for a new clause of the same type. Two ALU clauses are executed interleaved to hide the ALU latency. Each vector will have eight fetch and eight ALU clauses, but clauses do not need to contain instructions. A vector of pixels or vertices ping-pongs along the sequencer FIFO, bouncing from fetch reservation station to alu reservation station. A FIFO exists between each reservation stage, holding up vectors until the vector currently occupying a reservation station has left. A vector at a reservation station can be chosen to execute. The sequencer looks at all eight alu reservation stations to choose an alu clause to execute and all eight fetch stations to choose a fetch clause to execute. The arbitrator will give priority to clauses/reservation stations closer to the bottom of the pipeline. It will not execute an alu clause until the fetch fetches initiated by the previous fetch clause have completed. There are two separate sets of reservation stations, one for pixel vectors and one for vertices vectors. This way a pixel can pass a vertex and a vertex can pass a pixel.

To support the shader pipe the raster engine also contains the shader instruction cache and constant store. There are only one constant store for the whole chip and one instruction store. These will be shared among the four shader pipes. The four shader pipes also execute the same instuction thus there is only one sequencer for the whole chip.

There are two sets of the above figure, one for vertices and one for pixels.

~~The rasterizer always checks the vertices FIFO first and if allowed by the sequencer sends the data to the shader. If the vertex FIFO is empty then, the rasterizer takes the first entry of the pixel FIFO (a vector of 64 pixels) and sends it to the interpolators. Then the sequencer takes control of the packet~~Depending on the arbitration state, the sequencer will either choose a vertex or a pixel packet. The control packet consists of 21 bits of state, 6-7 bits for the base address of the Shader program and some information on the coverage to determine fetch LOD plus other various small state bits.

On receipt of a packet, the input state machine (not pictured but just before the first FIFO) allocated enough space in the registers to store the interpolated values and temporaries. Following this, the input state machine stacks the packet in the first FIFO.

On receipt of a command, the level 0 fetch machine issues a texure request and corresponding register address for the fetch address (ta). A small command (tcmd) is passed to the fetch system identifying the current level number (0) as well as the register write address for the fetch return data. One fetch request is sent every 4 clocks causing the texturing of sixteen 2x2s worth of data (or 64 vertices). Once all the requests are sent the packet is put in FIFO 1.

Upon recept of the return data, the fetch unit writes the data to the register file using the write address that was provided by the level 0 fetch machine and sends the clause number (0) to the level 0 fetch state machine to signify that the write is done and thus the data is ready. Then, the level 0 fetch machine increments the counter of FIFO 1 to signify to the ALU 1 that the data is ready to be processed.

On receipt of a command, the level 0 ALU machine first decrements the input FIFO counter and then issues a complete set of level 0 shader instructions. For each instruction, the state machine generates 3 source addresses, one destination address (3 cycles later) and an instruction. Once the last instruction as been issued, the packet is put into FIFO 2.

There will always be two active ALU clauses at any given time (and two arbitrers). One arbitrer will arbitrate over the odd instructions (4 clocks cycles) and the other one will arbitrate over the even instructions (4 clocks cycles). The only constraints between the two arbitrers is that they are not allowed to pick the same clause number as the~~y~~ other one is currently working on if the packet ~~os~~ is not of the same type (render state).

If the packet is a vertex packet, upon reaching ALU clause 3, it can export the position if the position is ready. So the arbitrer must prevent ALU clause 3 to be selected if the positional buffer is full (or can't be accessed). Along with the positional data, the location where the vertex data is to be put is also sent (parameter data pointers).

{ISSUE: How do we handle parameter cache pointers (computed, semi-computed or not computed)?}

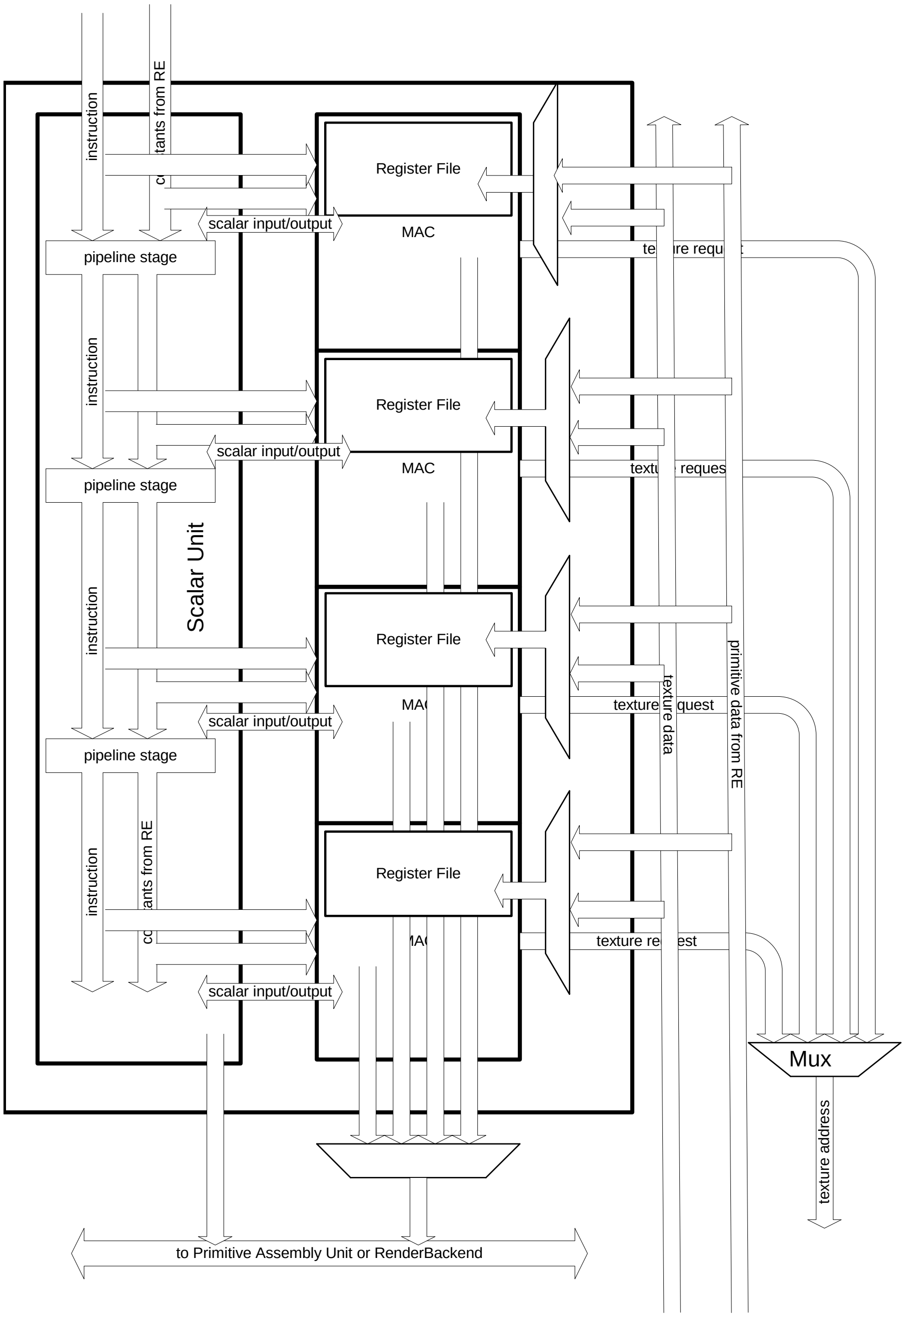
A special case is for HOS surfaces wich can export 12 parameters per last 6 clauses to the output buffer. If the output buffer is full or doesn't have enough space the sequencer will prevent such a vertex group to enter an exporting clause.

Regular pixel and vertex shaders can export 12 parameters to memory from the last clause only (7).

All other level process in the same way until the packet finally reaches the last ALU machine (~~8~~7). On completion of the level ~~8~~ 7 ALU clause, a valid bit is sent to the Render Backend which picks up the color data. This requires that the last instruction writes to the output register – a condition that is almost always true. If the packet was a vertex packet, instead of sending the valid bit to the RB, it is sent to the PA so it can know that the data present in the parameter store is valid.

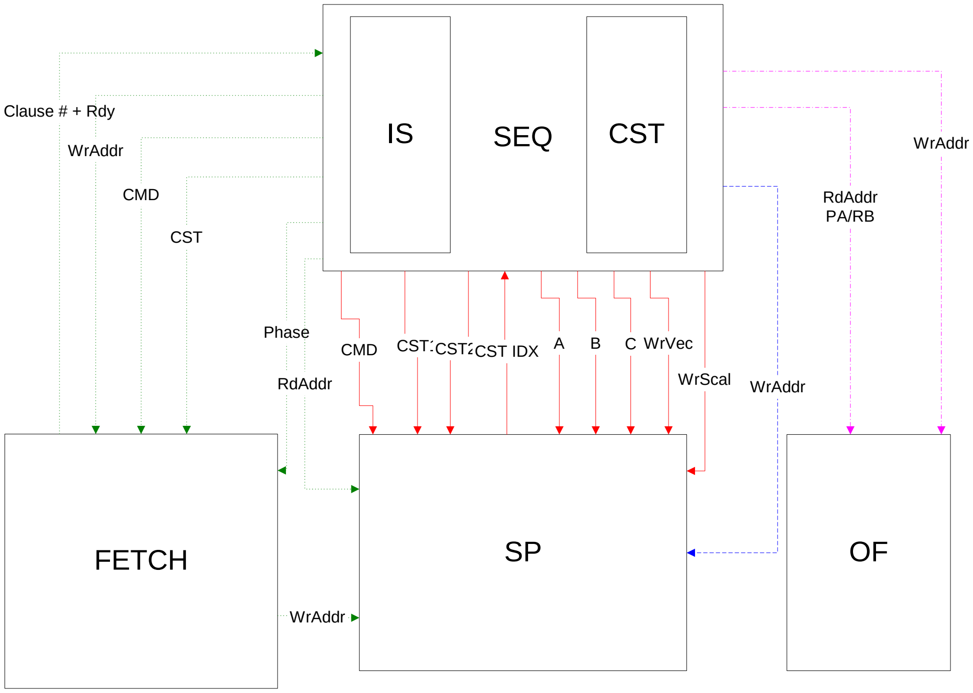
Only two ALU state machine may have access to the register file address bus or the instruction decode bus at one time. Similarly, only one fetch state machine may have access to the register file address bus at one time. Arbitration is performed by three arbitrer blocks (two for the ALU state machines and one for the fetch state machines). The arbitrers always favor the higher number state machines, preventing a bunch of half finished jobs from clogging up the register files.

1.2 Data Flow graph



The gray area represents blocks that are replicated 4 times per shader pipe (16 times on the overall chip).

1.3 Control Graph



In green is represented the Fetch control interface, in red the ALU control interface, in blue the Interpolated/Vector control interface and in purple is the output file control interface.

2. Interpolated data bus

The interpolators contain an IJ buffer to pack the information as much as possible before writing it to the register file.

P0

P1

Above is an example of a tile we might receive. The IJ information is packed in the IJ buffer 2 quads at a time. The sequencer allows at any given time as many as four quads to interpolate a parameter. They all have to come from the same primitive. Then the sequencer controls the write mask to the register to write the valid data in.

3. Instruction Store

There is going to be only one instruction store for the whole chip. It will contain 4096 instructions of 96 bits each. There is also going to be a control instruction store of size 256(512?)x32.

{ISSUE : The instruction store is loaded by the sequencer using the memory hub ?}.

The read bandwith from this store is 96*2 bits/ 4 clocks (48 bits/clock). It is likely to be a 1 port memory; we use 1 clock to load the ALU instruction, 1 clocks to load the Fetch instruction, 1 clock to load 2 control flow instructions and 1 clock to write instructions.

4. Sequencer Instructions

All control flow instructions and move instructions are handled by the sequencer only. The ALUs will perform NOPs during this time (MOV PV,PV, PS,PS).

5. Constant Store

The constant store is managed by the CP. The sequencer is aware of where the constants are using a remaping table also managed by the CP. A likely size for the constant store is 512x128 bits. The constant store is also planned to be shared. The read BW from the constant store is 128 bits/clock and the write bandwith is 32/4 bits/clock.

In order to do constant store indexing, the sequencer must be loaded first with the indexes (that come from the GPRs). There are 144 wires from the exit of the SP to the sequencer (9 bits pointers x 16 vertexes/clock). Since the data must pass thru the Shader pipe for the float to fixed convertion, there is a latency of 4 clocks (1 instruction) between the time the sequencer is loaded and the time one can index into the constant store. The assembly will look like this

```
MOVA  R1.X,R2.X       // Loads the sequencer with the content of R2.X, also copies the content of R2.X into R1.X
NOP                   // latency of the float to fixed conversion
ADD   R3,R4,C0[R2.X]// Uses the state from the sequencer to add R4 to C0[R2.X] into R3
```

Note that we don't really care about what is in the brackets because we use the state from the MOVA instruction. R2.X is just written again for the sake of simplicity.

The storage needed in the sequencer in order to support this feature is 2*64*9 bits = 1152 bits.

6. Looping and Branches

Loops and branches are planned to be supported and will have to be dealt with at the sequencer level. We plan on supporting constant loops and branches using a control program.

6.1 The controlling state.

As per Dx9 the following state is available for control flow:

Boolean[15:0]
loop_count[7:0][7:0]
        In addition:
loop_start [7:0] [7:0]
loop_step [7:0] [7:0]
        Exist to give more control to the controlling program.

We will extend that in the R400 to:

Boolean[255:0]
Loop_count[7:0][15:0]
Loop_Start[7:0] [15:0] times 2 (one for constant,registert)
Loop_Step[7:0] [15:0] times 2 (one for constant,register)
Loop_End[7:0] [15:0]

{ISSUE: How is the controlling state loaded and how many contexts do we have?}

We have a stack of 4 elements for calling subroutines and 4 loop counters to allow for nested loops.

We also keep 8 predicate vectors and 8 AND/OR sets of 3 bits. These bits can be 0: all 0s, 1: all ones and 11: mixed.

6.2 The Control Flow Program

The R300 uses a match method for control flow: The shader is executed, and at every instruction its address is compared with addresses (or address?) in a control table. The “event” in the control table can redirect operations in the program.

The Method chosen for the R400 is a “control program”. The control program has ten basic instructions:

Execute
Conditional_execute
Conditional_Execute_Predicates
Conditional_execute_or_Jump
Conditional_jump
Call
Return
Loop_start
Loop_end
End_of_clause

Execute, causes the specified number of instructions in instruction store to be executed.
Conditional_execute checks a condition first, and if true, causes the specified number of instructions in instruction store to be executed.
Loop_start resets the corresponding loop counter to the start value on the first pass after it checks for the end condition and if met jumps over to a specified address.
Loop_end increments (decrements?) the loop counter and jumps back the specified number of instructions.
Call jumps to an address and pushes the IP counter on the stack. On the return instruction, the IP is poped from the stack.
Conditional_execute_or_Jump executes a block of instructions or jumps to an address is the condition is not met.
Conditional_execute_Predicates executes a block of instructions if all bits in the predicate vectors meet the condition.
End_of_clause marks the end of a clause.
Conditional_jumps jumps to an address if the condition is met.
NOP is a regular NOP

NOTE THAT ALL JUMPS MUST JUMP TO EVEN CFP ADDRESSES. Thus the compiler must insert NOPs where needed to align the jumps on even CFP addresses.

Also if the jump is logically bigger than ~~4096~~ pshader_cntl_size (or vshader_cntl_size) we break the program (clause) and set the debug registers. If an execute or conditional_execute is lower than cntl_size or bigger than size we also break the program (clause) and set the debug registers.

We have to fit instructions into 48 bits in order to be able to put two control flow instruction per line in the instruction store.

Execute				
47	46… 42	41 … 24	23 … 12	11 … 0
Addressing	00001	RESERVED	Instruction _count	Exec Address

Execute up to 4k instructions at the specified address in the instruction memory.

NOP		
47	46 … 42	41 … 0
Addressing	00010	RESERVED

If the specified boolean (8 bits can address 256 booleans) meets the specified condition then execute the specified instructions (up to 512 instructions) or if the condition is not met jump to the jump address in the control flow program. This MUST be a forward jump.

Conditionnal_Execute						
47	46 … 42	41 … 34	33	32 … 24	23 … 12	11 … 0
Addressing	00011	Boolean address	Condition	RESERVED	Instruction_count	Exec Address

If the specified boolean (8 bits can address 256 booleans) meets the specified condition then execute the specified instructions (up to 4k instructions)

Conditionnal_Execute_Predicates						
47	46 … 42	41 … 38	37	36 … 24	23 … 12	11 … 0
Addressing	00100	Predicate vector	Condition	RESERVED	Instruction_count	Exec Address

Check the AND/OR of all current predicate bits. If AND/OR matches the condition execute the specified number of instructions.

Loop_Start				
47	46 … 42	41 … 16	15 … 4	3 … 0
Addressing	00101	RESERVED	Jump address	Loop ID

Loop Start. Compares the loop count with the end value. If loop condition not met jump to the address. Forward jump only. Also computes the index value.

Loop_End				
47	46 … 42	41 … 16	15 … 4	3 … 0
Addressing	00111	RESERVED	Start address	Loop ID

Loop end. Increments the counter by one and jumps BACK only to the start of the loop.

The way this is described does not prevent nested loops, and the inclusion of the loop id make this easy to do.

Call			
47	46 … 42	41…12	11 … 0
Addressing	01000	RESERVED	Address

Jumps to the specified address and pushes the IP counter on the stack.

Return		
47	46 … 42	41 … 0
Addressing	01001	RESERVED

Pops the topmost address from the stack and jumps to that address. If nothing is on the stack, the program will just continue to the next instruction.

Conditional_Jump						
47	46 … 42	41 … 34	33	32 … 13~~2~~	12	11 … 0
Addressing	01010	Boolean address	Condition	RESERVED	FW only	Address

If condition met, jumps to the address. FORWARD jump only allowed if bit 12 set. Bit 12 is only an optimization for the compiler and should NOT be exposed to the API.

End_of_Clause		
47	46 … 42	41 … 0

Addressing	01011	RESERVED

Marks the end of a clause.

To prevent infinite loops, we will keep 9 bits loop counters instead of 8 (we are only able to loop 256 times). If the counter goes higher than 255 then the loop_end or the loop_start is going to break the loop and set de debug registers. The sequencer will keep two loop indexes values:

IC index for constant indexing (9 bits)
IR index for register file indexing (7 bits)

This will be updated everytime we loop and can only be used to index the constant store and the register file. The way to compute this value is:

Index = Loop_counter*Loop_iterator + Loop_init.

The IC for constant is going to return 0 if it is out of the constant range. The IR index is going to break the program if the index exeeds the number of requested registers.

The basic model is as follows:

The render state defined the clause boundaries:

Vertex_shader_fetch[7:0][7:0]	// eight 8 bit pointers to the location where each clauses control program is located
Vertex_shader_alu[7:0][7:0]	// eight 8 bit pointers to the location where each clauses control program is located
Pixel_shader_fetch[7:0][7:0]	// eight 8 bit pointers to the location where each clauses control program is located
Pixel_shader_alu[7:0][7:0]	// eight 8 bit pointers to the location where each clauses control program is located

The control program for a given clause is executed to completion before moving to another clause, (with the exception of the pick two nature of the alu execution). The control program is the only program aware of the clause boundaries.

6.3 Data dependant predicate instructions

Data dependant conditionals will be supported in the R400. The only way we plan to support those is by supporting three vector/scalar predicate operations of the form:

PRED_SETE_# - similar to SETE except that the result is 'exported' to the sequencer.
PRED_SETGT_# - similar to SETGT except that the result is 'exported' to the sequencer
PRED_SETGTE_# - similar to SETGTE except that the result is 'exported' to the sequencer

For the scalar operations only we will also support the two following instructions:

PRED_SETE0_# – SETE0
PRED_SETE1_# – SETE1

The export is a single bit - 1 or 0 that is sent using the same data path as the MOVA instruction. The sequencer will maintain 4 sets of 64 bit predicate vectors (in fact 8 sets because we interleave two programs but only 4 will be exposed) and use it to control the write masking. This predicate is not maintained across clause boundaries. The # sign is used to specify wich predicate set you want to use 0 thru 3.

Then we have two conditional execute bits. The first bit is a conditional execute "on" bit and the second bit tells us if we execute on 1 or 0. For exemple, the ~~instruction :~~instruction:

P0_ADD_# R0,R1,R2

Is only going to write the result of the ADD into those GPRs whose predicate bit is 0. Alternatively, P1_ADD_# would only write the results to the GPRs whose predicate bit is set. The use of the P0 or P1 without precharging the sequencer with a PRED instruction is undefined.

{Issue: do we have to have a NOP between PRED and the first instruction that uses a predicate?}

6.4 Register file indexing

Because we can have loops in fetch clause, we need to be able to index into the register file in order to retrieve the data created in a fetch clause loop and use it into an ALU clause. The instruction will include the base address for register indexing and the instruction will contain these controls :

Bit7	Bit 6	
0	0	'absolute register'
0	1	'relative register'
1	0	'previous vector'
1	1	'previous scalar'

In the case of an absolute register we just take the address as is. In the case of a relative register read we take the base address and we add to it the loop_index and this becomes our new address that we give to the shader pipe.

Formatted: Bullets and Numbering

7. Pixel Kill Mask

A vector of 64 bits is kept per group of pixels/vertices. Its purpose is to optimize the texture fetch requests and allow the shader pipe to kill pixels using the following instructions:

MASK_SETE
MASK_SETGT
MASK_SETGTE

However, if the driver sets the kill_vector_on register to 0 (don't use) then the 64 bit kill mask becomes the 5th predicate vector and is kept across clause boundaries (thus allowing predicated instructions to be used in texture clauses). In this mode, the sequencer is going to send all 1s to the RBs for coverage mask information.

Formatted

Formatted: Bullets and Numbering

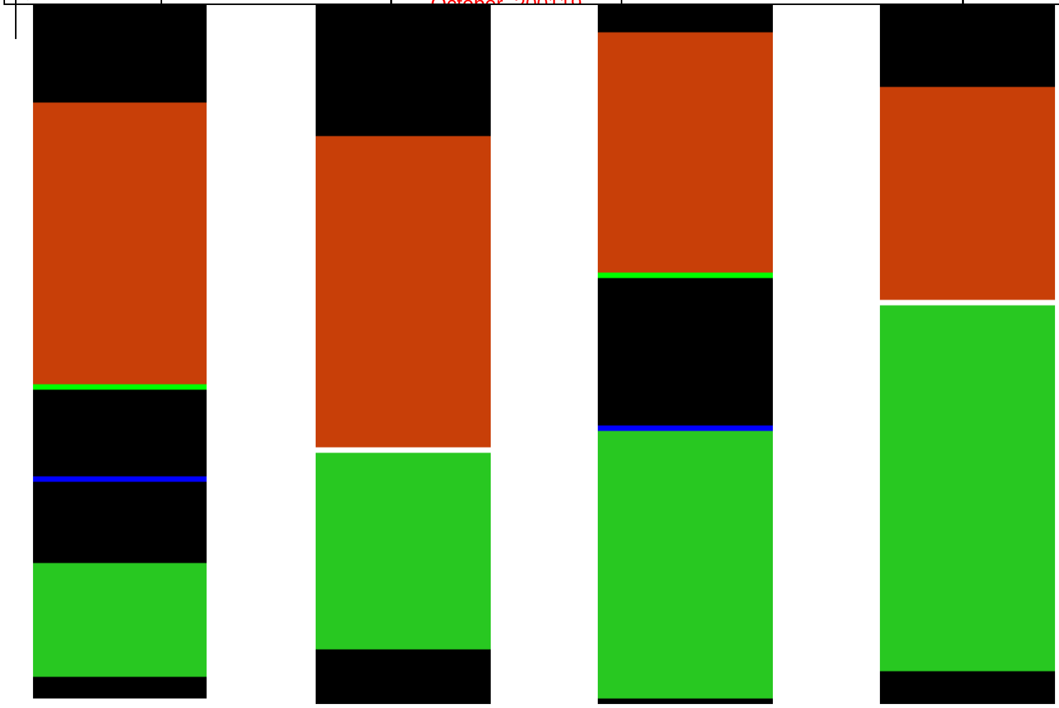
~~7.~~8. HOS surfaces

HOS surfaces are able to export from ~~any~~ the 6 last clauses but to memory ONLY. If they want to export to the parameter cache they have to do it in the last clause (7). They can also export position in clause 3. The buffer they want to export into must be specified in the "exports" field of the state registers.

Formatted: Bullets and Numbering

~~8.~~9. Register file allocation

The register file allocation for vertices and pixels can either be static or dynamic. In both cases, the register file in managed using two round robins (one for pixels and one for vertices). In the dynamic case the boundary between pixels and vertices is allowed to move, in the static case it is fixed to VERTEX_REG_SIZE for vertices and 256-VERTEX_REG_SIZE for pixels.



Above is an example of how the algorithm works. Vertices come in from top to bottom; pixels come in from bottom to top. Vertices are in orange and pixels in green. The blue line is the tail of the vertices and the green line is the tail of the pixels. Thus anything between the two lines is shared. When pixels meets vertices the line turns white and the boundary is static until both vertices and pixels share the same “unallocated bubble”. Then the boundary is allowed to move again.

Formatted: Bullets and Numbering

~~9.~~10. Fetch Arbitration

The fetch arbitration logic chooses one of the 8 potentially pending fetch clauses to be executed. The choice is made by looking at the fifos from 7 to 0 and picking the first one ready to execute. Once chosen, the clause state machine will send one 2x2 fetch per clock (or 4 fetches in one clock every 4 clocks) until all the fetch instructions of the clause are sent. This means that there cannot be any dependencies between two fetches of the same clause.

The arbitrator will not wait for the fetches to return prior to selecting another clause for execution. The fetch pipe will be able to handle up to X(?) in flight fetches and thus there can be a fair number of active clauses waiting for their fetch return data.

Formatted: Bullets and Numbering

~~10.~~11. ALU Arbitration

ALU arbitration proceeds in almost the same way than fetch arbitration. The ALU arbitration logic chooses one of the 8 potentially pending ALU clauses to be executed. The choice is made by looking at the fifos from 7 to 0 and picking the first one ready to execute. There are two ALU arbitrers, one for the even clocks and one for the odd clocks. For exemple, here is the sequencing of two interleaved ALU clauses (E and O stands for Even and Odd sets of 4 clocks):

Einst0 Oinst0 Einst1 Oinst1 Einst2 Oinst2 Einst0 Oinst3 Einst1 Oinst4 Einst2 Oinst0…
Proceeding this way hides the latency of 8 clocks of the ALUs.

~~11.~~12. Handling Stalls

Formatted: Bullets and Numbering

When the output file is full, the sequencer prevents the ALU arbitration logic to select the last clause (this way nothing can exit the shader pipe until there is place in the output file. If the packet is a vertex packet and the position buffer is full (POS_FULL) then the sequencer also prevents a thread to enter the exporting clause (4?). The sequencer will set the OUT_FILE_FULL signal n clocks before the output file is actually full and thus the ALU arbitrer will be able read this signal and act accordingly by not preventing exporting clauses to proceed.

~~12.~~13. Content of the reservation station FIFOs

Formatted: Bullets and Numbering

21 bits of Render State 7 bits for the base address of the GPRs, some bits for LOD correction and coverage mask information in order to fetch fetch for only valid pixels, quad address and 1 bit to specify if the vector is of pixels or vertices. Since pixels and vertices are kept in order in the shader pipe, we only need two fifos (one for vertices and one for pixels) deep enough to cover the shader pipe latency. This size will be determined later when we will know the size of the small fifos between the reservation stations.

~~For texture clauses, 3 bits * 4 are going to be kept. These are the AND/OR of the predicate vectors. 0 for all 0s, 1 for all ones and MIXED.~~

~~13.~~14. The Output File

Formatted: Bullets and Numbering

The output file is where pixels are put before they go to the RBs. The write BW to this store is 256 bits/clock. Just before this output file are staging registers with write BW 512 bits/clock and read BW 256 bits/clock. For this reason only ONE concurrent program can be of clause 8 (exporting clause) the other program MUST not. The staging registers are 4x128 (and there are 16 of those on the whole chip).

~~14.~~15. IJ Format

Formatted: Bullets and Numbering

The IJ information sent by the PA is of this format on a per quad basis:

We have a vector of IJ's (one IJ per pixel at the centroid of the fragment or at the center of the pixel depending on the mode bit). The interpolation is done at a different precision across the 2x2. The upper left pixel's parameters are always interpolated at full 19x24 mantissa precision. Then the result of the interpolation along with the difference in IJ in reduced precision is used to interpolate the parameter for the other three pixels of the 2x2. Here is how we do it:

Assuming P0 is the interpolated parameter at Pixel 0 having the barycentric coordinates I(0), J(0) and so on for P1,P2 and P3. Also assuming that A is the parameter value at V0 (interpolated with I), B is the parameter value at V1 (interpolated with J) and C is the parameter value at V2 (interpolated with (1-I-J).

$$\Delta 01I = I(1) - I(0)$$
$$\Delta 01J = J(1) - J(0)$$
$$\Delta 02I = I(2) - I(0)$$
$$\Delta 02J = J(2) - J(0)$$
$$\Delta 03I = I(3) - I(0)$$
$$\Delta 03J = J(3) - J(0)$$

P0	P1
P2	P3

$$P0 = C + I(0) * (A - C) + J(0) * (B - C)$$
$$P1 = P0 + \Delta 01I * (A - C) + \Delta 01J * (B - C)$$
$$P2 = P0 + \Delta 02I * (A - C) + \Delta 02J * (B - C)$$
$$P3 = P0 + \Delta 03I * (A - C) + \Delta 03J * (B - C)$$

P0 is computed at 19x24 mantissa precision and P1 to P3 are computed at 8X24 mantissa precision. So far no visual degradation of the image was seen using this scheme.

Multiples (Full Precision): 2
Multiples (Reduced precision): 6
Subtracts 19x24 (Parameters): 2
Adds: 8

FORMAT OF P0's IJ : Mantissa 19 Exp 4 for I + Sign
Mantissa 19 Exp 4 for J + Sign

FORMAT of Deltas (x3):Mantissa 8 Exp 4 for I + Sign
Mantissa 8 Exp 4 for J + Sign

Total number of bits : 19*2 + 8*6 + 4*8 + 4*2 = 126

Formatted: Bullets and Numbering

~~15.~~16. The parameter cache

The parameter cache is where the vertex shaders export their data. It consists of 16 128x128 memories (1R/1W). The reuse engine will make it so that all vertexes of a given primitive will hit different memories.

Formatted: Bullets and Numbering

~~16.~~17. Vertex position exporting

On clause 4 (or 5) the vertex shader can export to the PA both the vertex position and the point sprite. It can also do so at clause 8 if not done at clause 4. Along with the position is exported a pointer to the parameter cache where the data will be once the vertex shader exports. The storage needed to perform the position export is at least 64x128 memories for the position and 64x32 memories for the sprite size. It is going to be taken in the pixel output fifo.

Formatted: Bullets and Numbering

18. Exporting Arbitration

Here are the rules for co-issuing exporting ALU clauses.

Formatted: Bullets and Numbering

1) Position exports and position exports cannot be co-issued.
2) Position exports and memory exports cannot be co-issued.
3) Position exports and Z/Color exports cannot be co-issued.
4) Memory exports and Z/Color exports cannot be co-issued.
5) Memory exports and memory exports cannot be co-issued.
6) Z/color exports and Z/color exports cannot be co-issued.
7) Parameter exports and Z/Color exports CAN be co-issued.
8) Parameter exports and parameter exports CAN be co-issued.
~~1)~~9)Parameter exports and memory exports CAN be co-issued.

~~17.~~19. Real time commands

We are unable to use the parameter memory since there is no way for a command stream to write into it. Instead we need to add three 16x128 memories (one for each of three vertices x 16 interpolants). These will be mapped onto the register bus and written by type 0 packets, and output to the the parameter busses (the sequencer and/or PA need to be able to address the realtime parameter memory as well as the regular parameter store. For higher performance we should be able able to view them as two banks of 16 and do double buffering allowing one to be loaded, while the other is rasterized with. Most overlay shaders will need 2 or 4 scalar coordinates, one option might be to restrict the memory to 16x64 or 32x64 allowing only two interpolated scalars per cycle, the only problem I see with this is, if we view support for 16 vector-4 interpolants important (true only if we map microsoft's high priority stream to the realtime stream), then the PA/sequencer need to support a realtime-specific mode where we need to address 32 vectors of parameters instead of 16.

~~18.~~20. Registers

Formatted: Bullets and Numbering

20.1 Control

DYNAMIC_REG	Dynamic allocation (pixel/vertex) of the register file on or off.
VERTEX_REG_SIZE	What portion of the register file is reserved for vertices (static allocation only)
PIXEL_MIN_SIZE	Minimal size of the register file's pixel portion (dynamic only)
VERTEX_MIN_SIZE	Minimal size of the register file's vertex portion (dynamic only)
ARBITRATION_policy	policy of the arbitration between vetexes and pixels
CST_SIZE_P	Size of the constant store for pixels
CST_SIZE_V	Size of the constant store for vertexes
INST_STOR_ALLOC	interleaved, separate, interleaved+shared,separate+shared
VWRAP	wrap point for the vertex shader instruction store
PWRAP	wrap point for the pixel shader instruction store
NO_INTERLEAVE	debug state register. Only allows one program at a time into the GPRs

~~18.1~~20.2 Context

Formatted: Bullets and Numbering

Vshader_fetch[~~11~~7:0][7:0]	eight ~~12~~ 8 bit pointers to the location where each clauses control program is located
Vshader_alu[~~11~~7:0][7:0]	eight ~~12~~ 8 bit pointers to the location where each clauses control program is located
Pshader_fetch[~~11~~7:0][7:0]	eight ~~12~~ 8 bit pointers to the location where each clauses control program is located
Pshader_alu[~~11~~7:0][7:0]	eight ~~12~~ 8 bit pointers to the location where each clauses control program is located
PSHADER	base pointer for the pixel shader
VSHADER	base pointer for the vertex shader
Vshader_cntl_size	size of the vertex shader (# of instructions in control program/2)
Pshader_cntl_size	size of the pixel shader (# of instructions in control program/2)
Pshader_size	size of the pixel shader (cntl+instructions)
Vshader_size	size of the vertex shader (cntl+instructions)
~~VWRAP~~	~~wrap point for the vertex shader instruction store~~
~~PWRAP~~	~~wrap point for the pixel shader instruction store~~
REG_ALLOC_PIX	number of registers to allocate for pixel shader programs
REG_ALLOC_VERT	number of registers to allocate for vertex shader programs
~~PARAM_MASK[0…16]~~	~~parameter mask to specify how parameters maps in the pixel shader~~
FLAT_GOUR[0…1~~6~~5]	wich parameters are to be gouraud shaded
GEN_TEX~~[0….16]~~	~~for wich parameters do we need to generate tex coords.~~Do we generate texture coordinates for 1st parameter or not
CYL_WRAP[0…~~64~~63]	for wich parameters (and channels (xyzw)) do we do the cyl wrapping.
P_export_mode	0xxxx : Normal mode
	1xxxx : Multipass mode
	If normal, bbbz where bbb is how many colors (0-4) and z is export z or not
	If multipass 1-12 exports for color.
vshader_export_mask	wich of the last 6 ALU clauses is exporting
vshader_export_mode	0: position (1 vector), 1: position (2 vectors), 3:multipass
vshader_export_count[6]	# of interpolated parameters exported in clause 7 OR
	# of exported vectors to memory per clause in multipass mode (per clause)
kill_vector_on	use the mask kill vector to kill pixels and optimize texture pipe fetches OR use it as the fifth predicate vector wich is the only predicate vector kept across clause boundaries.
~~P_EXPORT[8]~~	~~number of exports for pixel shader~~
~~V_EXPORT[8]~~	~~number of exports for vertex shader for each clause. All numbers relate to the output buffer exports but for V_EXPORT[7] than can relate to the PC if Exports[7] is set to 00000.~~
~~ARBITRATION_policy~~	~~policy of the arbitration between vetexes and pixels~~
	~~Exports[8][6] Wich clause is exporting to the output buffer and what is it exporting.~~
	~~000000 : Not exporting (or exporting only to the PC)~~
	~~000001 : Exporting position (1)~~
	~~000010 : Exporting position (2)~~
	~~(1)00100 : Exporting RG~~

Formatted

~~(1)01000 : Exporting BA~~
~~(1)10000 : Exporting Z~~
~~If MSB set pixel shader exporting linear to memory not to Frame Buffer.~~
~~CST_SIZE_P Size of the constant store for pixels~~
~~CST_SIZE_V Size of the constant store for vertexes~~

~~19.~~21. DEBUG registers

Formatted: Bullets and Numbering

PROB_ADDR instruction address where the first problem occurred
PROB_COUNT number of problems encountered during the execution of the program

~~20.~~22. Interfaces

Formatted: Bullets and Numbering

~~20.1~~22.1 External Interfaces

~~20.1.1~~22.1.1 *PA/SC to ~~RE~~ SP0 : IJ bus*

This is a bus that sends the IJ information to the IJ fifos on the top of each shader pipe. At the same time the control information goes to the sequencer. There are 4 of these buses over the whole chip (SP0 thru 3)

Name	Direction	Bits	Description
IJs	PA→~~RE~~SP0	63	IJ information sent over 2 clocks
Mask	PA→~~RE~~SP0	1	Write Mask

~~20.1.2~~22.1.2 *PA/SC to SEQ : IJ Control bus*

Formatted: Bullets and Numbering

This is the control information sent to the sequencer in order to control the IJ fifos and all other information needed to execute a shader program on the sent pixels.

Name	Direction	Bits	Description
Write Mask	PA→SEQ(~~RE)~~SP)	4	Quad Write mask left to right
RB_ID	PA→SEQ(SP)~~PA→SEQ(RE)~~	8	RB id for each quad sent 2 bits per quad
LOD_CORRECT	PA→SEQ(SP)~~PA→SEQ(RE)~~	24	LOD correction per quad (6 bits per quad)
FVTX	PA→SEQ(SP)~~PA→SEQ(RE)~~	2	Provoking vertex for flat shading
PPTR0	PA→SEQ(SP)~~PA→SEQ(RE)~~	11	P Store pointer for vertex 0

FBFACE	PA→SEQ(SP)~~PA→SEQ(RE~~	1	Front face = 1, back face = 0

	~~)~~		
TYPE	PA→SEQ(SP)~~PA→SEQ(RE)~~	3	Stippled line and Real time command need to load tex cords from alternate buffer 000 : Normal 001 : Stippled line 011 : Real Time 100 : Line AA 101 : Point AA 110 : Sprite
RTRn	SEQ→PA	1	Stalls the PA in n clocks
RTS	PA→SEQ(SP)~~PA→SEQ(RE)~~	1	PA ready to send data

~~20.1.3~~22.1.3 *VGT to ~~RE~~ SP : Vertex Bus*

Formatted: Bullets and Numbering

Name	**Direction**	**Bits**	**Description**
Vertex indexes	VGT→RE	128	Pointers of indexes or HOS surface information
EOF_vector	VGT→RE	1	End of the vector
Inputs_vert	VGT→RE	1	0: Normal 128 bits per vert 1: double 256 bits per vert
STATE	VGT→SEQ	21	Render State (6*3+3 for constants)

~~20.1.4~~22.1.4 *CP to SEQ : Constant store load*

Formatted: Bullets and Numbering

Name	**Direction**	**Bits**	**Description**
Constant Address	CP→SEQ	8	Address of the block of 4 constants
Constant Data	CP→SEQ	512	Data sent over 4 clocks
Remap Address	CP→SEQ	10	Remaping address write address
Remap Data pointer	CP→SEQ	8	Remaping pointer

~~20.1.5~~22.1.5 *CP to SEQ : Fetch State store load*

Formatted: Bullets and Numbering

Name	**Direction**	**Bits**	**Description**
Constant Address	CP→SEQ	8	Address of the block of 4 state constants
Constant Data	CP→SEQ	512	Data sent over 4 clocks
Remap Address	CP→SEQ	10	Remaping address write address
Remap Data pointer	CP→SEQ	8	Remaping pointer

~~20.1.6~~22.1.6 *CP to SEQ : Control State store load*

Formatted: Bullets and Numbering

Name	**Direction**	**Bits**	**Description**

{ISSUE: How,Who and what is the size of this bus?}

~~20.1.7~~22.1.7 *MH to SEQ: Instruction store Load*

Formatted: Bullets and Numbering

Name	**Direction**	**Bits**	**Description**
Instruction address	MH→SEQ	12	Instruction address
Instruction	MH→SEQ	96	Instruction X times
Control Instruction address	MH→SEQ	9	Pointer to the control instruction store
Control Instruction	MH→SEQ	32	Control Instruction X times

{ISSUE: CP or MH?}

~~20.1.8~~22.1.8 *SP to RB : Pixel read from RBs*

Formatted: Bullets and Numbering

Name	**Direction**	**Bits**	**Description**
Export_data	SP→RB	64*16	32~~a~~ pairs of 32 bits channel values
~~ExportID~~Shader_Dest	SP→RB	~~9~~4	Specifies one of the of up to 12 export destinations~~0cvvvvhqq: Vertex data vvvv 0-15 from first or second clause (c=0 or 1), XY or ZW components (h=0~~

			~~or 1), quad 0-3 in the shader (qq= 0-3)~~ ~~1cbbkttqq: Pixel data for buffer bb (0-3) from first or second clause (0-1) killed or not (k=1 or 0) quad 0-3 in the shader and data is RG (tt=0), BA (tt=1) or Z (tt=2)~~
Shader_Count~~ExportMask~~	SP→RB	~~2~~3	Each set of four pixels or vectors is exported over eight clocks. This field specifies where the SP is in that sequence.~~Specifies whether to write low, high or both 32 bit words. If export mask is 00 data is invalid~~
Shader_Last~~ExportLast~~	SP→RB	1	The current export clause is over (true for one clock) The last export instruction creates *two* cycles to the RB. This needs to be set on or after the last RB cycle that is produced by the last export instruction, but before the first RB cycle of the first export instruction of the next clause.~~Last export instruction of the clause~~
Shader_PixelValid	SP→RB	4x4	Result of pixel kill in the shader pipe, which must be output for all pixel exports (depth and all color buffers). 4x4 because 16 pixels are computed per clock
Shader_WordValid	SP→RB	2	Specifies whether to write low and/or high 32-bit word of the 64-bit export data from each of the 16 pixels or vectors

~~20.1.9~~22.1.9 SEQ to RB : Control bus

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
Export_Pixel~~Type~~	SEQ→RB	1	1~~0~~: Pixel ~~1~~0: Vertex
Export_SEND~~Interleaving~~	SEQ→RB	1	Raised to indicate that the SQ is starting an export~~0: first interleaved clause~~ ~~1: second interleaved clause~~
Export_Clause~~Export_size~~	SEQ→RB	~~4~~3	Clause number, which is needed for vertex clauses~~0 thru 16 parameters exported for vertexes (vvvv) OR (bbzs) 1-4 color buffers (bb), two component (s=0) or 4 component colors (s=1) with z (z=1) or without z (z=0)~~
Export_State~~Valid~~	SEQ→RB	~~1~~21?	State ID, which is needed for vertex clauses~~Data valid~~

These fields are sent synchronously with SP export data, described in SP→RB interface

{ISSUE: Where are the PC pointers}~~Only one exporting clause (7) can be selected at any given time.~~

~~20.1.10~~22.1.10 RB to SEQ : Output file control

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
Export_RTS~~Buff_Full~~	RB→SEQ	1	Raised by RB to indicate that the following two fields reflect the result of the most recent export~~Set if full~~
Export_Position~~Avail_size~~	RB→SEQ	1~~6~~	Specifies whether there is room for another position.~~Size available in output buffers (in 32bits increments)~~
Export_Buffer	RB→SEQ	7	Specifies the space availble in the output buffers. 0: buffers are full 1: 2K-bits available (32-bits for each of the 64 pixels in a clause) ... 64: 128K-bits available (16 128-bit entries for each of 64 pixels) 65-127: RESERVED

~~20.1.11~~22.1.11 *SP to RB : Position return bus*

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
Position return	SP→RB	128	Position data or sprite size (per clock)
Parameter cache pointer	SP→RB	11	Pointer where the data will be in the parameter cache for each vertex

For point sprites and position exports the size and position are interleaved on a 16 x 16 basis. We export 1 position then 1 point sprite sizes. The storage used is of 64x128 bits for position and 64x32 bits for sprite size, it is taken from the output buffer. Additionnally,if needed the edge flags are packed into the bits of the sprite sizes.

~~20.1.12~~22.1.12 *Shader Engine to Fetch Unit Bus (Fast Bus)*

Formatted: Bullets and Numbering

Four quad's worth of addresses is transferred to Fetch Unit every clock. These are sourced from a different pixel within each of the sub-engines repeating every 4 clocks. The register file index to read must precede the data by 2 clocks. The Read address associated with Quad 0 must be sent 1 clock after the Instruction Start signal is sent, so that data is read 3 clocks after the Instruction Start.

Four Quad's worth of Fetch Data may be written to the Register file every clock. These are directed to a different pixel of the sub-engines repeating every 4 clocks. The register file index to write must accompany the data. Data and Index associated with the Quad 0 must be sent 3 clocks after the Instruction Start signal is sent.

Name	Direction	Bits	Description
Tex_RegFile_Read_Data	SP->TEX	2048	16 Fetch Addresses read from the Register file
Tex_RegFile_Write_Data	TEX→SP	2048	16 texture results

Formatted

~~20.1.13~~22.1.13 *Sequencer to Fetch Unit bus (Slow Bus)*

Formatted: Bullets and Numbering

Once every four clock, the fetch unit sends to the sequencer on wich clause it is now working and if the data in the registers is ready or not. This way the sequencer can update the fetch counters for the reservation station fifos. The sequencer also provides the intruction and constants for the fetch to execute and the address in the register file where to write the fetch return data.

Name	Direction	Bits	Description
Tex_Ready	TEX→ SEQ	1	Data ready
Tex_Clause_Num	TEX→ SEQ	3	Clause number
Tex_cst	SEQ→TEX	10	Fetch state address 10 bits sent over 4 clocks
Tex_Inst	SEQ→TEX	12	Fetch instruction address 12 bits sent over 4 clocks
EO_CLAUSE	SEQ→TEX	1	Last instruction of the clause
PHASE	SEQ→TEX	1	Write phase signal
LOD_CORRECT	SEQ→TEX	96	LOD correct 3 bits per comp 2 components per quad * 16 quads
Mask	SEQ→TEX	64	Pixel mask 1 bit per pixel
Tex_Clause_Num	SEQ→TEX	3	Clause number
Tex_Write_Register_Index	SEQ->TEX	7	Index into Register file for write of returned Fetch Data
Tex_Read_Register_Index	SEQ->SP	7	Index into Register files for reading Fetch Address (internal)

~~21.~~23. Internal interfaces

Formatted: Bullets and Numbering

~~21.1.1~~23.1.1 *RE to SEQ : Vertex Control Bus*

Name	Direction	Bits	Description
STATE	VGT→SEQ	21	Render State (6*3+3 for constants)
Vert counter	VGT→SEQ	6	Which vertices are valid
Inputs_vert	VGT→SEQ	1	0: Normal 128 bits per vert 1: double 256 bits per vert

This information is sent over 4 clocks.~~s information needs to be sent over 64 clocks.~~

Formatted: Bullets and Numbering

~~22.~~24. Examples of program executions

~~22.1.1~~24.1.1 *Sequencer Control of a Vector of Vertices*

1. PA sends a vector of 64 vertices (actually vertex indices – 32 bits/index for 2048 bit total) to the RE's Vertex FIFO
   - state pointer as well as tag into position cache is sent along with vertices
   - space was allocated in the position cache for transformed position before the vector was sent
   - **also before the vector is sent to the RE, the CP has loaded the global instruction store with the vertex shader program (using the MH?)**
   - The vertex program is assumed to be loaded when we receive the vertex vector.
     - the SEQ then accesses the IS base for this shader using the local state pointer (provided to all sequencers by the RBBM when the CP is done loading the program)
2. SEQ arbitrates between the Pixel FIFO and the Vertex FIFO – basically the Vertex FIFO always has priority
   - at this point the vector is removed from the Vertex FIFO
   - the arbitrer is not going to select a vector to be transformed if the parameter cache is full unless the pipe as nothing else to do (ie no pixels are in the pixel fifo).
3. SEQ allocates space in the SP register file for index data plus GPRs used by the program
   - the number of GPRs required by the program is stored in a local state register, which is accessed using the state pointer that came down with the vertices
   - SEQ will not send vertex data until space in the register file has been allocated
4. SEQ sends the vector to the SP register file over the RE_SP interface (which has a bandwidth of 2048 bits/cycle)
   - the 64 vertex indices are sent to the 64 register files over 4 cycles
     - RF0 of SU0, SU1, SU2, and SU3 is written the first cycle
     - RF1 of SU0, SU1, SU2, and SU3 is written the second cycle
     - RF2 of SU0, SU1, SU2, and SU3 is written the third cycle
     - RF3 of SU0, SU1, SU2, and SU3 is written the fourth cycle
   - the index is written to the least significant 32 bits **(floating point format?) (what about compound indices)** of the 128-bit location within the register file (w); the remaining data bits are set to zero (x, y, z)
5. SEQ constructs a control packet for the vector and sends it to the first reservation station (the FIFO in front of fetch state machine 0, or TSM0 FIFO)
   - the control packet contains the state pointer, the tag to the position cache and a register file base pointer.
6. TSM0 accepts the control packet and fetches the instructions for fetch clause 0 from the global instruction store
   - TSM0 was first selected by the TSM arbiter before it could start
7. all instructions of fetch clause 0 are issued by TSM0
8. the control packet is passed to the next reservation station (the FIFO in front of ALU state machine 0, or ASM0 FIFO)
   - TSM0 does not wait for requests made to the Fetch Unit to complete; it passes the register file write index for the fetch data to the TU, which will write the data to the RF as it is received
   - once the TU has written all the data to the register files, it increments a counter that is associated with ASM0 FIFO; a count greater than zero indicates that the ALU state machine can go ahead start to execute the ALU clause
9. ASM0 accepts the control packet (after being selected by the ASM arbiter) and gets the instructions for ALU clause 0 from the global instruction store
10. all instructions of ALU clause 0 are issued by ASM0, then the control packet is passed to the next reservation station (the FIFO in front of fetch state machine 1, or TSM1 FIFO)
11. the control packet continues to travel down the path of reservation stations until all clauses have been executed
    - position can be exported in ALU clause 3 (or 4?); the data (and the tag) is sent over a position bus (which is shared with all four shader pipes) back to the PA's position cache
    - A parameter cache pointer is also sent along with the position data. This tells to the PA where the data is going to be in the parameter cache.
      - there is a position export FIFO in the SP that buffers position data before it gets sent back to the PA

    - the ASM arbiter will prevent a packet from starting an exporting clause if the position export FIFO is full
- parameter data is exported in clause 7 (as well as position data if it was not exported earlier)
    - parameter data is sent to the Parameter Cache over a dedicated bus
    - the SEQ allocates storage in the Parameter Cache, and the SEQ deallocates that space when there is no longer a need for the parameters (it is told by the PA when using a token).
    - the ASM arbiter will prevent a packet from starting on ASM7 if the parameter cache (or the position buffer if position is being exported) is full

12. after the shader program has completed, the SEQ will free up the GPRs so that they can be used by another shader program

~~22.1.2~~24.1.2 *Sequencer Control of a Vector of Pixels*

Formatted: Bullets and Numbering

1. **As with vertex shader programs, pixel shaders are loaded into the global instruction store by the CP**
    - At this point it is assumed that the pixel program is loaded into the instruction store and thus ready to be read.
2. the RE's Pixel FIFO is loaded with the barycentric coordinates for pixel quads by the detailed walker
    - the state pointer and the LOD correction bits are also placed in the Pixel FIF0
    - the Pixel FIFO is wide enough to source four quad's worth of barycentrics per cycle
3. SEQ arbitrates between Pixel FIFO and Vertex FIFO – when there are no vertices pending OR there is no space left in the register files for vertices, the Pixel FIFO is selected
4. SEQ allocates space in the SP register file for all the GPRs used by the program
    - the number of GPRs required by the program is stored in a local state register, which is accessed using the state pointer
    - SEQ will not allow interpolated data to be sent to the shader until space in the register file has been allocated
5. SEQ controls the transfer of interpolated data to the SP register file over the RE_SP interface (which has a bandwidth of 2048 bits/cycle). See interpolated data bus diagrams for details.
6. SEQ constructs a control packet for the vector and sends it to the first reservation station (the FIFO in front of fetch state machine 0, or TSM0 FIFO)
    - note that there is a separate set of reservation stations/arbiters/state machines for vertices and for pixels
    - the control packet contains the state pointer, the register file base pointer, and the LOD correction bits
    - all other informations (such as quad address for example) travels in a separate FIFO
7. TSM0 accepts the control packet and fetches the instructions for fetch clause 0 from the global instruction store
    - TSM0 was first selected by the TSM arbiter before it could start
8. all instructions of fetch clause 0 are issued by TSM0
9. the control packet is passed to the next reservation station (the FIFO in front of ALU state machine 0, or ASM0 FIFO)
    - TSM0 does not wait for fetch requests made to the Fetch Unit to complete; it passes the register file write index for the fetch data to the TU, which will write the data to the RF as it is received
    - once the TU has written all the data for a particular clause to the register files, it increments a counter that is associated with the ASM0 FIFO; a count greater than zero indicates that the ALU state machine can go ahead and pop the FIFO and start to execute the ALU clause
10. ASM0 accepts the control packet (after being selected by the ASM arbiter) and gets the instructions for ALU clause 0 from the global instruction store
11. all instructions of ALU clause 0 are issued by ASM0, then the control packet is passed to the next reservation station (the FIFO in front of fetch state machine 1, or TSM1 FIFO)
12. the control packet continues to travel down the path of reservation stations until all clauses have been executed
    - pixel data is exported in the last ALU clause (clause 7)
        - it is sent to an output FIFO where it will be picked up by the render backend
        - the ASM arbiter will prevent a packet from starting on ASM7 if the output FIFO is full
13. after the shader program has completed, the SEQ will free up the GPRs so that they can be used by another shader program

~~22.1.3~~24.1.3 *Notes*

Formatted: Bullets and Numbering

14. T~~t~~he state machines and arbitrers will operate ahead of time so that they will be able to immediately start the real threads or stall.
15. T~~t~~he register file base pointer for a vector needs to travel with the vector through the reservation stations, but the instruction store base pointer does not – this is because the RF pointer is different for all threads, but the IS pointer is only different for each state and thus can be accessed via the state pointer
16. Waterfalling~~, parameter buffer allocation, loops and branches and parameter cache de-allocation~~ still needs to be specked out.

~~23.~~25. Open issues

Formatted: Bullets and Numbering

There is currently an issue with constants. If the constants are not the same for the whole vector of vertices, we don’t have the bandwith from the fetch store to feed the ALUs. Two solutions exists for this problem:

1) Let the compiler handle the case and put those instructions in a fetch clause so we can use the bandwith there to operate. This requires a significant amount of temporary storage in the register store.
2) Waterfall down the pipe allowing only at a given time the vertices having the same constants to operate in parrallel. This might in the worst case slow us down by a factor of 16.

Need to do some testing on the size of the register file as well as on the register file allocation method (dynamic VS static).

Saving power?

~~Size of the fifo containing the information of a vector of pixels/vertices. And size of the fifos before the reservation stations.~~

~~Loops and branches.~~

R400 Sequencer Specification

SEQ

Version 1.1~~0~~

Overview: This is an architectural specification for the R400 Sequencer block (SEQ). It provides an overview of the required capabilities and expected uses of the block. It also describes the block interfaces, internal sub-blocks, and provides internal state diagrams.

Revision Changes:

Rev 0.1 (Laurent Lefebvre) Date: May 7, 2001	First draft.
Rev 0.2 (Laurent Lefebvre) Date : July 9, 2001	Changed the interfaces to reflect the changes in the SP. Added some details in the arbitration section.
Rev 0.3 (Laurent Lefebvre) Date : August 6, 2001	Reviewed the Sequencer spec after the meeting on August 3, 2001.
Rev 0.4 (Laurent Lefebvre) Date : August 24, 2001	Added the dynamic allocation method for register file and an example (written in part by Vic) of the flow of pixels/vertices in the sequencer.
Rev 0.5 (Laurent Lefebvre) Date : September 7, 2001	Added timing diagrams (Vic)

Rev 0.6 (Laurent Lefebvre) Date : September 24, 2001	Changed the spec to reflect the new R400 architecture. Added interfaces.
Rev 0.7 (Laurent Lefebvre) Date : October 5, 2001	Added constant store management, instruction store management, control flow management and data dependant predication.
Rev 0.8 (Laurent Lefebvre) Date : October 8, 2001	Changed the control flow method to be more flexible. Also updated the external interfaces.
Rev 0.9 (Laurent Lefebvre) Date : October 17, 2001	Incorporated changes made in the 10/18/01 control flow meeting. Added a NOP instruction, removed the conditional_execute_or_jump. Added debug registers.
Rev 1.0 (Laurent Lefebvre) Date : October 19, 2001	Refined interfaces to RB. Added state registers.
Rev 1.1 (Laurent Lefebvre) Date : October 26, 2001	Added SEQ→SP0 interfaces. Changed delta precision. Changed VGT→SP0 interface. Debug Methods added.

1. Overview

The sequencer first arbitrates between vectors of 64 vertices that arrive directly from primitive assembly and vectors of 16 quads (64 pixels) that are generated in the raster engine.

The vertex or pixel program specifies how many GPR's it needs to execute. The sequencer will not start the next vector until the needed space is available.

The sequencer is based on the R300 design. It chooses two ALU clauses and a fetch clause to execute, and executes all of the instructions in a clause before looking for a new clause of the same type. Two ALU clauses are executed interleaved to hide the ALU latency. Each vector will have eight fetch and eight ALU clauses, but clauses do not need to contain instructions. A vector of pixels or vertices ping-pongs along the sequencer FIFO, bouncing from fetch reservation station to alu reservation station. A FIFO exists between each reservation stage, holding up vectors until the vector currently occupying a reservation station has left. A vector at a reservation station can be chosen to execute. The sequencer looks at all eight alu reservation stations to choose an alu clause to execute and all eight fetch stations to choose a fetch clause to execute. The arbitrator will give priority to clauses/reservation stations closer to the bottom of the pipeline. It will not execute an alu clause until the fetch fetches initiated by the previous fetch clause have completed. There are two separate sets of reservation stations, one for pixel vectors and one for vertices vectors. This way a pixel can pass a vertex and a vertex can pass a pixel.

To support the shader pipe the raster engine also contains the shader instruction cache and constant store. There are only one constant store for the whole chip and one instruction store. These will be shared among the four shader pipes. The four shader pipes also execute the same instuction thus there is only one sequencer for the whole chip.

There are two sets of the above figure, one for vertices and one for pixels.

Depending on the arbitration state, the sequencer will either choose a vertex or a pixel packet. The control packet consists of 21 bits of state, 6-7 bits for the base address of the Shader program and some information on the coverage to determine fetch LOD plus other various small state bits.

On receipt of a packet, the input state machine (not pictured but just before the first FIFO) allocated enough space in the registers to store the interpolated values and temporaries. Following this, the input state machine stacks the packet in the first FIFO.

On receipt of a command, the level 0 fetch machine issues a texure request and corresponding register address for the fetch address (ta). A small command (tcmd) is passed to the fetch system identifying the current level number (0) as well as the register write address for the fetch return data. One fetch request is sent every 4 clocks causing the texturing of sixteen 2x2s worth of data (or 64 vertices). Once all the requests are sent the packet is put in FIFO 1.

Upon recept of the return data, the fetch unit writes the data to the register file using the write address that was provided by the level 0 fetch machine and sends the clause number (0) to the level 0 fetch state machine to signify that the write is done and thus the data is ready. Then, the level 0 fetch machine increments the counter of FIFO 1 to signify to the ALU 1 that the data is ready to be processed.

On receipt of a command, the level 0 ALU machine first decrements the input FIFO counter and then issues a complete set of level 0 shader instructions. For each instruction, the state machine generates 3 source addresses, one destination address (3 cycles later) and an instruction. Once the last instruction as been issued, the packet is put into FIFO 2.

There will always be two active ALU clauses at any given time (and two arbitrers). One arbitrer will arbitrate over the odd instructions (4 clocks cycles) and the other one will arbitrate over the even instructions (4 clocks cycles). The only constraints between the two arbitrers is that they are not allowed to pick the same clause number as the other one is currently working on if the packet is not of the same type (render state).

If the packet is a vertex packet, upon reaching ALU clause 3, it can export the position if the position is ready. So the arbitrer must prevent ALU clause 3 to be selected if the positional buffer is full (or can’t be accessed). Along with the positional data, the location where the vertex data is to be put is also sent (parameter data pointers).

{ISSUE: How do we handle parameter cache pointers (computed, semi-computed or not computed)?}

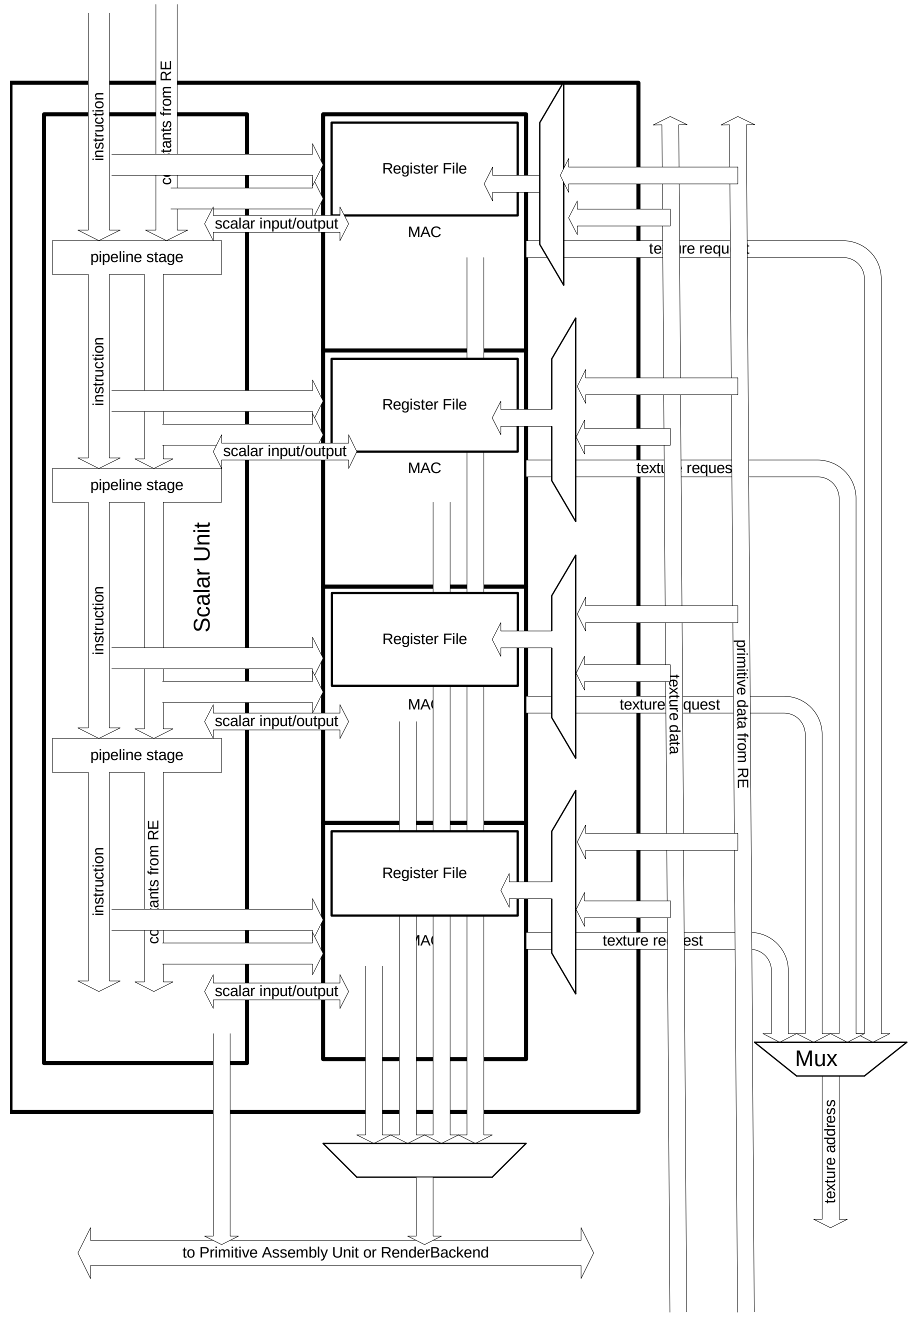
A special case is for HOS surfaces wich can export 12 parameters per last 6 clauses to the output buffer. If the output buffer is full or doesn’t have enough space the sequencer will prevent such a vertex group to enter an exporting clause.

Regular pixel and vertex shaders can export 12 parameters to memory from the last clause only (7).

All other level process in the same way until the packet finally reaches the last ALU machine (7). On completion of the level 7 ALU clause, a valid bit is sent to the Render Backend which picks up the color data. This requires that the last instruction writes to the output register – a condition that is almost always true. If the packet was a vertex packet, instead of sending the valid bit to the RB, it is sent to the PA so it can know that the data present in the parameter store is valid.

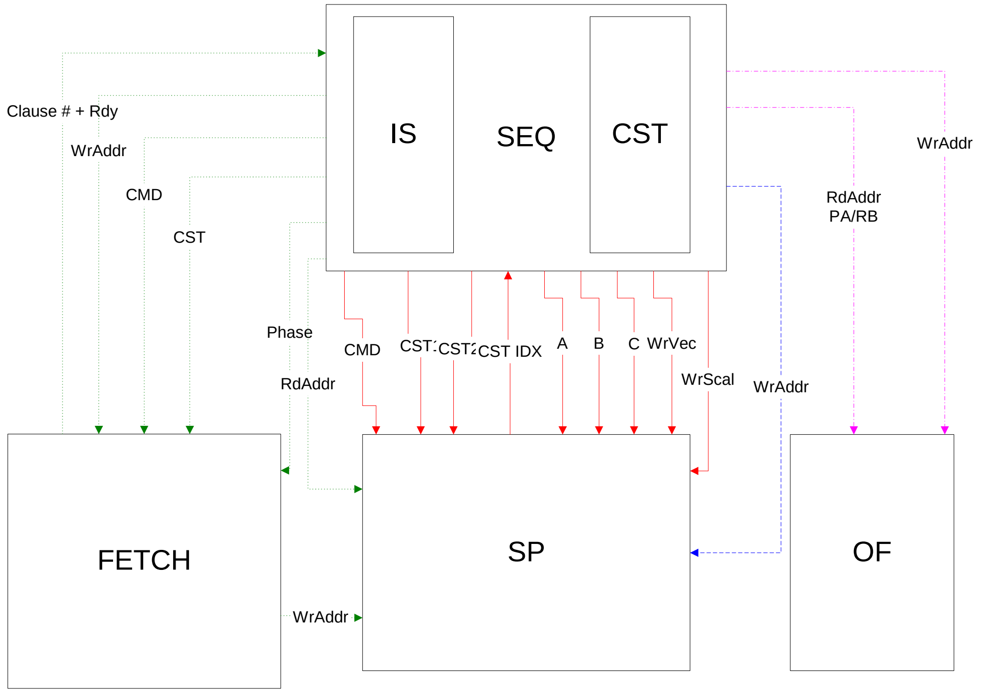
Only two ALU state machine may have access to the register file address bus or the instruction decode bus at one time. Similarly, only one fetch state machine may have access to the register file address bus at one time. Arbitration is performed by three arbitrer blocks (two for the ALU state machines and one for the fetch state machines). The arbitrers always favor the higher number state machines, preventing a bunch of half finished jobs from clogging up the register files.

1.2 Data Flow graph



The gray area represents blocks that are replicated 4 times per shader pipe (16 times on the overall chip).

1.3 Control Graph



In green is represented the Fetch control interface, in red the ALU control interface, in blue the Interpolated/Vector control interface and in purple is the output file control interface.

2. Interpolated data bus

The interpolators contain an IJ buffer to pack the information as much as possible before writing it to the register file.

P0

P1

Above is an example of a tile we might receive. The IJ information is packed in the IJ buffer 2 quads at a time. The sequencer allows at any given time as many as four quads to interpolate a parameter. They all have to come from the same primitive. Then the sequencer controls the write mask to the register to write the valid data in.

3. Instruction Store

There is going to be only one instruction store for the whole chip. It will contain 4096 instructions of 96 bits each. There is also going to be a control instruction store of size 256(512?)x32.

{ISSUE : The instruction store is loaded by the sequencer using the memory hub ?}.

The read bandwith from this store is 96*2 bits/ 4 clocks (48 bits/clock). It is likely to be a 1 port memory; we use 1 clock to load the ALU instruction, 1 clocks to load the Fetch instruction, 1 clock to load 2 control flow instructions and 1 clock to write instructions.

4. Sequencer Instructions

All control flow instructions and move instructions are handled by the sequencer only. The ALUs will perform NOPs during this time (MOV PV,PV, PS,PS).

5. Constant Store

The constant store is managed by the CP. The sequencer is aware of where the constants are using a remaping table also managed by the CP. A likely size for the constant store is 512x128 bits. The constant store is also planned to be shared. The read BW from the constant store is 128 bits/clock and the write bandwith is 32/4 bits/clock.

In order to do constant store indexing, the sequencer must be loaded first with the indexes (that come from the GPRs). There are 144 wires from the exit of the SP to the sequencer (9 bits pointers x 16 vertexes/clock). Since the data must pass thru the Shader pipe for the float to fixed convertion, there is a latency of 4 clocks (1 instruction) between the time the sequencer is loaded and the time one can index into the constant store. The assembly will look like this

```
MOVA  R1.X,R2.X        // Loads the sequencer with the content of R2.X, also copies the content of R2.X into R1.X
NOP                    // latency of the float to fixed conversion
ADD   R3,R4,C0[R2.X]// Uses the state from the sequencer to add R4 to C0[R2.X] into R3
```

Note that we don't really care about what is in the brackets because we use the state from the MOVA instruction. R2.X is just written again for the sake of simplicity.

The storage needed in the sequencer in order to support this feature is 2*64*9 bits = 1152 bits.

6. Looping and Branches

Loops and branches are planned to be supported and will have to be dealt with at the sequencer level. We plan on supporting constant loops and branches using a control program.

6.1 The controlling state.

As per Dx9 the following state is available for control flow:

Boolean[15:0]
loop_count[7:0][7:0]
 In addition:
loop_start [7:0] [7:0]
loop_step [7:0] [7:0]
 Exist to give more control to the controlling program.

We will extend that in the R400 to:

Boolean[255:0]
Loop_count[7:0][15:0]
Loop_Start[7:0] [15:0] times 2 (one for constant,registert)
Loop_Step[7:0] [15:0] times 2 (one for constant,register)
Loop_End[7:0] [15:0]

{ISSUE: How is the controlling state loaded and how many contexts do we have?}

We have a stack of 4 elements for calling subroutines and 4 loop counters to allow for nested loops.

~~We also keep 8 predicate vectors and 8 AND/OR sets of 3 bits. These bits can be 0: all 0s, 1: all ones and 11: mixed.~~

6.2 The Control Flow Program

The R300 uses a match method for control flow: The shader is executed, and at every instruction its address is compared with addresses (or address?) in a control table. The “event” in the control table can redirect operations in the program.

The Method chosen for the R400 is a “control program”. The control program has ten basic instructions:

Execute
Conditional_execute
Conditional_Execute_Predicates
~~Conditional_execute_or_Jump~~
Conditional_jump
Call
Return
Loop_start
Loop_end
End_of_clause
NOP

Execute, causes the specified number of instructions in instruction store to be executed.
Conditional_execute checks a condition first, and if true, causes the specified number of instructions in instruction store to be executed.
Loop_start resets the corresponding loop counter to the start value on the first pass after it checks for the end condition and if met jumps over to a specified address.
Loop_end increments (decrements?) the loop counter and jumps back the specified number of instructions.
Call jumps to an address and pushes the IP counter on the stack. On the return instruction, the IP is poped from the stack.
Conditional_execute_or_Jump executes a block of instructions or jumps to an address is the condition is not met.
Conditional_execute_Predicates executes a block of instructions if all bits in the predicate vectors meet the condition.
End_of_clause marks the end of a clause.
Conditional_jumps jumps to an address if the condition is met.
NOP is a regular NOP

NOTE THAT ALL JUMPS MUST JUMP TO EVEN CFP ADDRESSES. Thus the compiler must insert NOPs where needed to align the jumps on even CFP addresses.

Also if the jump is logically bigger than pshader_cntl_size (or vshader_cntl_size) we break the program (clause) and set the debug registers. If an execute or conditional_execute is lower than cntl_size or bigger than size we also break the program (clause) and set the debug registers.

We have to fit instructions into 48 bits in order to be able to put two control flow instruction per line in the instruction store.

Execute				
47	46… 42	41 … 24	23 … 12	11 … 0

Addressing	00001	RESERVED	Instruction _count	Exec Address

Execute up to 4k instructions at the specified address in the instruction memory.

NOP		
47	46 … 42	41 … 0
Addressing	00010	RESERVED

If the specified boolean (8 bits can address 256 booleans) meets the specified condition then execute the specified instructions (up to 512 instructions) or if the condition is not met jump to the jump address in the control flow program. This MUST be a forward jump.

Conditionnal_Execute						
47	46 … 42	41 … 34	33	32 … 24	23 … 12	11 … 0
Addressing	00011	Boolean address	Condition	RESERVED	Instruction_count	Exec Address

If the specified boolean (8 bits can address 256 booleans) meets the specified condition then execute the specified instructions (up to 4k instructions)

Conditionnal_Execute_Predicates						
47	46 … 42	41 … 38	37	36 … 24	23 … 12	11 … 0
Addressing	00100	Predicate vector	Condition	RESERVED	Instruction_count	Exec Address

Check the AND/OR of all current predicate bits. If AND/OR matches the condition execute the specified number of instructions.

Loop_Start				
47	46 … 42	41 … 16	15 … 4	3 … 0
Addressing	00101	RESERVED	Jump address	Loop ID

Loop Start. Compares the loop count with the end value. If loop condition not met jump to the address. Forward jump only. Also computes the index value.

Loop_End				
47	46 … 42	41 … 16	15 … 4	3 … 0
Addressing	00111	RESERVED	Start address	Loop ID

Loop end. Increments the counter by one and jumps BACK only to the start of the loop.

The way this is described does not prevent nested loops, and the inclusion of the loop id make this easy to do.

Call			
47	46 … 42	41…12	11 … 0
Addressing	01000	RESERVED	Address

Jumps to the specified address and pushes the IP counter on the stack.

Return		
47	46 … 42	41 … 0
Addressing	01001	RESERVED

Pops the topmost address from the stack and jumps to that address. If nothing is on the stack, the program will just continue to the next instruction.

Conditionnal_Jump						
47	46 … 42	41 … 34	33	32 … 13	12	11 … 0
Addressing	01010	Boolean address	Condition	RESERVED	FW only	Address

If condition met, jumps to the address. FORWARD jump only allowed if bit 12 set. Bit 12 is only an optimization for the compiler and should NOT be exposed to the API.

End_of_Clause		
47	46 … 42	41 … 0

Addressing	01011	RESERVED

Marks the end of a clause.

To prevent infinite loops, we will keep 9 bits loop counters instead of 8 (we are only able to loop 256 times). If the counter goes higher than 255 then the loop_end or the loop_start is going to break the loop and set de debug registers. The sequencer will keep two loop indexes values:

IC index for constant indexing (9 bits)
IR index for register file indexing (7 bits)

This will be updated ~~everytime~~every time we loop and can only be used to index the constant store and the register file. The way to compute this value is:

Index = Loop_counter*Loop_iterator + Loop_init.

The IC for constant is going to return 0 if it is out of the constant range. The IR index is going to break the program if the index ~~exeeds~~exceeds the number of requested registers.

The basic model is as follows:

The render state defined the clause boundaries:

Vertex_shader_fetch[7:0][7:0]	// eight 8 bit pointers to the location where each clauses control program is located
Vertex_shader_alu[7:0][7:0]	// eight 8 bit pointers to the location where each clauses control program is located
Pixel_shader_fetch[7:0][7:0]	// eight 8 bit pointers to the location where each clauses control program is located
Pixel_shader_alu[7:0][7:0]	// eight 8 bit pointers to the location where each clauses control program is located

A pointer value of FF means that the clause doesn't contain any instructions.

The control program for a given clause is executed to completion before moving to another clause, (with the exception of the pick two nature of the alu execution). The control program is the only program aware of the clause boundaries.

6.3 Data dependant predicate instructions

Data dependant conditionals will be supported in the R400. The only way we plan to support those is by supporting three vector/scalar predicate operations of the form:

PRED_SETE_# - similar to SETE except that the result is 'exported' to the sequencer.
PRED_SETGT_# - similar to SETGT except that the result is 'exported' to the sequencer
PRED_SETGTE_# - similar to SETGTE except that the result is 'exported' to the sequencer

For the scalar operations only we will also support the two following instructions:
PRED_SETE0_# – SETE0
PRED_SETE1_# – SETE1

The export is a single bit - 1 or 0 that is sent using the same data path as the MOVA instruction. The sequencer will maintain 4 sets of 64 bit predicate vectors (in fact 8 sets because we interleave two programs but only 4 will be exposed) and use it to control the write masking. This predicate is not maintained across clause boundaries. The # sign is used to specify ~~wich~~which predicate set you want to use 0 thru 3.

Then we have two conditional execute bits. The first bit is a conditional execute "on" bit and the second bit tells us if we execute on 1 or 0. For ~~exemple~~example, the instruction:

P0_ADD_# R0,R1,R2

Is only going to write the result of the ADD into those GPRs whose predicate bit is 0. Alternatively, P1_ADD_# would only write the results to the GPRs whose predicate bit is set. The use of the P0 or P1 without precharging the sequencer with a PRED instruction is undefined.

{Issue: do we have to have a NOP between PRED and the first instruction that uses a predicate?}

6.4 HW Detection of PV,PS

Formatted: Bullets and Numbering

Because of the control program, the compiler cannot detect statically dependant instructions. In the case of non-masked writes and subsequent reads the sequencer will insert uses of PV,PS as needed. This will be done by comparing the read address and the write address of consecutive instructions. For masked writes, the sequencer will insert NOPs wherever there is a dependant read/write.

The sequencer will also have to insert NOPs between PRED_SET and MOVA instructions and their uses.

~~6.4~~6.5 Register file indexing

Formatted: Bullets and Numbering

Because we can have loops in fetch clause, we need to be able to index into the register file in order to retrieve the data created in a fetch clause loop and use it into an ALU clause. The instruction will include the base address for register indexing and the instruction will contain these ~~controls :~~controls:

Bit7	Bit 6	
0	0	'absolute register'
0	1	'relative register'
1	0	'previous vector'
1	1	'previous scalar'

In the case of an absolute register we just take the address as is. In the case of a relative register read we take the base address and we add to it the loop_index and this becomes our new address that we give to the shader pipe.

6.6 Predicated Instruction support for Texture clauses

Formatted: Bullets and Numbering

For texture clauses, we support the following optimization: we keep 1 bit (thus 4 bits for the four predicate vectors) per predicate vector in the reservation stations. A value of 1 means that one ore more elements in the vector have a value of one (thus we have to do the texture fetches for the whole vector. A value of 0 means that no elements in the vector have his predicate bit set and we can thus skip over the texture fetch.

6.7 Debugging the Shaders

Formatted: Bullets and Numbering

In order to be able to debug the pixel/vertex shaders efficiently, we provide 3 methods.

6.7.1 *Method 1: Debugging registers*

Formatted: Bullets and Numbering

Current plans are to expose 2 debugging, or error notification, registers:
1. address register where the first error occurred
2. count of the number of errors

The sequencer will detect the following groups of errors:
- count overflow
- jump error
 relative jump address > size of the control flow program
 relative jump address > length of the shader program
- constant overflow
- register overflow
- call stack
 call with stack full
 return with stack empty

With two of the errors, a jump error or a register overflow will cause the program to break. In this case, a break means that a clause will halt execution, but allowing further clauses to be executed.

With the other errors, program can continue to run, potentially to worst-case limits.

If indexing outside of the constant range, causing an overflow error, the hardware is specified to return the value with an index of 0. This could be exploited to generate error tokens, by reserving and initializing the 0th register (or constant) for errors.

6.7.2 Method 2: Exporting the values in the GPRs (12)

Formatted: Bullets and Numbering

The sequencer will have a count register and an address register for this mode and 3 bits per clause specifying the execution mode for each clause. The modes can be :

1) Normal
2) Debug Kill
3) Debug Addr
4) Debug Count

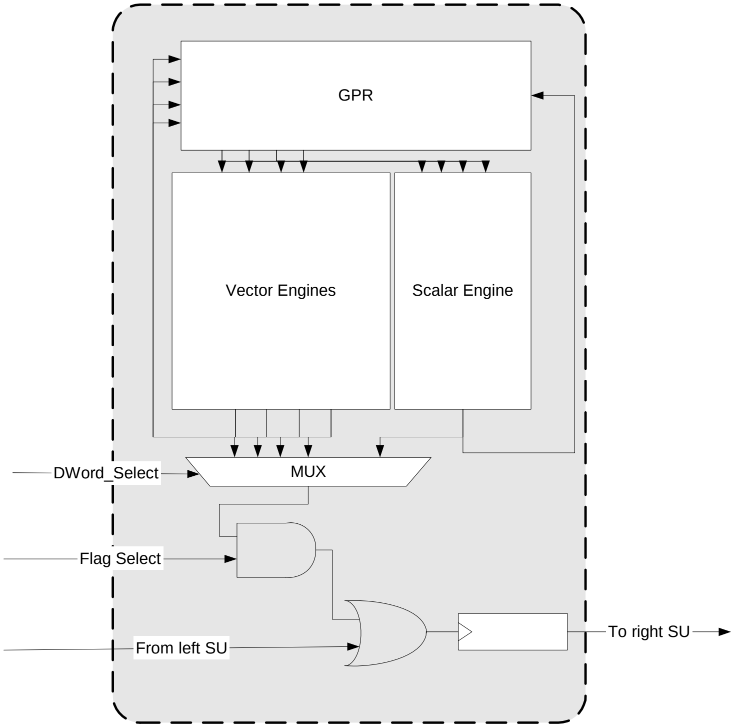
Formatted: Bullets and Numbering

Under the normal mode execution follows the normal course. Under the kill mode, all control flow instructions are executed but all normal shader instructions of the clause are replaced by NOPs. Only debug_export instructions of clause 7 will be executed under the debug kill setting. Under the two other modes, normal execution is done until we reach an address specified by the address register or an instruction count (useful for loops) specified by the count register. After we have hit the address or the count we change to the kill mode for the rest of the clause.

6.7.3 Method 3: Selective export of a 32 bit Dword.

Formatted: Bullets and Numbering

The third debug option will be mainly used for HW debug. For this mode, the sequencer will keep the following control debug registers: Shader_pipe (6 bits), Mode(1 bit), Dword_select (3 bits), clause_+count (16 bits?),address (12 bits) Vector_number (8 bits), Render_state (21 bits). The shader pipe register selects a shader pipe amongst the 64, the dword_select selects a channel (0…3 of vector or scalar), the clause_+count selects at which clause and which count we export, the Render_state specifies which render state is concerned, the Vector_number specifies which vector is concerned and the mode selects count export, or address export.



Flag Select is a combination of Shader pipe, clause +count, address, Vector number and render state. It is only active for 1 shader pipe at a time and for 1 vector of a given state. The driver is responsible to reset the output register to 0 before executing a given program.

7. Pixel Kill Mask

A vector of 64 bits is kept per group of pixels/vertices. Its purpose is to optimize the texture fetch requests and allow the shader pipe to kill pixels using the following instructions:

MASK_SETE
MASK_SETGT
MASK_SETGTE

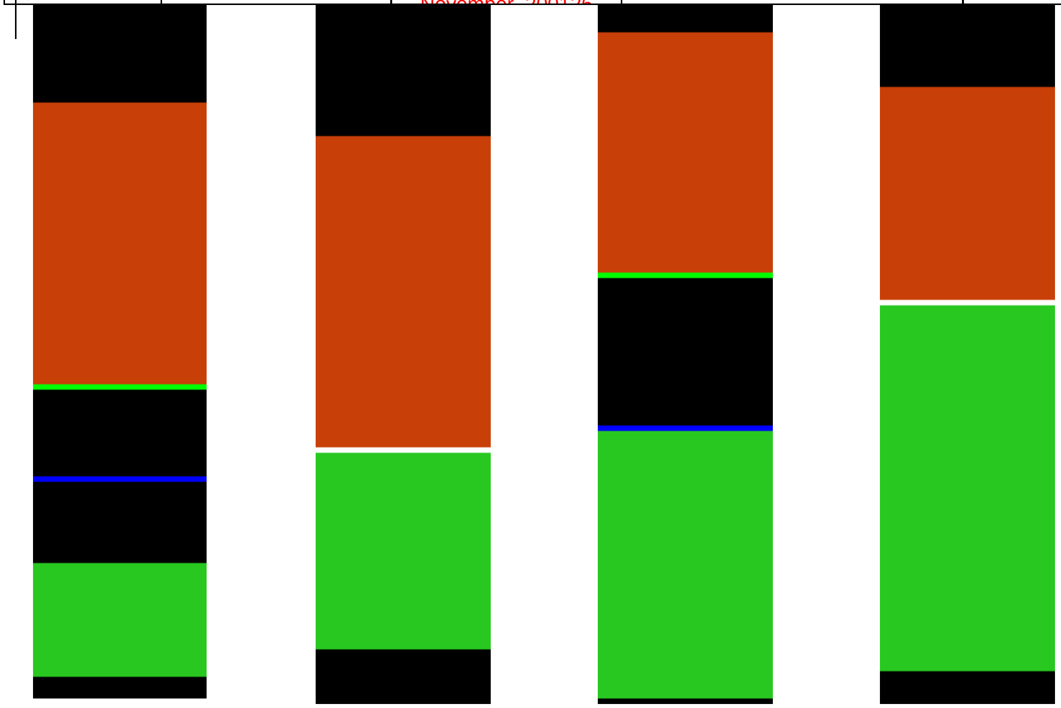
~~However, if the driver sets the kill_vector_on register to 0 (don't use) then the 64 bit kill mask becomes the 5th predicate vector and is kept across clause boundaries (thus allowing predicated instructions to be used in texture clauses). In this mode, the sequencer is going to send all 1s to the RBs for coverage mask information.~~

8. HOS surfaces

HOS surfaces are able to export from the 6 last clauses but to memory ONLY. If they want to export to the parameter cache they have to do it in the last clause (7). They can also export position in clause 3. ~~The buffer they want to export into must be specified in the "exports" field of the state registers.~~

9. Register file allocation

The register file allocation for vertices and pixels can either be static or dynamic. In both cases, the register file in managed using two round robins (one for pixels and one for vertices). In the dynamic case the boundary between pixels and vertices is allowed to move, in the static case it is fixed to VERTEX_REG_SIZE for vertices and 256-VERTEX_REG_SIZE for pixels.



Above is an example of how the algorithm works. Vertices come in from top to bottom; pixels come in from bottom to top. Vertices are in orange and pixels in green. The blue line is the tail of the vertices and the green line is the tail of the pixels. Thus anything between the two lines is shared. When pixels meets vertices the line turns white and the boundary is static until both vertices and pixels share the same "unallocated bubble". Then the boundary is allowed to move again.

10. Fetch Arbitration

The fetch arbitration logic chooses one of the 8 potentially pending fetch clauses to be executed. The choice is made by looking at the fifos from 7 to 0 and picking the first one ready to execute. Once chosen, the clause state machine will send one 2x2 fetch per clock (or 4 fetches in one clock every 4 clocks) until all the fetch instructions of the clause are sent. This means that there cannot be any dependencies between two fetches of the same clause.

The arbitrator will not wait for the fetches to return prior to selecting another clause for execution. The fetch pipe will be able to handle up to X(?) in flight fetches and thus there can be a fair number of active clauses waiting for their fetch return data.

11. ALU Arbitration

ALU arbitration proceeds in almost the same way than fetch arbitration. The ALU arbitration logic chooses one of the 8 potentially pending ALU clauses to be executed. The choice is made by looking at the fifos from 7 to 0 and picking the first one ready to execute. There are two ALU arbitrers, one for the even clocks and one for the odd clocks. For exemple, here is the sequencing of two interleaved ALU clauses (E and O stands for Even and Odd sets of 4 clocks):

Einst0 Oinst0 Einst1 Oinst1 Einst2 Oinst2 Einst0 Oinst3 Einst1 Oinst4 Einst2 Oinst0…
Proceeding this way hides the latency of 8 clocks of the ALUs.

12. Handling Stalls

When the output file is full, the sequencer prevents the ALU arbitration logic to select the last clause (this way nothing can exit the shader pipe until there is place in the output file. If the packet is a vertex packet and the position buffer is full (POS_FULL) then the sequencer also prevents a thread to enter the exporting clause (4?). The sequencer will set the OUT_FILE_FULL signal n clocks before the output file is actually full and thus the ALU arbitrer will be able read this signal and act accordingly by not preventing exporting clauses to proceed.

13. Content of the reservation station FIFOs

21 bits of Render State 7 bits for the base address of the GPRs, some bits for LOD correction and coverage mask information in order to fetch fetch for only valid pixels, quad address and 1 bit to specify if the vector is of pixels or vertices. Since pixels and vertices are kept in order in the shader pipe, we only need two fifos (one for vertices and one for pixels) deep enough to cover the shader pipe latency. This size will be determined later when we will know the size of the small fifos between the reservation stations.

14. The Output File

The output file is where pixels are put before they go to the RBs. The write BW to this store is 256 bits/clock. Just before this output file are staging registers with write BW 512 bits/clock and read BW 256 bits/clock. For this reason only ONE concurrent program can be of clause 8 (exporting clause) the other program MUST not. The staging registers are 4x128 (and there are 16 of those on the whole chip).

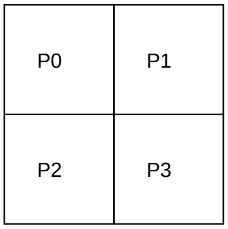
15. IJ Format

The IJ information sent by the PA is of this format on a per quad basis:

We have a vector of IJ's (one IJ per pixel at the centroid of the fragment or at the center of the pixel depending on the mode bit). The interpolation is done at a different precision across the 2x2. The upper left pixel's parameters are always interpolated at full ~~19x24~~ 20x24 mantissa precision. Then the result of the interpolation along with the difference in IJ in reduced precision is used to interpolate the parameter for the other three pixels of the 2x2. Here is how we do it:

Assuming P0 is the interpolated parameter at Pixel 0 having the barycentric coordinates I(0), J(0) and so on for P1,P2 and P3. Also assuming that A is the parameter value at V0 (interpolated with I), B is the parameter value at V1 (interpolated with J) and C is the parameter value at V2 (interpolated with (1-I-J).

$$\Delta 01I = I(1) - I(0)$$
$$\Delta 01J = J(1) - J(0)$$
$$\Delta 02I = I(2) - I(0)$$
$$\Delta 02J = J(2) - J(0)$$
$$\Delta 03I = I(3) - I(0)$$
$$\Delta 03J = J(3) - J(0)$$



$$P0 = C + I(0)*(A - C) + J(0)*(B - C)$$
$$P1 = P0 + \Delta 01I*(A - C) + \Delta 01J*(B - C)$$
$$P2 = P0 + \Delta 02I*(A - C) + \Delta 02J*(B - C)$$
$$P3 = P0 + \Delta 03I*(A - C) + \Delta 03J*(B - C)$$

P0 is computed at ~~19x24~~ 20x24 mantissa precision and P1 to P3 are computed at 8X24 mantissa precision. So far no visual degradation of the image was seen using this scheme.

Multiplies (Full Precision): 2
Multiplies (Reduced precision): 6
Subtracts 19x24 (Parameters): 2
Adds: 8

FORMAT OF P0’s IJ : Mantissa ~~19~~ 20 Exp 4 for I + Sign
Mantissa ~~19~~ 20 Exp 4 for J + Sign

FORMAT of Deltas (x3):Mantissa 8 Exp 4 for I + Sign
Mantissa 8 Exp 4 for J + Sign

Total number of bits : 19*2 + 8*6 + 4*8 + 4*2 = 128

The Deltas have a leading 1, the Full precision IJs don’t. This means that in the case of the deltas we MUST be able to shift 8 right (exponent value of 0 means number = 0, exponent value of 1 means shift right 8). This means that the maximum range for the IJs (Full precision) is +/- 64 and the range for the Deltas is +/- 128.~~6~~

16. The parameter cache

The parameter cache is where the vertex shaders export their data. It consists of 16 128x128 memories (1R/1W). The reuse engine will make it so that all vertexes of a given primitive will hit different memories.

17. Vertex position exporting

On clause 4 (or 5) the vertex shader can export to the PA both the vertex position and the point sprite. It can also do so at clause 8 if not done at clause 4. Along with the position is exported a pointer to the parameter cache where the data will be once the vertex shader exports. The storage needed to perform the position export is at least 64x128 memories for the position and 64x32 memories for the sprite size. It is going to be taken in the pixel output fifo.

18. Exporting Arbitration

Here are the rules for co-issuing exporting ALU clauses.

1) Position exports and position exports cannot be co-issued.
2) Position exports and memory exports cannot be co-issued.
3) Position exports and Z/Color exports cannot be co-issued.
4) Memory exports and Z/Color exports cannot be co-issued.
5) Memory exports and memory exports cannot be co-issued.
6) Z/color exports and Z/color exports cannot be co-issued.
7) Parameter exports and Z/Color exports CAN be co-issued.
8) Parameter exports and parameter exports CAN be co-issued.
9) Parameter exports and memory exports CAN be co-issued.

19. Real time commands

We are unable to use the parameter memory since there is no way for a command stream to write into it. Instead we need to add three 16x128 memories (one for each of three vertices x 16 interpolants). These will be mapped onto the register bus and written by type 0 packets, and output to the the parameter busses (the sequencer and/or PA need to be able to address the realtime parameter memory as well as the regular parameter store. For higher performance we should be able able to view them as two banks of 16 and do double buffering allowing one to be loaded, while the other is rasterized with. Most overlay shaders will need 2 or 4 scalar coordinates, one option might be to restrict the memory to 16x64 or 32x64 allowing only two interpolated scalars per cycle, the only problem I see with this is, if we view support for 16 vector-4 interpolants important (true only if we map microsoft's high priority stream to the realtime stream), then the PA/sequencer need to support a realtime-specific mode where we need to address 32 vectors of parameters instead of 16.

20. Registers

20.1 Control

DYNAMIC_REG	Dynamic allocation (pixel/vertex) of the register file on or off.
VERTEX_REG_SIZE	What portion of the register file is reserved for vertices (static allocation only)
PIXEL_MIN_SIZE	Minimal size of the register file's pixel portion (dynamic only)
VERTEX_MIN_SIZE	Minimal size of the register file's vertex portion (dynamic only)
ARBITRATION_policy	policy of the arbitration between ~~vetexes~~vertexes and pixels
CST_SIZE_P	Size of the constant store for pixels
CST_SIZE_V	Size of the constant store for vertexes
INST_STOR_ALLOC	interleaved, separate, interleaved+shared,separate+shared
~~VWRAP~~PWRAP	~~wrap~~start point for the ~~vertex~~pixel shader instruction store (vertex shader always starts at 0)
~~PWRAP~~SHAREDWRAP	~~wrap~~start point for the ~~pixel shader~~shared instruction store
RTWRAP	start point for the RT instruction store (RT always ends at the end of the IM)
NO_INTERLEAVE	debug state register. Only allows one program at a time into the GPRs

20.2 Context

Vshader_fetch[7:0][7:0]	eight 8 bit pointers to the location where each clauses control program is located
Vshader_alu[7:0][7:0]	eight 8 bit pointers to the location where each clauses control program is located
Pshader_fetch[7:0][7:0]	eight 8 bit pointers to the location where each clauses control program is located
Pshader_alu[7:0][7:0]	eight 8 bit pointers to the location where each clauses control program is located
PSHADER	base pointer for the pixel shader
VSHADER	base pointer for the vertex shader
Vshader_cntl_size	size of the vertex shader (# of instructions in control program/2)
Pshader_cntl_size	size of the pixel shader (# of instructions in control program/2)
Pshader_size	size of the pixel shader (cntl+instructions)
Vshader_size	size of the vertex shader (cntl+instructions)
REG_ALLOC_PIX	number of registers to allocate for pixel shader programs
REG_ALLOC_VERT	number of registers to allocate for vertex shader programs
FLAT_GOUR[0…15]	~~wich~~which parameters are to be gouraud shaded
~~GEN_TEX~~	~~Do we generate texture coordinates for 1st parameter or not~~
CYL_WRAP[0…63]	for ~~wich~~which parameters (and channels (xyzw)) do we do the cyl wrapping.
P_export_mode	0xxxx : Normal mode 1xxxx : Multipass mode If normal, bbbz where bbb is how many colors (0-4) and z is export z or not If multipass 1-12 exports for color.
vshader_export_mask	~~wich~~which of the last 6 ALU clauses is exporting
vshader_export_mode	0: position (1 vector), 1: position (2 vectors), 3:multipass
vshader_export_count[6]	# of interpolated parameters exported in clause 7 OR # of exported vectors to memory per clause in multipass mode (per clause)
kill_vector_on	use the mask kill vector to kill pixels and optimize texture pipe fetches OR use it as the fifth predicate vector ~~wich~~which is the only predicate vector kept across clause boundaries.

21. DEBUG registers

21.1 Control

Formatted: Bullets and Numbering

Shader_pipe	# of the shader pipe for method 3 (0…64)
Count_+clause	instruction count and clause number for method 3
Dword_select	channel select for method 3

Mode	operating mode for method 3
Rstate	render state method 3 is operating on
Vector_count	vector number the method 3 will export

21.2 Context

Formatted: Bullets and Numbering

PROB_ADDR	instruction address where the first problem occurred
PROB_COUNT	number of problems encountered during the execution of the program
Count	instruction counter for debug method 2
Clause_mode[3]	clause mode for debug method 2

22. Interfaces

22.1 External Interfaces

22.1.1 *PA/SC to SP0 : IJ bus*

This is a bus that sends the IJ information to the IJ fifos on the top of each shader pipe. At the same time the control information goes to the sequencer. There are 4 of these buses over the whole chip (SP0 thru 3)

Name	Direction	Bits	Description
IJs	PA→SP0	64~~3~~	IJ information sent over 2 clocks
Mask	PA→SP0	1	Write Mask

22.1.2 *PA/SC to SEQ : IJ Control bus*

This is the control information sent to the sequencer in order to control the IJ fifos and all other information needed to execute a shader program on the sent pixels.

Name	Direction	Bits	Description
Write Mask	PA→SEQ(SP)	4	Quad Write mask left to right
LOD_CORRECT	PA→SEQ(SP)	24	LOD correction per quad (6 bits per quad)
FVTX	PA→SEQ(SP)	2	Provoking vertex for flat shading
PPTR0	PA→SEQ(SP)	11	P Store pointer for vertex 0
PPRT1	PA→SEQ(SP)	11	P Store pointer for vertex 1
PPTR2	PA→SEQ(SP)	11	P Store pointer for vertex 2
E_OFF_VECTOR	PA→SEQ(SP)	1	End of the vector
DEALLOC	PA→SEQ(SP)	1	Deallocation token for the P Store
STATE	PA→SEQ(SP)	21	State/constant pointer (6*3+3)
VALID	PA→SEQ(SP)	16	Valid bits for all pixels
NULL	PA→SEQ(SP)	1	Null Primitive (for PC deallocation purposes)
E_OFF_PRIM	PA→SEQ(SP)	1	End Of the primitive

Control Instruction	MH→SEQ	32	Control Instruction X times

{ISSUE: CP or MH?}

~~22.1.8~~22.1.12 SP0 to ~~RB~~ SX0 : Pixel read from RBs

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
Export_data	SP0→~~RB~~SX0	64*16	32 pairs of 32 bits channel values
Shader_Dest	SP0→SX0~~SP→RB~~	4	Specifies one of the of up to 12 export destinations
Shader_Count	SP0→SX0~~SP→RB~~	3	Each set of four pixels or vectors is exported over eight clocks. This field specifies where the SP is in that sequence.
Shader_Last	SP0→SX0~~SP→RB~~	1	The current export clause is over (true for one clock) The last export instruction creates *two* cycles to the RB. This needs to be set on or after the last RB cycle that is produced by the last export instruction, but before the first RB cycle of the first export instruction of the next clause.
Shader_PixelValid	SP0→SX0~~SP→RB~~	4x4	Result of pixel kill in the shader pipe, which must be output for all pixel exports (depth and all color buffers). 4x4 because 16 pixels are computed per clock
Shader_WordValid	SP0→SX0~~SP→RB~~	2	Specifies whether to write low and/or high 32-bit word of the 64-bit export data from each of the 16 pixels or vectors

~~22.1.9~~22.1.13 SEQ to ~~RB~~ SX0 : Control bus

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
Export_Pixel	SEQ→~~RB~~SX0	1	1: Pixel 0: Vertex
Export_SEND	SEQ→SX0~~SEQ→RB~~	1	Raised to indicate that the SQ is starting an export
Export_Clause	SEQ→SX0~~SEQ→RB~~	3	Clause number, which is needed for vertex clauses
Export_State	SEQ→SX0~~SEQ→RB~~	21?	State ID, which is needed for vertex clauses

These fields are sent synchronously with SP export data, described in SP0→~~RB~~ SX0 interface

{ISSUE: Where are the PC pointers}

~~22.1.10~~22.1.14 ~~RB~~ SX0 to SEQ : Output file control

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
Export_RTS	~~RB~~SX0→SEQ	1	Raised by ~~RB~~ SX0 to indicate that the following two fields reflect the result of the most recent export
Export_Position	SX0→SEQ~~RB→SEQ~~	1	Specifies whether there is room for another position.
Export_Buffer	SX0→SEQ~~RB→SEQ~~	7	Specifies the space availble in the output buffers. 0: buffers are full

			1: 2K-bits available (32-bits for each of the 64 pixels in a clause) ... 64: 128K-bits available (16 128-bit entries for each of 64 pixels) 65-127: RESERVED

Formatted: Bullets and Numbering

~~22.1.11~~22.1.15 *SP0 to ~~RB~~ SX0 : Position return bus*

Name	Direction	Bits	Description
Position return	SP0→~~RB~~SX0	128	Position data or sprite size (per clock)

~~For point sprites and position exports the size and position are interleaved on a 16 x 16 basis. We export 1 position then 1 point sprite sizes. The storage used is of 64x128 bits for position and 64x32 bits for sprite size, it is taken from the output buffer. Additionnally,if needed the edge flags are packed into the bits of the sprite sizes.~~

Formatted: Bullets and Numbering

~~22.1.12~~22.1.16 *Shader Engine to Fetch Unit Bus (Fast Bus)*

Four quad's worth of addresses is transferred to Fetch Unit every clock. These are sourced from a different pixel within each of the sub-engines repeating every 4 clocks. The register file index to read must precede the data by 2 clocks. The Read address associated with Quad 0 must be sent 1 clock after the Instruction Start signal is sent, so that data is read 3 clocks after the Instruction Start.

Four Quad's worth of Fetch Data may be written to the Register file every clock. These are directed to a different pixel of the sub-engines repeating every 4 clocks. The register file index to write must accompany the data. Data and Index associated with the Quad 0 must be sent 3 clocks after the Instruction Start signal is sent.

Name	Direction	Bits	Description
Tex_RegFile_Read_Data	SP->TEX	2048	16 Fetch Addresses read from the Register file
Tex_RegFile_Write _Data	TEX→SP	2048	16 texture results

Formatted: Bullets and Numbering

~~22.1.13~~22.1.17 *Sequencer to Fetch Unit bus (Slow Bus)*

Once every four clock, the fetch unit sends to the sequencer on wich clause it is now working and if the data in the registers is ready or not. This way the sequencer can update the fetch counters for the reservation station fifos. The sequencer also provides the intruction and constants for the fetch to execute and the address in the register file where to write the fetch return data.

Name	Direction	Bits	Description
Tex_Ready	TEX→ SEQ	1	Data ready
Tex_Clause_Num	TEX→ SEQ	3	Clause number
Tex_cst	SEQ→TEX	10	Fetch state address 10 bits sent over 4 clocks
Tex_Inst	SEQ→TEX	12	Fetch instruction address 12 bits sent over 4 clocks
EO_CLAUSE	SEQ→TEX	1	Last instruction of the clause
PHASE	SEQ→TEX	1	Write phase signal
LOD CORRECT	SEQ→TEX	96	LOD correct 3 bits per comp 2 components per quad * 16 quads
Mask	SEQ→TEX	64	Pixel mask 1 bit per pixel
Tex_Clause_Num	SEQ→TEX	3	Clause number
Tex_Write_Register_Index	SEQ->TEX	7	Index into Register file for write of returned Fetch Data
Tex_Read_Register_Index	SEQ->SP	7	Index into Register files for reading Fetch Address (internal)

Formatted: Bullets and Numbering

23. ~~Internal interfaces~~

23.1.1 ~~*RE to SEQ : Vertex Control Bus*~~

~~This information is sent over 4 clocks.~~

Formatted: Bullets and Numbering

~~24.~~23. Examples of program executions

~~24.1.1~~23.1.1 *Sequencer Control of a Vector of Vertices*

1. PA sends a vector of 64 vertices (actually vertex indices – 32 bits/index for 2048 bit total) to the RE's Vertex FIFO
   - state pointer as well as tag into position cache is sent along with vertices
   - space was allocated in the position cache for transformed position before the vector was sent
   - **also before the vector is sent to the RE, the CP has loaded the global instruction store with the vertex shader program (using the MH?)**
   - The vertex program is assumed to be loaded when we receive the vertex vector.
     - the SEQ then accesses the IS base for this shader using the local state pointer (provided to all sequencers by the RBBM when the CP is done loading the program)
2. SEQ arbitrates between the Pixel FIFO and the Vertex FIFO – basically the Vertex FIFO always has priority
   - at this point the vector is removed from the Vertex FIFO
   - the arbitrer is not going to select a vector to be transformed if the parameter cache is full unless the pipe as nothing else to do (ie no pixels are in the pixel fifo).
3. SEQ allocates space in the SP register file for index data plus GPRs used by the program
   - the number of GPRs required by the program is stored in a local state register, which is accessed using the state pointer that came down with the vertices
   - SEQ will not send vertex data until space in the register file has been allocated
4. SEQ sends the vector to the SP register file over the RE_SP interface (which has a bandwidth of 2048 bits/cycle)
   - the 64 vertex indices are sent to the 64 register files over 4 cycles
     - RF0 of SU0, SU1, SU2, and SU3 is written the first cycle
     - RF1 of SU0, SU1, SU2, and SU3 is written the second cycle
     - RF2 of SU0, SU1, SU2, and SU3 is written the third cycle
     - RF3 of SU0, SU1, SU2, and SU3 is written the fourth cycle
   - the index is written to the least significant 32 bits **(floating point format?) (what about compound indices)** of the 128-bit location within the register file (w); the remaining data bits are set to zero (x, y, z)
5. SEQ constructs a control packet for the vector and sends it to the first reservation station (the FIFO in front of fetch state machine 0, or TSM0 FIFO)
   - the control packet contains the state pointer, the tag to the position cache and a register file base pointer.
6. TSM0 accepts the control packet and fetches the instructions for fetch clause 0 from the global instruction store
   - TSM0 was first selected by the TSM arbiter before it could start
7. all instructions of fetch clause 0 are issued by TSM0
8. the control packet is passed to the next reservation station (the FIFO in front of ALU state machine 0, or ASM0 FIFO)
   - TSM0 does not wait for requests made to the Fetch Unit to complete; it passes the register file write index for the fetch data to the TU, which will write the data to the RF as it is received
   - once the TU has written all the data to the register files, it increments a counter that is associated with ASM0 FIFO; a count greater than zero indicates that the ALU state machine can go ahead start to execute the ALU clause
9. ASM0 accepts the control packet (after being selected by the ASM arbiter) and gets the instructions for ALU clause 0 from the global instruction store
10. all instructions of ALU clause 0 are issued by ASM0, then the control packet is passed to the next reservation station (the FIFO in front of fetch state machine 1, or TSM1 FIFO)
11. the control packet continues to travel down the path of reservation stations until all clauses have been executed
    - position can be exported in ALU clause 3 (or 4?); the data (and the tag) is sent over a position bus (which is shared with all four shader pipes) back to the PA's position cache
    - A parameter cache pointer is also sent along with the position data. This tells to the PA where the data is going to be in the parameter cache.
      - there is a position export FIFO in the SP that buffers position data before it gets sent back to the PA

    - the ASM arbiter will prevent a packet from starting an exporting clause if the position export FIFO is full
- parameter data is exported in clause 7 (as well as position data if it was not exported earlier)
    - parameter data is sent to the Parameter Cache over a dedicated bus
    - the SEQ allocates storage in the Parameter Cache, and the SEQ deallocates that space when there is no longer a need for the parameters (it is told by the PA when using a token).
    - the ASM arbiter will prevent a packet from starting on ASM7 if the parameter cache (or the position buffer if position is being exported) is full

12. after the shader program has completed, the SEQ will free up the GPRs so that they can be used by another shader program

~~24.1.2~~23.1.2 *Sequencer Control of a Vector of Pixels*

Formatted: Bullets and Numbering

1. **As with vertex shader programs, pixel shaders are loaded into the global instruction store by the CP**
    - At this point it is assumed that the pixel program is loaded into the instruction store and thus ready to be read.
2. the RE's Pixel FIFO is loaded with the barycentric coordinates for pixel quads by the detailed walker
    - the state pointer and the LOD correction bits are also placed in the Pixel FIF0
    - the Pixel FIFO is wide enough to source four quad's worth of barycentrics per cycle
3. SEQ arbitrates between Pixel FIFO and Vertex FIFO – when there are no vertices pending OR there is no space left in the register files for vertices, the Pixel FIFO is selected
4. SEQ allocates space in the SP register file for all the GPRs used by the program
    - the number of GPRs required by the program is stored in a local state register, which is accessed using the state pointer
    - SEQ will not allow interpolated data to be sent to the shader until space in the register file has been allocated
5. SEQ controls the transfer of interpolated data to the SP register file over the RE_SP interface (which has a bandwidth of 2048 bits/cycle). See interpolated data bus diagrams for details.
6. SEQ constructs a control packet for the vector and sends it to the first reservation station (the FIFO in front of fetch state machine 0, or TSM0 FIFO)
    - note that there is a separate set of reservation stations/arbiters/state machines for vertices and for pixels
    - the control packet contains the state pointer, the register file base pointer, and the LOD correction bits
    - all other informations (such as quad address for example) travels in a separate FIFO
7. TSM0 accepts the control packet and fetches the instructions for fetch clause 0 from the global instruction store
    - TSM0 was first selected by the TSM arbiter before it could start
8. all instructions of fetch clause 0 are issued by TSM0
9. the control packet is passed to the next reservation station (the FIFO in front of ALU state machine 0, or ASM0 FIFO)
    - TSM0 does not wait for fetch requests made to the Fetch Unit to complete; it passes the register file write index for the fetch data to the TU, which will write the data to the RF as it is received
    - once the TU has written all the data for a particular clause to the register files, it increments a counter that is associated with the ASM0 FIFO; a count greater than zero indicates that the ALU state machine can go ahead and pop the FIFO and start to execute the ALU clause
10. ASM0 accepts the control packet (after being selected by the ASM arbiter) and gets the instructions for ALU clause 0 from the global instruction store
11. all instructions of ALU clause 0 are issued by ASM0, then the control packet is passed to the next reservation station (the FIFO in front of fetch state machine 1, or TSM1 FIFO)
12. the control packet continues to travel down the path of reservation stations until all clauses have been executed
    - pixel data is exported in the last ALU clause (clause 7)
        - it is sent to an output FIFO where it will be picked up by the render backend
        - the ASM arbiter will prevent a packet from starting on ASM7 if the output FIFO is full
13. after the shader program has completed, the SEQ will free up the GPRs so that they can be used by another shader program

~~24.1.3~~23.1.3 *Notes*

Formatted: Bullets and Numbering

14. The state machines and arbitrers will operate ahead of time so that they will be able to immediately start the real threads or stall.
15. The register file base pointer for a vector needs to travel with the vector through the reservation stations, but the instruction store base pointer does not – this is because the RF pointer is different for all threads, but the IS pointer is only different for each state and thus can be accessed via the state pointer
16. Waterfalling still needs to be specked out.

~~25.~~24. Open issues

Formatted: Bullets and Numbering

There is currently an issue with constants. If the constants are not the same for the whole vector of vertices, we don't have the bandwith from the fetch store to feed the ALUs. Two solutions exists for this problem:

1) Let the compiler handle the case and put those instructions in a fetch clause so we can use the bandwith there to operate. This requires a significant amount of temporary storage in the register store.
2) Waterfall down the pipe allowing only at a given time the vertices having the same constants to operate in parrallel. This might in the worst case slow us down by a factor of 16.

Need to do some testing on the size of the register file as well as on the register file allocation method (dynamic VS static).

Saving power?

Revision Changes:

Rev 0.1 (Laurent Lefebvre) Date: May 7, 2001	First draft.
Rev 0.2 (Laurent Lefebvre) Date : July 9, 2001	Changed the interfaces to reflect the changes in the SP. Added some details in the arbitration section.
Rev 0.3 (Laurent Lefebvre) Date : August 6, 2001	Reviewed the Sequencer spec after the meeting on August 3, 2001.
Rev 0.4 (Laurent Lefebvre) Date : August 24, 2001	Added the dynamic allocation method for register file and an example (written in part by Vic) of the

	flow of pixels/vertices in the sequencer.
Rev 0.5 (Laurent Lefebvre) Date : September 7, 2001	Added timing diagrams (Vic)
Rev 0.6 (Laurent Lefebvre) Date : September 24, 2001	Changed the spec to reflect the new R400 architecture. Added interfaces.
Rev 0.7 (Laurent Lefebvre) Date : October 5, 2001	Added constant store management, instruction store management, control flow management and data dependant predication.
Rev 0.8 (Laurent Lefebvre) Date : October 8, 2001	Changed the control flow method to be more flexible. Also updated the external interfaces.
Rev 0.9 (Laurent Lefebvre) Date : October 17, 2001	Incorporated changes made in the 10/18/01 control flow meeting. Added a NOP instruction, removed the conditional_execute_or_jump. Added debug registers.
Rev 1.0 (Laurent Lefebvre) Date : October 19, 2001	Refined interfaces to RB. Added state registers.
Rev 1.1 (Laurent Lefebvre) Date : October 26, 2001	Added SEQ→SP0 interfaces. Changed delta precision. Changed VGT→SP0 interface. Debug Methods added.
Rev 1.2 (Laurent Lefebvre) Date : November 16, 2001	Interfaces greatly refined. Cleaned up the spec.

1. Overview

The sequencer first arbitrates between vectors of 64 vertices that arrive directly from primitive assembly and vectors of 16 quads (64 pixels) that are generated in the raster engine.

The vertex or pixel program specifies how many GPR's it needs to execute. The sequencer will not start the next vector until the needed space is available.

The sequencer is based on the R300 design. It chooses two ALU clauses and a fetch clause to execute, and executes all of the instructions in a clause before looking for a new clause of the same type. Two ALU clauses are executed interleaved to hide the ALU latency. Each vector will have eight fetch and eight ALU clauses, but clauses do not need to contain instructions. A vector of pixels or vertices ping-pongs along the sequencer FIFO, bouncing from fetch reservation station to alu reservation station. A FIFO exists between each reservation stage, holding up vectors until the vector currently occupying a reservation station has left. A vector at a reservation station can be chosen to execute. The sequencer looks at all eight alu reservation stations to choose an alu clause to execute and all eight fetch stations to choose a fetch clause to execute. The arbitrator will give priority to clauses/reservation stations closer to the bottom of the pipeline. It will not execute an alu clause until the fetch fetches initiated by the previous fetch clause have completed. There are two separate sets of reservation stations, one for pixel vectors and one for vertices vectors. This way a pixel can pass a vertex and a vertex can pass a pixel.

To support the shader pipe the raster engine also contains the shader instruction cache and constant store. There are only one constant store for the whole chip and one instruction store. These will be shared among the four shader pipes. The four shader pipes also execute the same ~~instuction~~instruction thus there is only one sequencer for the whole chip.

texture arbitrator

There are two sets of the above figure, one for vertices and one for pixels.

Depending on the arbitration state, the sequencer will either choose a vertex or a pixel packet. The control packet consists of ~~21~~3 bits of state, 6-7 bits for the base address of the Shader program and some information on the coverage to determine fetch LOD plus other various small state bits.

On receipt of a packet, the input state machine (not pictured but just before the first FIFO) allocated enough space in the registers to store the interpolated values and temporaries. Following this, the input state machine stacks the packet in the first FIFO.

On receipt of a command, the level 0 fetch machine issues a ~~texure~~texture request and corresponding register address for the fetch address (ta). A small command (tcmd) is passed to the fetch system identifying the current level number (0) as well as the register write address for the fetch return data. One fetch request is sent every 4 clocks causing the texturing of sixteen 2x2s worth of data (or 64 vertices). Once all the requests are sent the packet is put in FIFO 1.

Upon recept of the return data, the fetch unit writes the data to the register file using the write address that was provided by the level 0 fetch machine and sends the clause number (0) to the level 0 fetch state machine to signify that the write is done and thus the data is ready. Then, the level 0 fetch machine increments the counter of FIFO 1 to signify to the ALU 1 that the data is ready to be processed.

On receipt of a command, the level 0 ALU machine first decrements the input FIFO counter and then issues a complete set of level 0 shader instructions. For each instruction, the state machine generates 3 source addresses, one destination address (3 cycles later) and an instruction. Once the last instruction as been issued, the packet is put into FIFO 2.

There will always be two active ALU clauses at any given time (and two ~~arbitrers~~arbiters). One ~~arbitrer~~arbiter will arbitrate over the odd instructions (4 clocks cycles) and the other one will arbitrate over the even instructions (4 clocks cycles). The only constraints between the two ~~arbitrers~~arbiters is that they are not allowed to pick the same clause number as the other one is currently working on if the packet is not of the same type (render state).

If the packet is a vertex packet, upon reaching ALU clause 3, it can export the position if the position is ready. So the ~~arbitrer~~arbiter must prevent ALU clause 3 to be selected if the positional buffer is full (or can't be accessed). Along with the positional data, the location where the vertex data is to be put is also sent (parameter data pointers).

{ISSUE: How do we handle parameter cache pointers (computed, semi-computed or not computed)?}

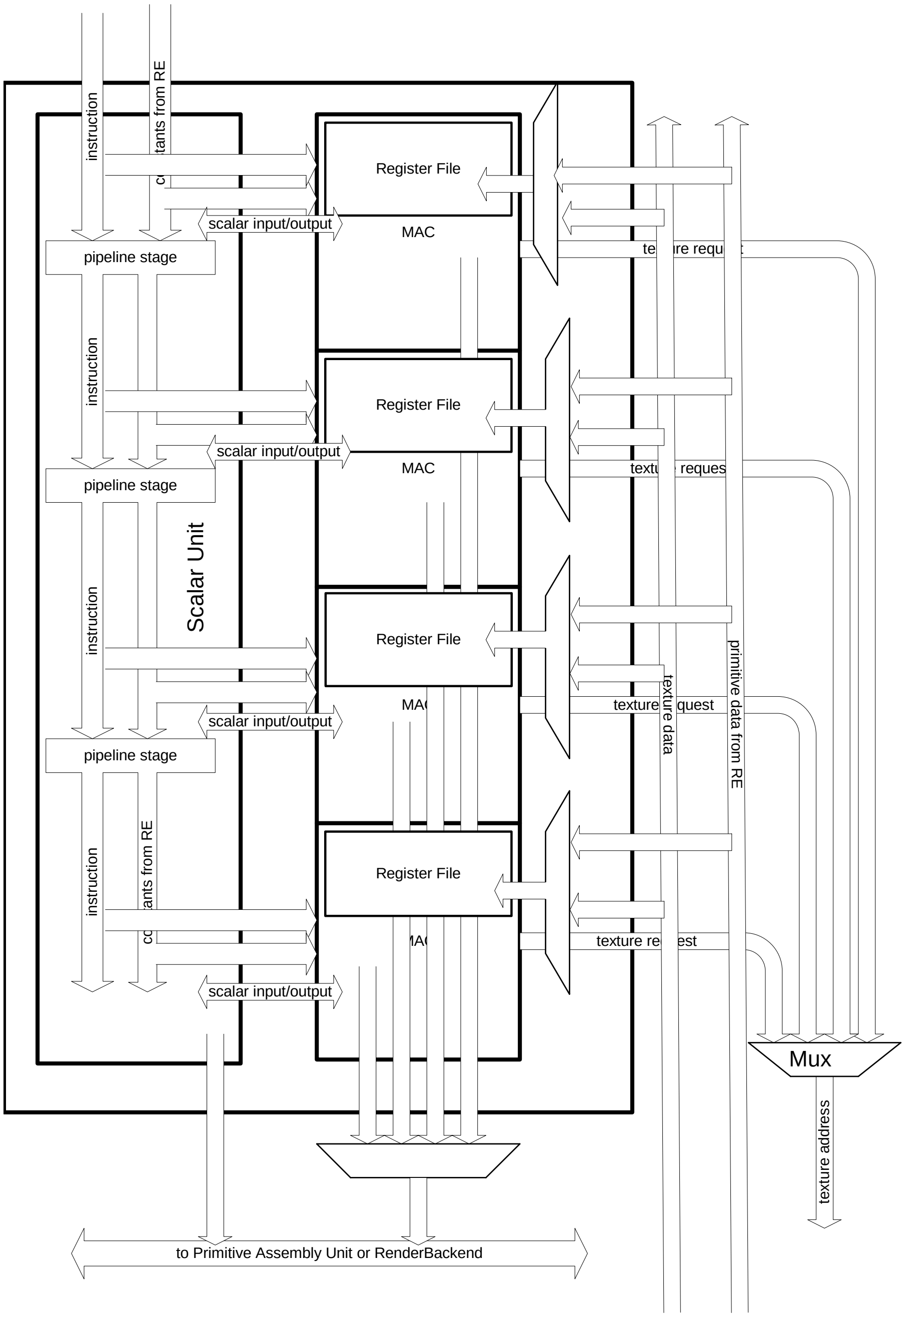
A special case is for HOS surfaces wich can export 12 parameters per last 6 clauses to the output buffer. If the output buffer is full or doesn't have enough space the sequencer will prevent such a vertex group to enter an exporting clause.

Regular pixel and vertex shaders can export 12 parameters to memory from the last clause only (7).

All other level process in the same way until the packet finally reaches the last ALU machine (7). On completion of the level 7 ALU clause, a valid bit is sent to the Render Backend which picks up the color data. This requires that the last instruction writes to the output register – a condition that is almost always true. If the packet was a vertex packet, instead of sending the valid bit to the RB, it is sent to the PA so it can know that the data present in the parameter store is valid.

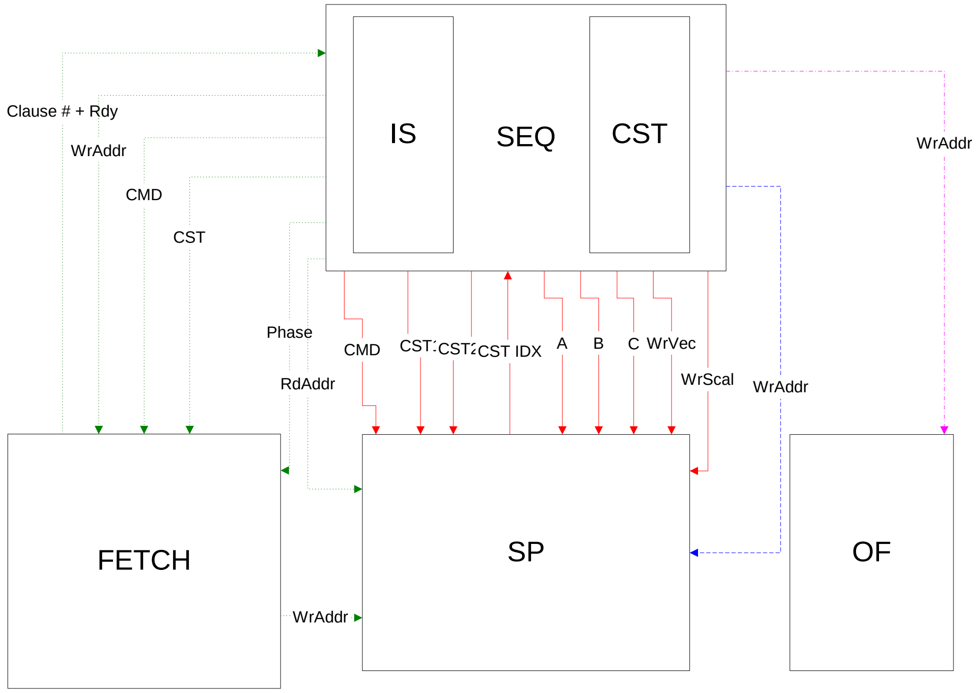
Only two ALU state machine may have access to the register file address bus or the instruction decode bus at one time. Similarly, only one fetch state machine may have access to the register file address bus at one time. Arbitration is performed by three ~~arbitrer~~arbiter blocks (two for the ALU state machines and one for the fetch state machines). The ~~arbitrers~~arbiters always favor the higher number state machines, preventing a bunch of half finished jobs from clogging up the register files.

1.2 Data Flow graph



The gray area represents blocks that are replicated 4 times per shader pipe (16 times on the overall chip).

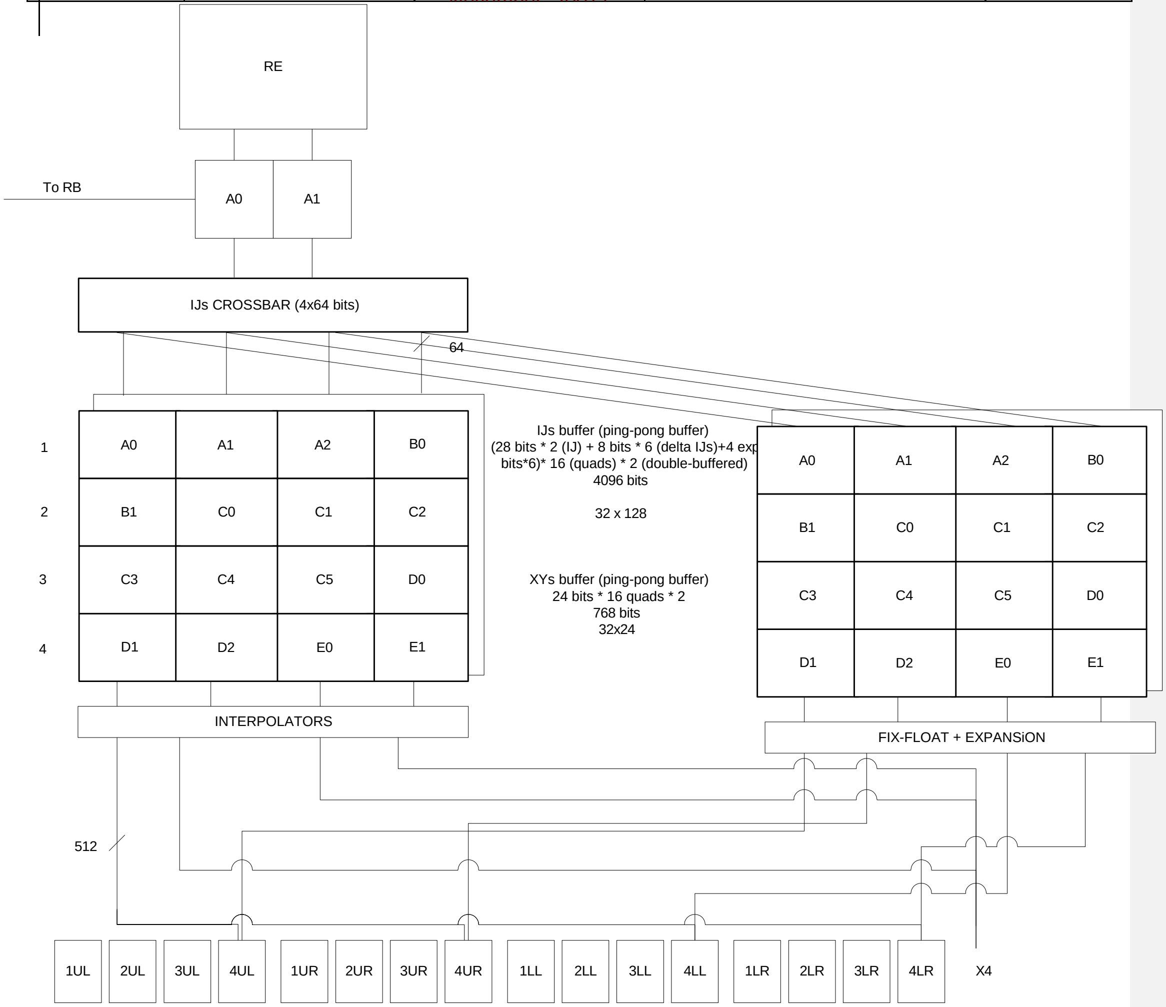
1.3 Control Graph



In green is represented the Fetch control interface, in red the ALU control interface, in blue the Interpolated/Vector control interface and in purple is the output file control interface.

2. Interpolated data bus

The interpolators contain an IJ buffer to pack the information as much as possible before writing it to the register file.



IJs buffer (ping-pong buffer)
(28 bits * 2 (IJ) + 8 bits * 6 (delta IJs)+4 exp
bits*6)* 16 (quads) * 2 (double-buffered)
4096 bits

32 x 128

XYs buffer (ping-pong buffer)
24 bits * 16 quads * 2
768 bits
32x24

	T0	T1	T2	T3	T4	T5	T6	T7	T8	T9	T10	T11	T12	T13	T14	T15	T16	T17	T18	T19	T20	T21	T22	T23
SP 0	A0	B1	C3	D1					A0	B1	C3	D1					XY 0-3	XY 16-19	XY 32-35	XY 48-51	V 0-3	V 16-19	V 32-35	V 48-51

SP 2	A2		C5			C1		E0	A2		C5			C1		E0	XY 8-11	XY 24-27	XY 40-43	XY 56-59	V 8-11	V 24-27	V 40-43	V 56-59
SP 3					B0	C2	D0	E1					B0	C2	D0	E1	XY 12-15	XY 28-31	XY 44-47	XY 60-63	V 12-15	V 28-31	V 44-47	V 60-63
				P0								P1						XY				VTX		

Above is an example of a tile we might receive. The IJ information is packed in the IJ buffer 2 quads at a time. The sequencer allows at any given time as many as four quads to interpolate a parameter. They all have to come from the same primitive. Then the sequencer controls the write mask to the register to write the valid data in.

3. Instruction Store

There is going to be only one instruction store for the whole chip. It will contain 4096 instructions of 96 bits each. ~~There is also going to be a control instruction store of size 256(512?)x32.~~

~~{ISSUE : The instruction store is loaded by the sequencer using the memory hub ?}.~~

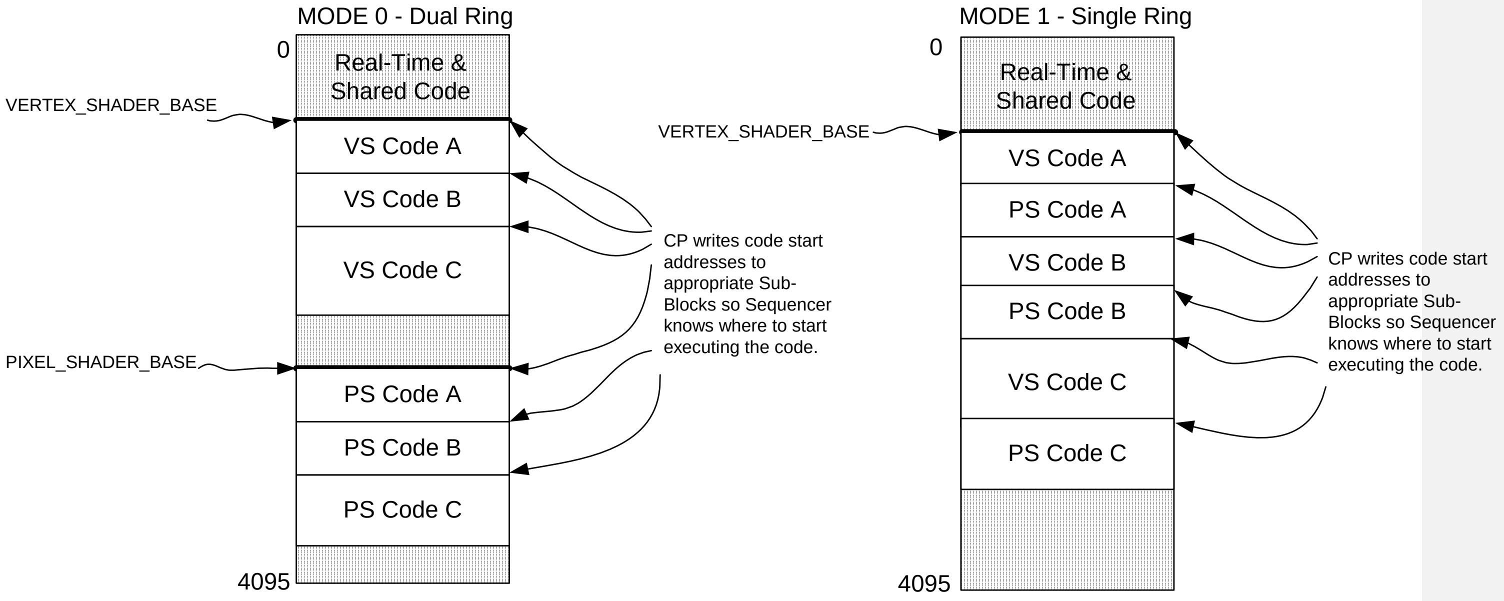
~~The read bandwith from this store is 96*2 bits/ 4 clocks (48 bits/clock).~~ It is likely to be a 1 port memory; we use 1 clock to load the ALU instruction, 1 clocks to load the Fetch instruction, 1 clock to load 2 control flow instructions and 1 clock to write instructions.

The instruction store is loaded by the CP thru the INSTRUCTION_DATA, INSTRUCTION_INDEX_PORT control registers. The INSTRUCTION_INDEX_PORT is auto-incremented on both reads and writes to the INSTRUCTION_DATA register.

The next picture shows the various modes the CP can load the memory. The Sequencer has to keep track of the loading modes in order to wrap around the correct boundaries. The MSB of the INSTRUCTION_INDEX_PORT register contains the packet type for the sequencer to know where it must wrap around. The wrap around points are arbitrary and they are specified in the VERTEX_SHADER_BASE and PIXEL_SHADER_BASE registers.

R400 CP's Views of Instruction Memory

Updated: 11/14/2001
John A. Carey



CP writes code start addresses to appropriate Sub-Blocks so Sequencer knows where to start executing the code.

CP writes code start addresses to appropriate Sub-Blocks so Sequencer knows where to start executing the code.

4. Sequencer Instructions

All control flow instructions and move instructions are handled by the sequencer only. The ALUs will perform NOPs during this time (MOV PV,PV, PS,PS).

5. Constant Stores

~~The constant store is managed by the CP.~~ The sequencer is aware of where the constants are using a remaping table~~ also managed by the CP~~. A likely size for the constant store is ~~512x128~~ 1024x128 bits. ~~The constant store is also planned to be shared.~~ The read BW from the constant store is 128 bits/clock and the write bandwith is 32/4 bits/clock.

In order to do constant store indexing, the sequencer must be loaded first with the indexes (that come from the GPRs). There are 144 wires from the exit of the SP to the sequencer (9 bits pointers x 16 vertexes/clock). Since the data must pass thru the Shader pipe for the float to fixed convertion, there is a latency of 4 clocks (1 instruction) between the time the sequencer is loaded and the time one can index into the constant store. The assembly will look like this

```
MOVA  R1.X,R2.X       // Loads the sequencer with the content of R2.X, also copies the content of R2.X into R1.X
NOP                   // latency of the float to fixed conversion
ADD   R3,R4,C0[R2.X]// Uses the state from the sequencer to add R4 to C0[R2.X] into R3
```

Note that we don't really care about what is in the brackets because we use the state from the MOVA instruction. R2.X is just written again for the sake of simplicity.

The storage needed in the sequencer in order to support this feature is 2*64*9 bits = 1152 bits.

The texture state is also kept in a similar memory. The size of this memory is 192x128. Which lets us load a texture state in ????

The control flow constant memory doesn't sit behind a renaming table. It is register mapped and thus the driver must reload its content each time there is a state change.

6. Looping and Branches

Loops and branches are planned to be supported and will have to be dealt with at the sequencer level. We plan on supporting constant loops and branches using a control program.

6.1 The controlling state.

As per Dx9 the following state is available for control flow:

Boolean[15:0]
loop_count[7:0][7:0]
In addition:
loop_start [7:0] [7:0]
loop_step [7:0] [7:0]
Exist to give more control to the controlling program.

We will extend that in the R400 to:
Boolean[255:0]
Loop_count[7:0][15:0]
Loop_Start[7:0] [15:0] times ~~2~~ 3 (one for constant,registert1, register2)
Loop_Step[7:0] [15:0] times ~~2~~ 3 (one for constant, registert1, register2~~register~~)
Loop_End[7:0] [15:0]

{ISSUE: How is the controlling state loaded and how many contexts do we have?}

We have a stack of 4 elements for calling subroutines and 4 loop counters to allow for nested loops.

6.2 The Control Flow Program

The R300 uses a match method for control flow: The shader is executed, and at every instruction its address is compared with addresses (or address?) in a control table. The “event” in the control table can redirect operations in the program.

The Method chosen for the R400 is a “control program”. The control program has ten basic instructions:

Execute
Conditional_execute
Conditional_Execute_Predicates
Conditional_jump
Call
Return
Loop_start
Loop_end
End_of_clause
NOP

Execute, causes the specified number of instructions in instruction store to be executed.
Conditional_execute checks a condition first, and if true, causes the specified number of instructions in instruction store to be executed.
Loop_start resets the corresponding loop counter to the start value on the first pass after it checks for the end condition and if met jumps over to a specified address.
Loop_end increments (decrements?) the loop counter and jumps back the specified number of instructions.
Call jumps to an address and pushes the IP counter on the stack. On the return instruction, the IP is poped from the stack.
Conditional_execute_or_Jump executes a block of instructions or jumps to an address is the condition is not met.
Conditional_execute_Predicates executes a block of instructions if all bits in the predicate vectors meet the condition.
End_of_clause marks the end of a clause.
Conditional_jumps jumps to an address if the condition is met.
NOP is a regular NOP

NOTE THAT ALL JUMPS MUST JUMP TO EVEN CFP ADDRESSES. Thus the compiler must insert NOPs where needed to align the jumps on even CFP addresses.

Also if the jump is logically bigger than pshader_cntl_size (or vshader_cntl_size) we break the program (clause) and set the debug registers. If an execute or conditional_execute is lower than cntl_size or bigger than size we also break the program (clause) and set the debug registers.

We have to fit instructions into 48 bits in order to be able to put two control flow instruction per line in the instruction store.

Execute				
47	46… 42	41 … 24	23 … 12	11 … 0
Addressing	00001	RESERVED	Instruction _count	Exec Address

Execute up to 4k instructions at the specified address in the instruction memory.

NOP		
47	46 … 42	41 … 0
Addressing	00010	RESERVED

~~If the specified boolean (8 bits can address 256 booleans) meets the specified condition then execute the specified instructions (up to 512 instructions) or if the condition is not met jump to the jump address in the control flow program. This MUST be a forward jump.~~This is a regular NOP.

Conditionnal_Execute						
47	46 … 42	41 … 34	33	32 … 24	23 … 12	11 … 0
Addressing	00011	Boolean address	Condition	RESERVED	Instruction_count	Exec Address

If the specified boolean (8 bits can address 256 booleans) meets the specified condition then execute the specified instructions (up to 4k instructions)

Conditionnal_Execute_Predicates						
47	46 … 42	41 … 38	37	36 … 24	23 … 12	11 … 0
Addressing	00100	Predicate vector	Condition	RESERVED	Instruction_count	Exec Address

Check the AND/OR of all current predicate bits. If AND/OR matches the condition execute the specified number of instructions. We need to AND/OR this with the kill mask in order not to consider the pixels that aren't valid.

Loop_Start				
47	46 … 42	41 … 16	15 … 4	3 … 0
Addressing	00101	RESERVED	Jump address	Loop ID

Loop Start. Compares the loop count with the end value. If loop condition not met jump to the address. Forward jump only. Also computes the index value.

Loop_End				
47	46 … 42	41 … 16	15 … 4	3 … 0
Addressing	00111	RESERVED	Start address	Loop ID

Loop end. Increments the counter by one and jumps BACK only to the start of the loop.

The way this is described does not prevent nested loops, and the inclusion of the loop id make this easy to do.

Call			
47	46 … 42	41…12	11 … 0
Addressing	01000	RESERVED	Address

Jumps to the specified address and pushes the IP counter on the stack.

Return		
47	46 … 42	41 … 0
Addressing	01001	RESERVED

Pops the topmost address from the stack and jumps to that address. If nothing is on the stack, the program will just continue to the next instruction.

Conditionnal_Jump						
47	46 … 42	41 … 34	33	32 … 13	12	11 … 0
Addressing	01010	Boolean address	Condition	RESERVED	FW only	Address

If condition met, jumps to the address. FORWARD jump only allowed if bit 12 set. Bit 12 is only an optimization for the compiler and should NOT be exposed to the API.

End_of_Clause		
47	46 … 42	41 … 0
Addressing	01011	RESERVED

Marks the end of a clause.

To prevent infinite loops, we will keep 9 bits loop counters instead of 8 (we are only able to loop 256 times). If the counter goes higher than 255 then the loop_end or the loop_start instruction is going to break the loop and set th~~d~~e debug registers. ~~The sequencer will keep two loop indexes values:~~

~~IC index for constant indexing (9 bits)~~

~~IR index for register file indexing (7 bits)~~

~~This will be updated every time we loop and can only be used to index the constant store and the register file. The way to compute this value is:~~

~~Index = Loop_counter*Loop_iterator + Loop_init.~~

~~The IC for constant is going to return 0 if it is out of the constant range. The IR index is going to break the program if the index exceeds the number of requested registers.~~

The basic model is as follows:

The render state defined the clause boundaries:

Vertex_shader_fetch[7:0][7:0]	// eight 8 bit pointers to the location where each clauses control program is located
Vertex_shader_alu[7:0][7:0]	// eight 8 bit pointers to the location where each clauses control program is located
Pixel_shader_fetch[7:0][7:0]	// eight 8 bit pointers to the location where each clauses control program is located
Pixel_shader_alu[7:0][7:0]	// eight 8 bit pointers to the location where each clauses control program is located

A pointer value of FF means that the clause doesn't contain any instructions.

Formatted

The control program for a given clause is executed to completion before moving to another clause, (with the exception of the pick two nature of the alu execution). The control program is the only program aware of the clause boundaries.

6.3 Data dependant predicate instructions

Data dependant conditionals will be supported in the R400. The only way we plan to support those is by supporting three vector/scalar predicate operations of the form:

PRED_SETE_# - similar to SETE except that the result is 'exported' to the sequencer.
PRED_SETGT_# - similar to SETGT except that the result is 'exported' to the sequencer
PRED_SETGTE_# - similar to SETGTE except that the result is 'exported' to the sequencer

For the scalar operations only we will also support the two following instructions:
PRED_SETE0_# – SETE0
PRED_SETE1_# – SETE1

The export is a single bit - 1 or 0 that is sent using the same data path as the MOVA instruction. The sequencer will maintain 4 sets of 64 bit predicate vectors (in fact 8 sets because we interleave two programs but only 4 will be exposed) and use it to control the write masking. This predicate is not maintained across clause boundaries. The # sign is used to specify which predicate set you want to use 0 thru 3.

Then we have two conditional execute bits. The first bit is a conditional execute "on" bit and the second bit tells us if we execute on 1 or 0. For example, the instruction:

P0_ADD_# R0,R1,R2

Is only going to write the result of the ADD into those GPRs whose predicate bit is 0. Alternatively, P1_ADD_# would only write the results to the GPRs whose predicate bit is set. The use of the P0 or P1 without precharging the sequencer with a PRED instruction is undefined.

{Issue: do we have to have a NOP between PRED and the first instruction that uses a predicate?}

6.4 HW Detection of PV,PS

Because of the control program, the compiler cannot detect statically dependant instructions. In the case of non-masked writes and subsequent reads the sequencer will insert uses of PV,PS as needed. This will be done by comparing the read address and the write address of consecutive instructions. For masked writes, the sequencer will insert NOPs wherever there is a dependant read/write.

The sequencer will also have to insert NOPs between PRED_SET and MOVA instructions and their uses.

6.5 Register file indexing

Because we can have loops in fetch clause, we need to be able to index into the register file in order to retrieve the data created in a fetch clause loop and use it into an ALU clause. The instruction will include the base address for register indexing and the instruction will contain these controls:

Bit7	Bit 6	
0	0	'absolute register'
0	1	'relative register'
1	0	'previous vector'
1	1	'previous scalar'

In the case of an absolute register we just take the address as is. In the case of a relative register read we take the base address and we add to it the loop_index and this becomes our new address that we give to the shader pipe.

The sequencer is going to keep a loop index computed as such:

Index = Loop_counter*Loop_iterator + Loop_init.

The index is going to return 0 if it is out of the range.

6.6 Predicated Instruction support for Texture clauses

For texture clauses, we support the following optimization: we keep 1 bit (thus 4 bits for the four predicate vectors) per predicate vector in the reservation stations. A value of 1 means that one ore more elements in the vector have a value of one (thus we have to do the texture fetches for the whole vector. A value of 0 means that no elements in the vector have his predicate bit set and we can thus skip over the texture fetch. **We have to make sure the invalid pixels aren't considered with this optimization.**

Formatted

6.7 Debugging the Shaders

In order to be able to debug the pixel/vertex shaders efficiently, we provide ~~3~~ 2 methods.

6.7.1 *Method 1: Debugging registers*

Current plans are to expose 2 debugging, or error notification, registers:
1. address register where the first error occurred
2. count of the number of errors

The sequencer will detect the following groups of errors:
- count overflow
- jump error
  relative jump address > size of the control flow program
  relative jump address > length of the shader program

- constant overflow
- register overflow
- call stack
  call with stack full
  return with stack empty

With two of the errors, a jump error or a register overflow will cause the program to break. In this case, a break means that a clause will halt execution, but allowing further clauses to be executed.

With the other errors, program can continue to run, potentially to worst-case limits.

If indexing outside of the constant range, causing an overflow error, the hardware is specified to return the value with an index of 0. This could be exploited to generate error tokens, by reserving and initializing the 0th register (or constant) for errors.

{ISSUE : Interrupt to the driver or not?}

6.7.2 *Method 2: Exporting the values in the GPRs (12)*

The sequencer will have a count register and an address register for this mode and 3 bits per clause specifying the execution mode for each clause. The modes can be :

1) Normal
2) Debug Kill
3) Debug Addr + Count

~~4)Debug Count~~

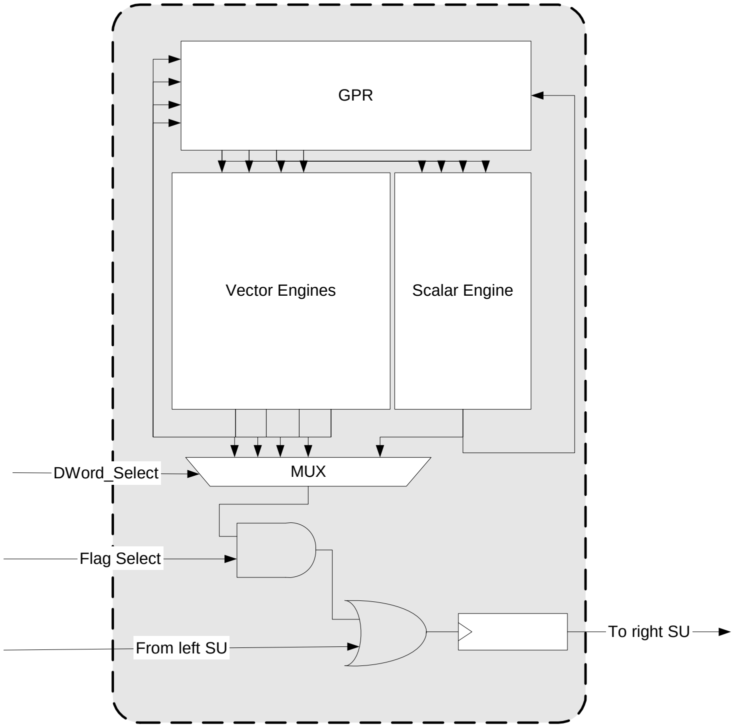
Formatted: Bullets and Numbering

Under the normal mode execution follows the normal course. Under the kill mode, all control flow instructions are executed but all normal shader instructions of the clause are replaced by NOPs. Only debug_export instructions of clause 7 will be executed under the debug kill setting. Under the ~~two~~ other mode~~s~~, normal execution is done until we reach an address specified by the address register ~~or~~ and instruction count (useful for loops) specified by the count register. ~~After we have hit the address or the count we change to the kill mode for the rest of the clause~~ After we have hit the instruction n times (n=count) we switch the clause to the kill mode.~~.~~

~~6.7.3 Method 3: Selective export of a 32 bit Dword.~~

Formatted: Bullets and Numbering

~~The third debug option will be mainly used for HW debug. For this mode, the sequencer will keep the following control debug registers: Shader_pipe (6 bits), Mode(1 bit), Dword_select (3 bits), clause_+count (16 bits?),address (12 bits) Vector_number (8 bits), Render_state (21 bits). The shader pipe register selects a shader pipe amongst the 64, the dword_select selects a channel (0…3 of vector or scalar), the clause_+count selects at which clause and which count we export, the Render_state specifies which render state is concerned, the Vector_number specifies which vector is concerned and the mode selects count export, or address export.~~



~~Flag Select is a combination of Shader_pipe, clause_+count, address, Vector_number and render_state. It is only active for 1 shader pipe at a time and for 1 vector of a given state. The driver is responsible to reset the output register to 0 before executing a given program.~~

7. Pixel Kill Mask

A vector of 64 bits is kept per group of pixels/vertices. Its purpose is to optimize the texture fetch requests and allow the shader pipe to kill pixels using the following instructions:

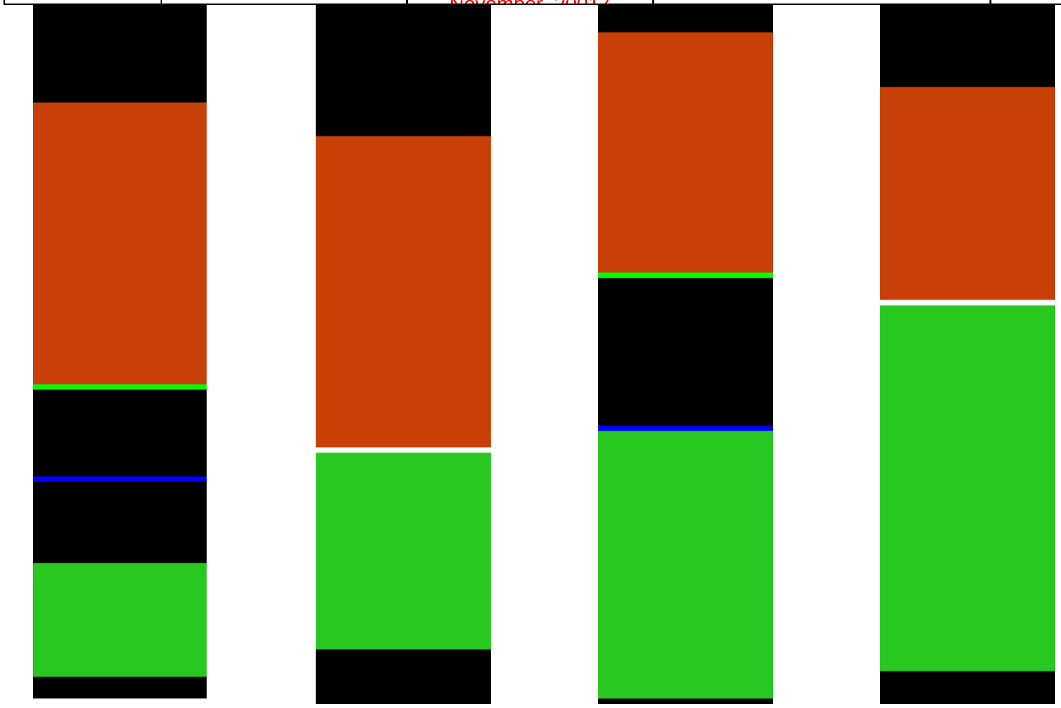
MASK_SETE
MASK_SETGT
MASK_SETGTE

8. HOS surfaces

HOS surfaces are able to export from the 6 last clauses but to memory ONLY. If they want to export to the parameter cache they have to do it in the last clause (7). They can also export position in clause 3.

9. Register file allocation

The register file allocation for vertices and pixels can either be static or dynamic. In both cases, the register file in managed using two round robins (one for pixels and one for vertices). In the dynamic case the boundary between pixels and vertices is allowed to move, in the static case it is fixed to VERTEX_REG_SIZE for vertices and 256-VERTEX_REG_SIZE for pixels.



Above is an example of how the algorithm works. Vertices come in from top to bottom; pixels come in from bottom to top. Vertices are in orange and pixels in green. The blue line is the tail of the vertices and the green line is the tail of the pixels. Thus anything between the two lines is shared. When pixels meets vertices the line turns white and the boundary is static until both vertices and pixels share the same "unallocated bubble". Then the boundary is allowed to move again.

10. Fetch Arbitration

The fetch arbitration logic chooses one of the 8 potentially pending fetch clauses to be executed. The choice is made by looking at the fifos from 7 to 0 and picking the first one ready to execute. Once chosen, the clause state machine will send one 2x2 fetch per clock (or 4 fetches in one clock every 4 clocks) until all the fetch instructions of the clause are sent. This means that there cannot be any dependencies between two fetches of the same clause.

The arbitrator will not wait for the fetches to return prior to selecting another clause for execution. The fetch pipe will be able to handle up to X(?) in flight fetches and thus there can be a fair number of active clauses waiting for their fetch return data.

11. ALU Arbitration

ALU arbitration proceeds in almost the same way than fetch arbitration. The ALU arbitration logic chooses one of the 8 potentially pending ALU clauses to be executed. The choice is made by looking at the fifos from 7 to 0 and picking the first one ready to execute. There are two ALU arbitrers, one for the even clocks and one for the odd clocks. For exemple, here is the sequencing of two interleaved ALU clauses (E and O stands for Even and Odd sets of 4 clocks):

Einst0 Oinst0 Einst1 Oinst1 Einst2 Oinst2 Einst0 Oinst3 Einst1 Oinst4 Einst2 Oinst0…
Proceeding this way hides the latency of 8 clocks of the ALUs.

12. Handling Stalls

When the output file is full, the sequencer prevents the ALU arbitration logic to select the last clause (this way nothing can exit the shader pipe until there is place in the output file. If the packet is a vertex packet and the position buffer is full (POS_FULL) then the sequencer also prevents a thread to enter the exporting clause (43?). The sequencer will set the OUT_FILE_FULL signal n clocks before the output file is actually full and thus the ALU ~~arbitrer~~arbiter will be able read this signal and act accordingly by not preventing exporting clauses to proceed.

13. Content of the reservation station FIFOs

21 bits of Render State 7 bits for the base address of the GPRs, some bits for LOD correction and coverage mask information in order to fetch fetch for only valid pixels, quad address and 1 bit to specify if the vector is of pixels or vertices. Since pixels and vertices are kept in order in the shader pipe, we only need two fifos (one for vertices and one for pixels) deep enough to cover the shader pipe latency. This size will be determined later when we will know the size of the small fifos between the reservation stations.

14. The Output File

The output file is where pixels are put before they go to the RBs. The write BW to this store is 256 bits/clock. Just before this output file are staging registers with write BW 512 bits/clock and read BW 256 bits/clock. ~~For this reason only ONE concurrent program can be of clause 8 (exporting clause) the other program MUST not.~~ The staging registers are 4x128 (and there are 16 of those on the whole chip).

15. IJ Format

The IJ information sent by the PA is of this format on a per quad basis:

We have a vector of IJ's (one IJ per pixel at the centroid of the fragment or at the center of the pixel depending on the mode bit). The interpolation is done at a different precision across the 2x2. The upper left pixel's parameters are always interpolated at full 20x24 mantissa precision. Then the result of the interpolation along with the difference in IJ in reduced precision is used to interpolate the parameter for the other three pixels of the 2x2. Here is how we do it:

Assuming P0 is the interpolated parameter at Pixel 0 having the barycentric coordinates I(0), J(0) and so on for P1,P2 and P3. Also assuming that A is the parameter value at V0 (interpolated with I), B is the parameter value at V1 (interpolated with J) and C is the parameter value at V2 (interpolated with (1-I-J).

$$\begin{aligned}
\Delta 01I &= I(1) - I(0)\\
\Delta 01J &= J(1) - J(0)\\
\Delta 02I &= I(2) - I(0)\\
\Delta 02J &= J(2) - J(0)\\
\Delta 03I &= I(3) - I(0)\\
\Delta 03J &= J(3) - J(0)
\end{aligned}$$

P0	P1
P2	P3

$$\begin{aligned}
P0 &= C + I(0)*(A-C) + J(0)*(B-C)\\
P1 &= P0 + \Delta 01I*(A-C) + \Delta 01J*(B-C)\\
P2 &= P0 + \Delta 02I*(A-C) + \Delta 02J*(B-C)\\
P3 &= P0 + \Delta 03I*(A-C) + \Delta 03J*(B-C)
\end{aligned}$$

P0 is computed at 20x24 mantissa precision and P1 to P3 are computed at 8X24 mantissa precision. So far no visual degradation of the image was seen using this scheme.

Multiplies (Full Precision): 2

Multiplies (Reduced precision): 6
Subtracts 19x24 (Parameters): 2
Adds: 8

FORMAT OF P0's IJ : Mantissa 20 Exp 4 for I + Sign
Mantissa 20 Exp 4 for J + Sign

FORMAT of Deltas (x3):Mantissa 8 Exp 4 for I + Sign
Mantissa 8 Exp 4 for J + Sign

Total number of bits : 19*2 + 8*6 + 4*8 + 4*2 = 128

The Deltas have a leading 1, the Full precision IJs don't. This means that in the case of the deltas we MUST be able to shift 8 right (exponent value of 0 means number = 0, exponent value of 1 means shift right 8). This means that the maximum range for the IJs (Full precision) is +/- 64 and the range for the Deltas is +/- 128.

16. The parameter cache

The parameter cache is where the vertex shaders export their data. It consists of 16 128x128 memories (1R/1W). The reuse engine will make it so that all vertexes of a given primitive will hit different memories.

17. Vertex position exporting

On clause ~~4 (or 5)~~3 the vertex shader can export to the PA both the vertex position and the point sprite. It can also do so at clause ~~8~~ 7 if not done at clause ~~4~~3. ~~Along with the position is exported a pointer to the parameter cache where the data will be once the vertex shader exports.~~ The storage needed to perform the position export is at least 64x128 memories for the position and 64x32 memories for the sprite size. It is going to be taken in the pixel output fifo from the SX blocks.

18. Exporting Arbitration

Here are the rules for co-issuing exporting ALU clauses.

1) Position exports and position exports cannot be co-issued.
2) Position exports and memory exports cannot be co-issued.
3) Position exports and Z/Color exports cannot be co-issued.
4) Memory exports and Z/Color exports cannot be co-issued.
5) Memory exports and memory exports cannot be co-issued.
6) Z/color exports and Z/color exports cannot be co-issued.
7) Parameter exports and Z/Color exports CAN be co-issued.
8) Parameter exports and parameter exports CAN be co-issued.
9) Parameter exports and memory exports CAN be co-issued.

19. Real time commands

We are unable to use the parameter memory since there is no way for a command stream to write into it. Instead we need to add three 16x128 memories (one for each of three vertices x 16 interpolants). These will be mapped onto the register bus and written by type 0 packets, and output to the the parameter busses (the sequencer and/or PA need to be able to address the realtime parameter memory as well as the regular parameter store. For higher performance we should be able able to view them as two banks of 16 and do double buffering allowing one to be loaded, while the other is rasterized with. Most overlay shaders will need 2 or 4 scalar coordinates, one option might be to restrict the memory to 16x64 or 32x64 allowing only two interpolated scalars per cycle, the only problem I see with this is, if we view support for 16 vector-4 interpolants important (true only if we map ~~microsoft's~~Microsoft's high priority stream to the realtime stream), then the PA/sequencer need to support a realtime-specific mode where we need to address 32 vectors of parameters instead of 16.

20. State management

Formatted: Bullets and Numbering

Every clock, the sequencer will report to the CP the oldest states still in the pipe. These are the states of the programs as they enter the last ALU clause.

21. XY Address imports

Formatted: Bullets and Numbering

The SC will be able to send the XY addresses to the GPRs. It does so by interleaving the writes of the IJs (to the IJ buffer) with XY writes (to the XY buffer). Then when writing the data to the GPRs, the sequencer is going to interpolate the IJ data or pass the XY data thru a Fix→float converter and expander and write the converted values to the GPRs. The Xys are currently SCREEN SPACE COORDINATES. The values in the XY buffers will wrap.

~~20.~~22. Registers

Formatted: Bullets and Numbering

~~20.1~~22.1 Control

DYNAMIC_REG	Dynamic allocation (pixel/vertex) of the register file on or off.
VERTEX_REG_SIZE	What portion of the register file is reserved for vertices (static allocation only)
PIXEL_MIN_SIZE	Minimal size of the register file's pixel portion (dynamic only)
VERTEX_MIN_SIZE	Minimal size of the register file's vertex portion (dynamic only)
ARBITRATION_policy	policy of the arbitration between vertexes and pixels
CST_SIZE_P	Size of the constant store for pixels
CST_SIZE_V	Size of the constant store for vertexes
INST_STOR_ALLOC	interleaved, separate, interleaved+shared,separate+shared
VERTEX_WRAP	start point for the vertex instruction store (RT always ends at vertex_wrap and Begins at 0)
PIXEL_WRAP	start point for the pixel shader instruction store ~~(vertex shader always starts at 0)~~
~~SHAREDWRAP~~	~~start point for the shared instruction store~~
~~RTWRAP~~	~~start point for the RT instruction store (RT always ends at the end of the IM)~~
NO_INTERLEAVE	debug state register. Only allows one program at a time into the GPRs
NO_INTERLEAVE_ALU	debug state register. Only allows one ALU program at a time to be executed (instead of 2)
NO_PRED_OPTIMIZE	turns off the predicate bit optimization (conditional_execute_predicates is always executed.
INSTRUCTION_INDEX _PORT	This is where the CP puts the base address of the instruction writes and type (auto-incremented on reads/writes)
INSTRUCTION_DATA	This is where the CP puts the actual data going to the instruction memory
CONSTANT_DATA	This is where the CP puts constant data

~~20.2~~22.2 Context

Formatted: Bullets and Numbering

Vshader_fetch[7:0][7:0]	eight 8 bit pointers to the location where each clauses control program is located
Vshader_alu[7:0][7:0]	eight 8 bit pointers to the location where each clauses control program is located
Pshader_fetch[7:0][7:0]	eight 8 bit pointers to the location where each clauses control program is located
Pshader_alu[7:0][7:0]	eight 8 bit pointers to the location where each clauses control program is located
PSHADER	base pointer for the pixel shader
VSHADER	base pointer for the vertex shader
Vshader_cntl_size	size of the vertex shader (# of instructions in control program/2)
Pshader_cntl_size	size of the pixel shader (# of instructions in control program/2)
Pshader_size	size of the pixel shader (cntl+instructions)
Vshader_size	size of the vertex shader (cntl+instructions)
REG_ALLOC_PIX	number of registers to allocate for pixel shader programs
REG_ALLOC_VERT	number of registers to allocate for vertex shader programs
FLAT_GOUR[0…15]	which parameters are to be gouraud shaded
CYL_WRAP[0…63]	for which parameters (and channels (xyzw)) do we do the cyl wrapping.
P_export_mode	0xxxx : Normal mode

1xxxx : Multipass mode
If normal, bbbz where bbb is how many colors (0-4) and z is export z or not
If multipass 1-12 exports for color.
vshader_export_mask which of the last 6 ALU clauses is exporting
vshader_export_mode 0: position (1 vector), 1: position (2 vectors), 3:multipass
vshader_export_count[6] # of interpolated parameters exported in clause 7 OR
# of exported vectors to memory per clause in multipass mode (per clause)
Control_Flow 24 Dwords that contain the control flow constants.~~kill_vector_on use the mask kill vector to kill pixels and optimize texture pipe fetches OR use it as the fifth predicate vector which is the only predicate vector kept across clause boundaries.~~

~~21.~~23. DEBUG registers

Formatted: Bullets and Numbering

~~21.1 Control~~

~~Shader_pipe # of the shader pipe for method 3 (0…64)~~
~~Count_+clause instruction count and clause number for method 3~~
~~Dword_select channel select for method 3~~
~~Mode operating mode for method 3~~
~~Rstate render state method 3 is operating on~~
~~Vector_count vector number the method 3 will export~~

~~21.2~~23.1 Context

Formatted: Bullets and Numbering

PROB_ADDR instruction address where the first problem occurred
PROB_COUNT number of problems encountered during the execution of the program
Count instruction counter for debug method 2
Addr break address for method number 2
Clause_mode[3] clause mode for debug method 2

~~22.~~24. Interfaces

Formatted: Bullets and Numbering

~~22.1~~24.1 External Interfaces

Whenever an x is used, it means that the bus is broadcast to all units of the same name. For example, if a bus is named SQ→SPx it means that SQ is going to broadcast the same information to all SP instances.

~~22.1.1~~24.1.1 *~~PA/~~SC to SP~~0~~ : IJ bus*

Formatted: Bullets and Numbering

This is a bus that sends the IJ information to the IJ fifos on the top of each shader pipe. At the same time the control information goes to the sequencer. There are 4 of these buses over the whole chip (SP0 thru 3)

Name	Direction	Bits	Description
~~IJs~~SC_SP0_data	~~PA~~SC→SP0	64	IJ information sent over 2 clocks (or XY info sent over 1 clock in the lower 24 LSBs of the interface)
~~Mask~~SC_SP0_q_wr_mask	~~PA~~SC→SP0	1	Write Mask
SC_SP0_dest	SC→SP0	1	Controls the write destination (XY buffer, IJ buffer)
SC_SP1_data	SC→SP1	64	IJ information sent over 2 clocks (or XY info sent over 1 clock in the lower 24 LSBs of the interface)
SC_SP1_q_wr_mask	SC→SP1	1	Write Mask
SC_SP1_dest	SC→SP1	1	Controls the write destination (XY buffer, IJ buffer)
SC_SP2_data	SC→SP2	64	IJ information sent over 2 clocks (or XY info sent over 1 clock in the lower 24 LSBs of the interface)
SC_SP2_q_wr_mask	SC→SP2	1	Write Mask
SC_SP2_dest	SC→SP2	1	Controls the write destination (XY buffer, IJ buffer)
SC_SP3_data	SC→SP3	64	IJ information sent over 2 clocks (or XY info sent over 1 clock in the lower 24 LSBs of the interface)
SC_SP3_q_wr_mask	SC→SP3	1	Write Mask
SC_SP3_dest	SC→SP3	1	Controls the write destination (XY buffer, IJ buffer)

~~22.1.2~~24.1.2 ~~PA/~~SC to SEQ : IJ Control bus

Formatted: Bullets and Numbering

This is the control information sent to the sequencer in order to control the IJ fifos and all other information needed to execute a shader program on the sent pixels. This information is sent over 2 clocks, if SENDXY is asserted the next control packet is going to be ignored and XY information is going to be sent on the IJ bus (for the quads that where just sent).

Name	Direction	Bits	Description
~~Write Mask~~SC_SQ_q_wr_mask	~~PA~~SC→S~~E~~Q~~(SP)~~	4	Quad Write mask left to right
~~LOD_CORRECT~~SC_SQ_lod_correct	SC→SQ~~PA→SEQ(SP)~~	24	LOD correction per quad (6 bits per quad)
~~FVTX~~SC_SQ_flat_vertex	SC→SQ~~PA→SEQ(SP)~~	2	Provoking vertex for flat shading
~~PPTR0~~SC_SQ_param_ptr0	SC→SQ~~PA→SEQ(SP)~~	11	P Store pointer for vertex 0
SC_SQ_param_ptr1~~PPRT1~~	SC→SQ~~PA→SEQ(SP)~~	11	P Store pointer for vertex 1
SC_SQ_param_ptr2~~PPTR2~~	SC→SQ~~PA→SEQ(SP)~~	11	P Store pointer for vertex 2
SC~~E_OFF_VECTOR~~_SQ_end_of_vect	SC→SQ~~PA→SEQ(SP)~~	1	End of the vector
~~DEALLOC~~SC_SQ_store_dealloc	SC→SQ~~PA→SEQ(SP)~~	1	Deallocation token for the P Store
~~STATE~~SC_SQ_state	SC→SQ~~PA→SEQ(SP)~~	~~21~~3	State/constant pointer (6*3+3)
~~VALID~~SC_SQ_valid_pixel	SC→SQ~~PA→SEQ(SP)~~	16	Valid bits for all pixels
~~NULL~~SC_SQ_null_prim	SC→SQ~~PA→SEQ(SP)~~	1	Null Primitive (for PC deallocation purposes)
SC_SQ_end_of_prim~~E_OFF_PRIM~~	SC→SQ~~PA→SEQ(SP)~~	1	End Of the primitive
~~FBFACE~~SC_SQ_fbface	SC→SQ~~PA→SEQ(SP)~~	1	Front face = 1, back face = 0
SC_SQ_send_xy	SC→SQ	1	Sending XY information [XY information is going to be sent on the next clock]
~~TYPE~~SC_SQ_prim_type	SC→SQ~~PA→SEQ(SP)~~	3	Stippled line and Real time command need to load tex cords from alternate buffer 000 : Normal ~~001 : Stippled line~~ 011 : Real Time 100 : Line AA 101 : Point AA 110 : Sprite
SC_SQ_RTRn	~~SEQ→PA~~SQ→SC	1	Stalls the PA in n clocks
SC_SQ_RTS	~~PA~~SC→~~SEQ(SP)~~SQ	1	~~PA~~SC ready to send data

~~22.1.3~~24.1.3 S~~E~~Q to SP~~0 ~~: Interpolator bus

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
~~TYPE~~SQ_SPx_interp_prim_type	S~~E~~Q→SPx~~0~~	3	Type of the primitive 000 : Normal ~~001 : Stippled line/Poly~~ 011 : Real Time 100 : Line AA 101 : Point AA 110 : Sprite
~~FVTX~~SQ_SPx_interp_flat_vtx	S~~E~~Q→SP~~0~~x	2	Provoking vertex for flat shading

~~FLAT_GOURAUD~~SQ_SPx_interp_flat_gouraud	S~~E~~Q→SP~~0~~x	1	Flat or gouraud shading
SQ_SPx_interp_cyl_wrap~~CYL_WRAP~~	S~~E~~Q→SP~~0~~x	4	Wich parameter needs to be cylindrical wrapped
SQ_SPx_interp_ijline~~IJ_Line number~~	S~~E~~Q→SPx~~0~~	2	Line in the IJ/XY buffer to use to interpolate
SQ_SPx_interp_buff_swap~~Swap_Buffers~~	S~~E~~Q→SP~~0~~x	1	Swap the IJ/XY buffers at the end of the interpolation
SQ_SPx_interp_ij_xy	SQ→SPx	1	Read from the IJ buffer or from the XY buffer
SQ_SPx_interp_param0~~Param_0~~	S~~E~~Q→SP~~0~~x	1	We are interpolating parameter 0

~~22.1.4~~24.1.4 S~~E~~Q to SP~~0~~ : Parameter ~~-~~Cache Read control bus

Formatted: Bullets and Numbering

The four following interfaces (SQ→SP, SQ→SX,SP→SX and SX→Interpolators) are all SYNCHRONIZED together.

Name	Direction	Bits	Description
SQ_SPx_~~P~~ptr0~~1~~	S~~E~~Q→SPx~~0~~	~~7~~9	Pointer of PC ~~(7 LSBs of Pointer)~~
SQ_SPx_~~P~~ptr1~~2~~	S~~E~~Q→SPx~~P0~~	~~7~~9	Pointer of PC ~~(7 LSBs of Pointer)~~
SQ_SPx_~~P~~ptr~~3~~2	S~~E~~Q→SPx~~0~~	9~~7~~	Pointer of PC ~~(7 LSBs of Pointer)~~
SQ_SP0_read_ena	SQ→SP0	4	Read enables for the 4 memories in the SP0
SQ_SP1_read_ena	SQ→SP1	4	Read enables for the 4 memories in the SP1
SQ_SP2_read_ena	SQ→SP2	4	Read enables for the 4 memories in the SP2
SQ_SP3_read_ena	SQ→SP3	4	Read enables for the 4 memories in the SP3

~~22.1.5~~24.1.5 S~~E~~Q to SX~~0~~ : Parameter Cache Mux control Bus

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
SQ_SXx_~~M~~mux0~~1~~	S~~E~~Q→SXx~~0~~	4	Mux control for PC (4 MSbs of Pointer)
SQ_SXx_~~M~~mux~~2~~1	S~~E~~Q→SXx~~0~~	4	Mux control for PC (4 MSbs of Pointer)
SQ_SXx_~~M~~mux~~3~~2	S~~E~~Q→SXx~~0~~	4	Mux control for PC (4 MSbs of Pointer)

24.1.6 SP to SX: Parameter data

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
SP0_SX0_data0	SP0→SX0	128	Parameter data 0
SP0_SX0_data1	SP0→SX0	128	Parameter data 1
SP0_SX0_data2	SP0→SX0	128	Parameter data 2
SP0_SX0_data3	SP0→SX0	128	Parameter data 3
SP1_SX1_data0	SP1→SX1	128	Parameter data 0
SP1_SX1_data1	SP1→SX1	128	Parameter data 1
SP1_SX1_data2	SP1→SX1	128	Parameter data 2
SP1_SX1_data3	SP1→SX1	128	Parameter data 3
SP2_SX0_data0	SP2→SX0	128	Parameter data 0
SP2_SX0_data1	SP2→SX0	128	Parameter data 1
SP2_SX0_data2	SP2→SX0	128	Parameter data 2
SP2_SX0_data3	SP2→SX0	128	Parameter data 3
SP3_SX1_data0	SP3→SX1	128	Parameter data 0
SP3_SX1_data1	SP3→SX1	128	Parameter data 1
SP3_SX1_data2	SP3→SX1	128	Parameter data 2
SP3_SX1_data3	SP3→SX1	128	Parameter data 3

~~22.1.6~~24.1.7 SX~~0~~ to ~~SP0~~ Interpolators: Parameter Cache Return bus

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
SXx_SPx_~~V~~vtx_data_~~1~~0	SXx~~0~~→SPx~~0~~	128	Vertex data to interpolate
SXx_SPx_~~V~~vtx_data_~~2~~1	SXx~~0~~→SPx~~0~~	128	Vertex data to interpolate
SXx_SPx_~~V~~vtx_data_~~3~~2	SXx~~0~~→SPx~~0~~	128	Vertex data to interpolate

~~22.1.7~~24.1.8 VGT to SP~~0~~0/S~~E~~Q : Vertex Bus

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
VGT_SP0_vrtx_indexes~~Vertex indexes~~	VGT→SP0	128	Pointers of indexes or HOS surface information
VGT_SP0_end_of_vect~~EOF_vector~~	VGT→SP0~~/SEQ~~	1	End of the vector
VGT_SP0_vrtx_format~~Inputs_vert~~	VGT→SP0~~/SEQ~~	1	0: Normal 128 bits per vert 1: double 256 bits per vert
VGT_SQ_end_of_vect	VGT→SQ	1	End of the vector
VGT_SQ_vrtx_format	VGT→SQ	1	0: Normal 128 bits per vert 1: double 256 bits per vert
VGT_SQ_state~~STATE~~	VGT→S~~E~~Q	~~21~~3	Render State (6*3+3 for constants)

~~22.1.8 CP to SEQ : Constant store load~~

Formatted: Bullets and Numbering

~~22.1.9CP to SEQ : Fetch State store load~~

~~22.1.10CP to SEQ : Control State store load~~

Formatted: Bullets and Numbering

~~{ISSUE: How,Who and what is the size of this bus?}~~

~~22.1.11 MH to SEQ: Instruction store Load~~

Formatted: Bullets and Numbering

24.1.9 SEQ to CP: State report

Name	Direction	Bits	Description
SQ_CP_vrtx_ state	SEQ→CP	3	Oldest vertex state still in the pipe
SQ_CP_pix_state	SEQ→CP	3	Oldest pixel state still in the pipe

~~{ISSUE: CP or MH?}~~

~~22.1.12~~24.1.10 SP~~0~~ to SX~~0~~ : Pixel/Vertex ~~read from RBs~~write to SX

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
SP0_SX0_Export_data	SP0→SX0	~~64*16~~256	4~~32~~ pair~~s~~s of 32 bits channel values
SP0_SX0_Shader_Dest	SP0→SX0	4	Specifies one of the of up to 12 export destinations
SP1_SX1_Export_data	SP1→SX1	256	4 pairs of 32 bits channel values
SP1_SX1_Shader_Dest	SP1→SX1	4	Specifies one of the of up to 12 export destinations
SP2_SX0_Export_data	SP2→SX0	256	4 pairs of 32 bits channel values
SP2_SX0_Shader_Dest	SP2→SX0	4	Specifies one of the of up to 12 export destinations
SP3_SX1_Export_data	SP3→SX1	256	4 pairs of 32 bits channel values
SP3_SX1_Shader_Dest	SP3→SX1	4	Specifies one of the of up to 12 export destinations
SPx_SXx_Shader_Count	SP0→SX0	3	Each set of four pixels or vectors is exported over eight clocks. This field specifies where the SP is in that sequence.
SPx_SXx_Shader_Last	SP0→SX0	1	~~The current export clause is over (true for one clock)~~ ~~The last export instruction creates *two* cycles to the RB. This needs to be set on or after the last RB cycle that is produced by the last export instruction, but before the first RB cycle of the first export instruction of the next clause.~~Asserted on the first shader count of the last export of the clause
SP0_SX0_Shader_PixelValid	SP0→SX0	4~~x4~~	Result of pixel kill in the shader pipe, which must be output for all pixel exports (depth and all color buffers). 4x4 because 16 pixels are computed per clock

SP0_SX0_Shader_WordValid	SP0→SX0	2	Specifies whether to write low and/or high 32-bit word of the 64-bit export data from each of the 16 pixels or vectors
SP1_SX1_Shader_PixelValid	SP1→SX1	4	Result of pixel kill in the shader pipe, which must be output for all pixel exports (depth and all color buffers). 4x4 because 16 pixels are computed per clock
SP1_SX1_Shader_WordValid	SP1→SX1	2	Specifies whether to write low and/or high 32-bit word of the 64-bit export data from each of the 16 pixels or vectors
SP2_SX0_Shader_PixelValid	SP2→SX0	4	Result of pixel kill in the shader pipe, which must be output for all pixel exports (depth and all color buffers). 4x4 because 16 pixels are computed per clock
SP2_SX0_Shader_WordValid	SP2→SX0	2	Specifies whether to write low and/or high 32-bit word of the 64-bit export data from each of the 16 pixels or vectors
SP3_SX1_Shader_PixelValid	SP3→SX1	4	Result of pixel kill in the shader pipe, which must be output for all pixel exports (depth and all color buffers). 4x4 because 16 pixels are computed per clock
SP3_SX1_Shader_WordValid	SP3→SX1	2	Specifies whether to write low and/or high 32-bit word of the 64-bit export data from each of the 16 pixels or vectors

~~22.1.13~~24.1.11 *S~~E~~Q to SX~~X0~~ : Control bus*

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
SQ_SXx_Export_Pixel	S~~E~~Q→SXx~~0~~	1	1: Pixel 0: Vertex
SQ_SXx_Export_SEND	S~~E~~Q→SXx~~0~~	1	Raised to indicate that the SQ is starting an export
SQ_SXx_Export_Clause	S~~E~~Q→SXx~~0~~	3	Clause number, which is needed for vertex clauses
SQ_SXx_Export_State	S~~E~~Q→SXx~~0~~	~~21?~~3	State ID, which is needed for vertex clauses

These fields are sent synchronously with SP export data, described in SP0→SX0 interface
{ISSUE: Where are the PC pointers}

~~22.1.14~~24.1.12 *SX~~0~~ to S~~E~~Q : Output file control*

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
SXx_SQ_Export_~~RTS~~count_rdy	~~SX0~~SXx→S~~E~~Q	1	Raised by SX0 to indicate that the following two fields reflect the result of the most recent export
SXx_SQ_Export_Position	SXx~~0~~→S~~E~~Q	1	Specifies whether there is room for another position.
SXx_SQ_Export_Buffer	SX~~0~~x→S~~E~~Q	7	Specifies the space ~~availble~~available in the output buffers. 0: buffers are full 1: 2K-bits available (32-bits for each of the 64 pixels in a clause) ... 64: 128K-bits available (16 128-bit entries for each of 64 pixels) 65-127: RESERVED

~~22.1.15 SP0 to SX0 : Position return bus~~

Formatted: Bullets and Numbering

~~22.1.16~~24.1.13 Shader Engine to Fetch Unit Bus ~~(Fast Bus)~~

Four quad's worth of addresses is transferred to Fetch Unit every clock. These are sourced from a different pixel within each of the sub-engines repeating every 4 clocks. The register file index to read must precede the data by 2 clocks. The Read address associated with Quad 0 must be sent 1 clock after the Instruction Start signal is sent, so that data is read 3 clocks after the Instruction Start.

Four Quad's worth of Fetch Data may be written to the Register file every clock. These are directed to a different pixel of the sub-engines repeating every 4 clocks. The register file index to write must accompany the data. Data and Index associated with the Quad 0 must be sent 3 clocks after the Instruction Start signal is sent.

Name	Direction	Bits	Description
~~Tex_RegFile_Read_Data~~SP0_TP0_fetch_addr	SP0->T~~EX~~P0	~~2048~~512	~~16~~ 4 Fetch Addresses read from the Register file
~~Tex_RegFile_Write _Data~~TP0_SP0_data	TP0~~EX~~→SP0	~~2048~~512	~~16~~ 4 texture results
SP1_TP1_fetch_addr	SP1->TP1	512	4 Fetch Addresses read from the Register file
TP1_SP1_data	TP1→SP1	512	4 texture results
SP2_TP2_fetch_addr	SP2->TP2	512	4 Fetch Addresses read from the Register file
TP2_SP2_data	TP2→SP2	512	4 texture results
SP3_TP3_fetch_addr	SP3->TP3	512	4 Fetch Addresses read from the Register file
TP3_SP3_data	TP3→SP3	512	4 texture results
TPx_SPx_gpr_dst	TPx→SPx	7	Write address into the gprs
TPx_SPx_gpr_cmask	TPx→SPx	4	Channel mask

~~22.1.17~~24.1.14 Sequencer to Fetch Unit bus ~~(Slow Bus)~~

Formatted: Bullets and Numbering

Once every ~~four~~ clock, the fetch unit sends to the sequencer on ~~wich~~which clause it is now working and if the data in the registers is ready or not. This way the sequencer can update the fetch counters for the reservation station fifos. The sequencer also provides the ~~intruction~~instruction and constants for the fetch to execute and the address in the register file where to write the fetch return data.

Name	Direction	Bits	Description
~~Tex_Ready~~TPx_SQ_data_rdy	T~~EX~~Px→ S~~E~~Q	1	Data ready
TPx_SQ_clause_num~~Tex_Clause_Num~~	T~~EX~~Px→ S~~E~~Q	3	Clause number

24.1.15 Sequencer to SP: GPR control

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
SQ_SPx_gpr_wr_addr	SQ→SPx	7	Write address
SQ_SPx_gpr_rd_addr	SQ→SPx	7	Read address
SQ_SPx_gpr_re_addr	SQ→SPx	1	Read Enable
SQ_SPx_gpr_we_addr	SQ→SPx	1	Write Enable
SQ_SPx_gpr_phase_mux	SQ→SPx	2	The phase mux
SQ_SPx_gpr_channel_mask	SQ→SPx	4	The channel mask
SQ_SP0_gpr_pixel_mask	SQ→SP0	4	The pixel mask
SQ_SP1_gpr_pixel_mask	SQ→SP1	4	The pixel mask
SQ_SP2_gpr_pixel_mask	SQ→SP2	4	The pixel mask
SQ_SP3_gpr_pixel_mask	SQ→SP3	4	The pixel mask

24.1.16 Sequencer to SPx: Parameter cache write control

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
SQ_SPx_pc_wr_addr	SQ→SPx	7	Write address
SQ_SPx_pc_we_addr	SQ→SPx	1	Write Enable
SQ_SPx_pc_phase_mux	SQ→SPx	1	The output selector mux (gpr vs parameter cache)

24.1.17 Sequencer to SPx: Instructions

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
SQ_SPx_instruct_start	SQ→SPx	1	Instruction start
SQ_SP_instruct	SQ→SPx	20	Instruction sent over 4 clocks
SQ_SPx_stall	SQ→SPx	1	Stall signal
SQ_SPx_Shader_Count	SQ→SPx	3	Each set of four pixels or vectors is exported over eight clocks. This field specifies where the SP is in that sequence.
SQ_SPx_Shader_Last	SQ→SPx	1	Asserted on the first shader count of the last export of the clause
SQ_SP0_Shader_PixelValid	SQ→SP0	4	Result of pixel kill in the shader pipe, which must be output for all pixel exports (depth and all color buffers). 4x4 because 16 pixels are computed per clock
SQ_SP0_Shader_WordValid	SQ→SP0	2	Specifies whether to write low and/or high 32-bit word of the 64-bit export data from each of the 16 pixels or vectors
SQ_SP1_Shader_PixelValid	SQ→SP1	4	Result of pixel kill in the shader pipe, which must be output for all pixel exports (depth and all color buffers). 4x4 because 16 pixels are computed per clock
SQ_SP1_Shader_WordValid	SQ→SP1	2	Specifies whether to write low and/or high 32-bit word of the 64-bit export data from each of the 16 pixels or vectors
SQ_SP2_Shader_PixelValid	SQ→SP2	4	Result of pixel kill in the shader pipe, which must be output for all pixel exports (depth and all color buffers). 4x4 because 16 pixels are computed per clock
SQ_SP2_Shader_WordValid	SQ→SP2	2	Specifies whether to write low and/or high 32-bit word of the 64-bit export data from each of the 16 pixels or vectors
SQ_SP3_Shader_PixelValid	SQ→SP3	4	Result of pixel kill in the shader pipe, which must be output for all pixel exports (depth and all color buffers). 4x4 because 16 pixels are computed per clock
SQ_SP3_Shader_WordValid	SQ→SP3	2	Specifies whether to write low and/or high 32-bit

			word of the 64-bit export data from each of the 16 pixels or vectors

24.1.18 SP to Sequencer: Constant address load

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
SP0_SQ_const_addr	SP0→SQ	36	Constant address load to the sequencer
SP0_SQ_valid	SP0→SQ	1	Data valid
SP1_SQ_const_addr	SP1→SQ	36	Constant address load to the sequencer
SP1_SQ_valid	SP1→SQ	1	Data valid
SP2_SQ_const_addr	SP2→SQ	36	Constant address load to the sequencer
SP2_SQ_valid	SP2→SQ	1	Data valid
SP3_SQ_const_addr	SP3→SQ	36	Constant address load to the sequencer
SP3_SQ_valid	SP3→SQ	1	Data valid

24.1.20 SP0 to Sequencer: Kill vector load

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
SP0_SQ_kill_vect	SP0→SQ	4	Kill vector load
SP1_SQ_kill_vect	SP1→SQ	4	Kill vector load
SP2_SQ_kill_vect	SP2→SQ	4	Kill vector load
SP3_SQ_kill_vect	SP3→SQ	4	Kill vector load

24.1.21 SQ to CP: RBBM bus

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
SQ_RBB_rs	SQ→CP	1	Read Strobe
SQ_RBB_rd	SQ→CP	32	Read Data
SQ_RBBM_nrtrtr	SQ→CP	1	Optional
SQ_RBBM_rtr	SQ→CP	1	Real-Time (Optional)

24.1.22 CP to SQ: RBBM bus

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
rbbm_we	CP→SQ	1	Write Enable
rbbm_a	CP→SQ	18	Address -- Upper Extent is TBD
rbbm_wd	CP→SQ	32	Data
rbbm_be	CP→SQ	4	Byte Enables
rbbm_re	CP→SQ	1	Read Enable
rbb_rs0	CP→SQ	1	Read Return Strobe 0
rbb_rs1	CP→SQ	1	Read Return Strobe 1
rbb_rd0	CP→SQ	32	Read Data 0
rbb_rd1	CP→SQ	32	Read Data 0
RBBM_SQ_soft_reset	CP→SQ	1	Soft Reset

~~23.~~25. Examples of program executions

Formatted: Bullets and Numbering

~~23.1.1~~25.1.1 Sequencer Control of a Vector of Vertices

1. PA sends a vector of 64 vertices (actually vertex indices – 32 bits/index for 2048 bit total) to the RE's Vertex FIFO
   - state pointer as well as tag into position cache is sent along with vertices
   - space was allocated in the position cache for transformed position before the vector was sent

- **also before the vector is sent to the RE, the CP has loaded the global instruction store with the vertex shader program (using the MH?)**
- The vertex program is assumed to be loaded when we receive the vertex vector.
  - the SEQ then accesses the IS base for this shader using the local state pointer (provided to all sequencers by the RBBM when the CP is done loading the program)

2. SEQ arbitrates between the Pixel FIFO and the Vertex FIFO – basically the Vertex FIFO always has priority
   - at this point the vector is removed from the Vertex FIFO
   - the ~~arbitrer~~arbiter is not going to select a vector to be transformed if the parameter cache is full unless the pipe as nothing else to do (ie no pixels are in the pixel fifo).

3. SEQ allocates space in the SP register file for index data plus GPRs used by the program
   - the number of GPRs required by the program is stored in a local state register, which is accessed using the state pointer that came down with the vertices
   - SEQ will not send vertex data until space in the register file has been allocated

4. SEQ sends the vector to the SP register file over the RE_SP interface (which has a bandwidth of 2048 bits/cycle)
   - the 64 vertex indices are sent to the 64 register files over 4 cycles
     - RF0 of SU0, SU1, SU2, and SU3 is written the first cycle
     - RF1 of SU0, SU1, SU2, and SU3 is written the second cycle
     - RF2 of SU0, SU1, SU2, and SU3 is written the third cycle
     - RF3 of SU0, SU1, SU2, and SU3 is written the fourth cycle
   - the index is written to the least significant 32 bits **(floating point format?) (what about compound indices)** of the 128-bit location within the register file (w); the remaining data bits are set to zero (x, y, z)

5. SEQ constructs a control packet for the vector and sends it to the first reservation station (the FIFO in front of fetch state machine 0, or TSM0 FIFO)
   - the control packet contains the state pointer, the tag to the position cache and a register file base pointer.

6. TSM0 accepts the control packet and fetches the instructions for fetch clause 0 from the global instruction store
   - TSM0 was first selected by the TSM arbiter before it could start

7. all instructions of fetch clause 0 are issued by TSM0

8. the control packet is passed to the next reservation station (the FIFO in front of ALU state machine 0, or ASM0 FIFO)
   - TSM0 does not wait for requests made to the Fetch Unit to complete; it passes the register file write index for the fetch data to the TU, which will write the data to the RF as it is received
   - once the TU has written all the data to the register files, it increments a counter that is associated with ASM0 FIFO; a count greater than zero indicates that the ALU state machine can go ahead start to execute the ALU clause

9. ASM0 accepts the control packet (after being selected by the ASM arbiter) and gets the instructions for ALU clause 0 from the global instruction store

10. all instructions of ALU clause 0 are issued by ASM0, then the control packet is passed to the next reservation station (the FIFO in front of fetch state machine 1, or TSM1 FIFO)

11. the control packet continues to travel down the path of reservation stations until all clauses have been executed
    - position can be exported in ALU clause 3 (or 4?); the data (and the tag) is sent over a position bus (which is shared with all four shader pipes) back to the PA's position cache
    - A parameter cache pointer is also sent along with the position data. This tells to the PA where the data is going to be in the parameter cache.
      - there is a position export FIFO in the SP that buffers position data before it gets sent back to the PA
      - the ASM arbiter will prevent a packet from starting an exporting clause if the position export FIFO is full
    - parameter data is exported in clause 7 (as well as position data if it was not exported earlier)
      - parameter data is sent to the Parameter Cache over a dedicated bus
      - the SEQ allocates storage in the Parameter Cache, and the SEQ deallocates that space when there is no longer a need for the parameters (it is told by the PA when using a token).
      - the ASM arbiter will prevent a packet from starting on ASM7 if the parameter cache (or the position buffer if position is being exported) is full

12. after the shader program has completed, the SEQ will free up the GPRs so that they can be used by another shader program

~~23.1.2~~25.1.2 *Sequencer Control of a Vector of Pixels*

Formatted: Bullets and Numbering

1. **As with vertex shader programs, pixel shaders are loaded into the global instruction store by the CP**
   - At this point it is assumed that the pixel program is loaded into the instruction store and thus ready to be read.
2. the RE's Pixel FIFO is loaded with the barycentric coordinates for pixel quads by the detailed walker
   - the state pointer and the LOD correction bits are also placed in the Pixel FIF0
   - the Pixel FIFO is wide enough to source four quad's worth of barycentrics per cycle
3. SEQ arbitrates between Pixel FIFO and Vertex FIFO – when there are no vertices pending OR there is no space left in the register files for vertices, the Pixel FIFO is selected
4. SEQ allocates space in the SP register file for all the GPRs used by the program
   - the number of GPRs required by the program is stored in a local state register, which is accessed using the state pointer
   - SEQ will not allow interpolated data to be sent to the shader until space in the register file has been allocated
5. SEQ controls the transfer of interpolated data to the SP register file over the RE_SP interface (which has a bandwidth of 2048 bits/cycle). See interpolated data bus diagrams for details.
6. SEQ constructs a control packet for the vector and sends it to the first reservation station (the FIFO in front of fetch state machine 0, or TSM0 FIFO)
   - note that there is a separate set of reservation stations/arbiters/state machines for vertices and for pixels
   - the control packet contains the state pointer, the register file base pointer, and the LOD correction bits
   - all other ~~informations~~information (such as quad address for example) travels in a separate FIFO
7. TSM0 accepts the control packet and fetches the instructions for fetch clause 0 from the global instruction store
   - TSM0 was first selected by the TSM arbiter before it could start
8. all instructions of fetch clause 0 are issued by TSM0
9. the control packet is passed to the next reservation station (the FIFO in front of ALU state machine 0, or ASM0 FIFO)
   - TSM0 does not wait for fetch requests made to the Fetch Unit to complete; it passes the register file write index for the fetch data to the TU, which will write the data to the RF as it is received
   - once the TU has written all the data for a particular clause to the register files, it increments a counter that is associated with the ASM0 FIFO; a count greater than zero indicates that the ALU state machine can go ahead and pop the FIFO and start to execute the ALU clause
10. ASM0 accepts the control packet (after being selected by the ASM arbiter) and gets the instructions for ALU clause 0 from the global instruction store
11. all instructions of ALU clause 0 are issued by ASM0, then the control packet is passed to the next reservation station (the FIFO in front of fetch state machine 1, or TSM1 FIFO)
12. the control packet continues to travel down the path of reservation stations until all clauses have been executed
   - pixel data is exported in the last ALU clause (clause 7)
      - it is sent to an output FIFO where it will be picked up by the render backend
      - the ASM arbiter will prevent a packet from starting on ASM7 if the output FIFO is full
13. after the shader program has completed, the SEQ will free up the GPRs so that they can be used by another shader program

~~23.1.3~~25.1.3 *Notes*

Formatted: Bullets and Numbering

14. The state machines and ~~arbitrers~~arbiters will operate ahead of time so that they will be able to immediately start the real threads or stall.

15. The register file base pointer for a vector needs to travel with the vector through the reservation stations, but the instruction store base pointer does not – this is because the RF pointer is different for all threads, but the IS pointer is only different for each state and thus can be accessed via the state pointer

16. Waterfalling still needs to be specked out.

~~24.~~26. Open issues

Formatted: Bullets and Numbering

There is currently an issue with constants. If the constants are not the same for the whole vector of vertices, we don't have the ~~bandwith~~bandwidth from the fetch store to feed the ALUs. Two solutions exists for this problem:

1) Let the compiler handle the case and put those instructions in a fetch clause so we can use the ~~bandwith~~bandwidth there to operate. This requires a significant amount of temporary storage in the register store.
2) Waterfall down the pipe allowing only at a given time the vertices having the same constants to operate in ~~parrallel~~parallel. This might in the worst case slow us down by a factor of 16.

Need to do some testing on the size of the register file as well as on the register file allocation method (dynamic VS static).

Saving power?

R400 Sequencer Specification

S~~E~~Q

Version 1.4~~3~~

Overview: This is an architectural specification for the R400 Sequencer block (SEQ). It provides an overview of the required capabilities and expected uses of the block. It also describes the block interfaces, internal sub-blocks, and provides internal state diagrams.

Revision Changes:

Rev 0.1 (Laurent Lefebvre) Date: May 7, 2001	First draft.
Rev 0.2 (Laurent Lefebvre) Date : July 9, 2001	Changed the interfaces to reflect the changes in the SP. Added some details in the arbitration section.
Rev 0.3 (Laurent Lefebvre) Date : August 6, 2001	Reviewed the Sequencer spec after the meeting on August 3, 2001.
Rev 0.4 (Laurent Lefebvre) Date : August 24, 2001	Added the dynamic allocation method for register file and an example (written in part by Vic) of the flow of pixels/vertices in the sequencer.
Rev 0.5 (Laurent Lefebvre) Date : September 7, 2001	Added timing diagrams (Vic)
Rev 0.6 (Laurent Lefebvre) Date : September 24, 2001	Changed the spec to reflect the new R400 architecture. Added interfaces.
Rev 0.7 (Laurent Lefebvre) Date : October 5, 2001	Added constant store management, instruction store management, control flow management and data dependant predication.
Rev 0.8 (Laurent Lefebvre) Date : October 8, 2001	Changed the control flow method to be more flexible. Also updated the external interfaces.
Rev 0.9 (Laurent Lefebvre) Date : October 17, 2001	Incorporated changes made in the 10/18/01 control flow meeting. Added a NOP instruction, removed the conditional_execute_or_jump. Added debug registers.
Rev 1.0 (Laurent Lefebvre) Date : October 19, 2001	Refined interfaces to RB. Added state registers.
Rev 1.1 (Laurent Lefebvre) Date : October 26, 2001	Added SEQ→SP0 interfaces. Changed delta precision. Changed VGT→SP0 interface. Debug Methods added.
Rev 1.2 (Laurent Lefebvre) Date : November 16, 2001	Interfaces greatly refined. Cleaned up the spec.
Rev 1.3 (Laurent Lefebvre) Date : November 26, 2001	Added the different interpolation modes.
Rev 1.4 (Laurent Lefebvre) Date : December 6, 2001	Added the auto incrementing counters. Changed the VGT→SQ interface. Added content on constant management. Updated registers.

1. Overview

The sequencer is based on the R300 design. It chooses two ALU clauses and a fetch clause to execute, and executes all of the instructions in a clause before looking for a new clause of the same type. Two ALU clauses are executed interleaved to hide the ALU latency. Each vector will have eight fetch and eight ALU clauses, but clauses do not need to contain instructions. A vector of pixels or vertices ping-pongs along the sequencer FIFO, bouncing from fetch reservation station to alu reservation station. A FIFO exists between each reservation stage, holding up vectors until the vector currently occupying a reservation station has left. A vector at a reservation station can be chosen to execute. The sequencer looks at all eight alu reservation stations to choose an alu clause to execute and all eight fetch stations to choose a fetch clause to execute. The arbitrator will give priority to clauses/reservation stations closer to the bottom of the pipeline. It will not execute an alu clause until the fetch fetches initiated by the previous fetch clause have completed. There are two separate sets of reservation stations, one for pixel vectors and one for vertices vectors. This way a pixel can pass a vertex and a vertex can pass a pixel.

To support the shader pipe the sequencer also contains the shader instruction cache, constant store, control flow constants and texture state. The four shader pipes also execute the same instruction thus there is only one sequencer for the whole chip.

The sequencer first arbitrates between vectors of 64 vertices that arrive directly from primitive assembly and vectors of 16 quads (64 pixels) that are generated in the scan converter.

The vertex or pixel program specifies how many GPRs it needs to execute. The sequencer will not start the next vector until the needed space is available in the GPRs.

There are two sets of the above figure, one for vertices and one for pixels.

Depending on the arbitration state, the sequencer will either choose a vertex or a pixel packet. The control packet consists of 3 bits of state, 7 bits for the base address of the Shader program and some information on the coverage to determine fetch LOD plus other various small state bits.

On receipt of a packet, the input state machine (not pictured but just before the first FIFO) allocated enough space in the registers to store the interpolated values and temporaries. Following this, the barycentric coordinates (and XY screen position if needed) are sent to the interpolator buffers which are going to use these barycentric coordinates to interpolate the parameters and place the interpolated values into the GPRs. Then, the input state machine stacks the packet in the first FIFO.

On receipt of a command, the level 0 fetch machine issues a texture request and corresponding register address for the fetch address (ta). A small command (tcmd) is passed to the fetch system identifying the current level number (0) as well as the register write address for the fetch return data. One fetch request is sent every 4 clocks causing the texturing of sixteen 2x2s worth of data (or 64 vertices). Once all the requests are sent the packet is put in FIFO 1.

Upon receipt of the return data, the fetch unit writes the data to the register file using the write address that was provided by the level 0 fetch machine and sends the clause number (0) to the level 0 fetch state machine to signify that the write is done and thus the data is ready. Then, the level 0 fetch machine increments the counter of FIFO 1 to signify to the ALU 1 that the data is ready to be processed.

On receipt of a command, the level 0 ALU machine first decrements the input FIFO counter and then issues a complete set of level 0 shader instructions. For each instruction, the state machine generates 3 source addresses, one destination address (3 cycles later) and an instruction. Once the last instruction as been issued, the packet is put into FIFO 2.

There will always be two active ALU clauses at any given time (and two arbiters). One arbiter will arbitrate over the odd instructions (4 clocks cycles) and the other one will arbitrate over the even instructions (4 clocks cycles). The only constraints between the two arbiters is that they are not allowed to pick the same clause number as the other one is currently working on if the packet is not of the same type (render state).

If the packet is a vertex packet, upon reaching ALU clause 3, it can export the position if the position is ready. So the arbiter must prevent ALU clause 3 to be selected if the positional buffer is full (or can't be accessed). Along with the positional data, if needed the sprite size and/or edge flags can also be sent.

{ISSUE: How do we handle parameter cache pointers (computed, semi-computed or not computed)?}

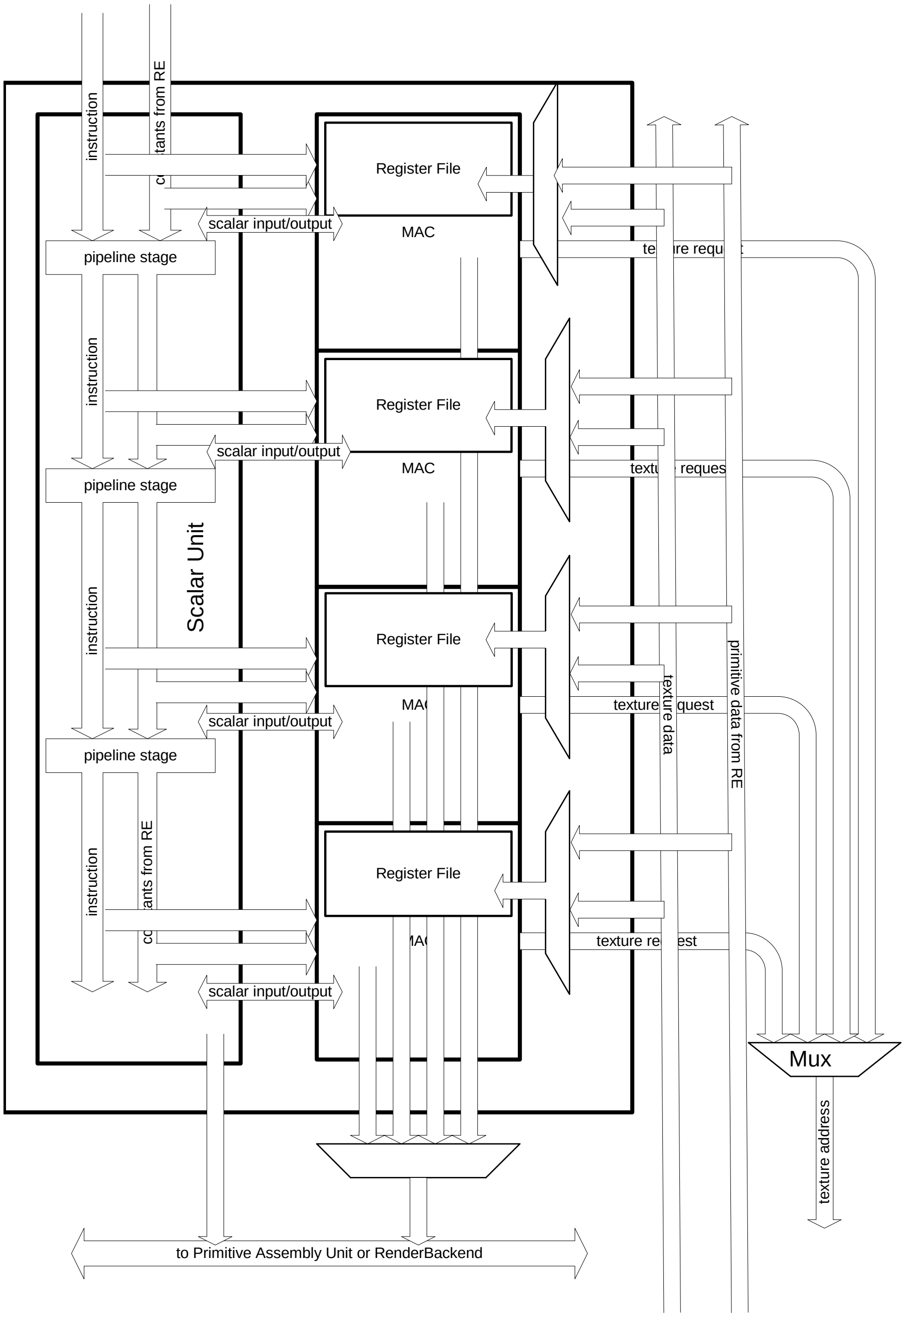
A special case is for multipass vertex ~~shaders which~~shaders, which can export 12 parameters per last 6 clauses to the output buffer. If the output buffer is full or doesn't have enough space the sequencer will prevent such a vertex group to enter an exporting clause.

Multipass pixel shaders can export 12 parameters to memory from the last clause only (7).

All other level process in the same way until the packet finally reaches the last ALU machine (7). ~~Upon completion of a vertex shader, a bit is sent to the SC to let it know that it can begin sending pixels of this group to the sequencer.~~

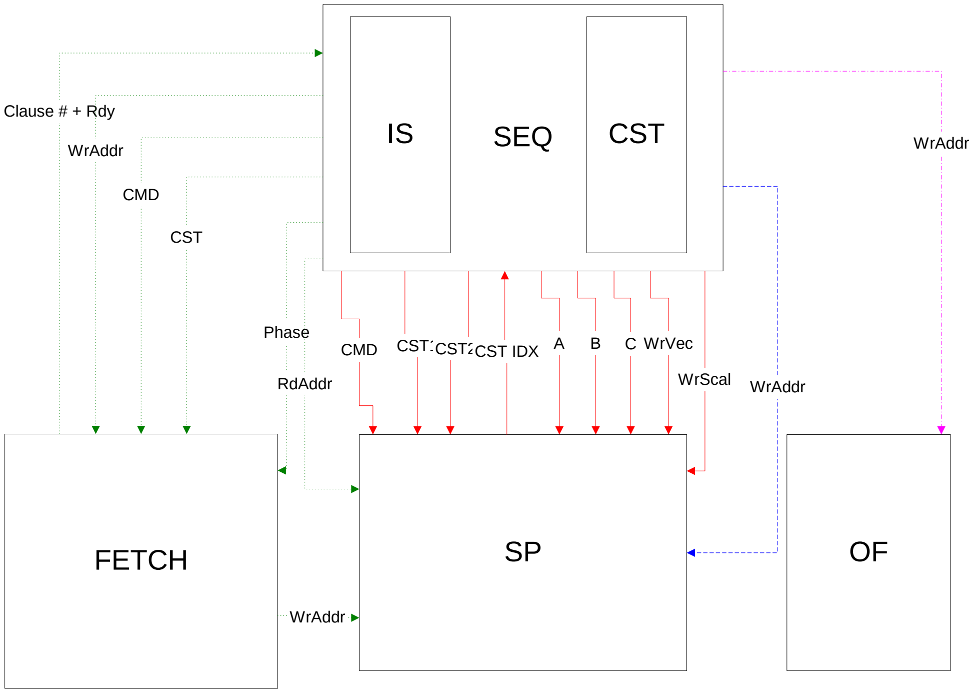
Only two ALU state machine may have access to the register file address bus or the instruction decode bus at one time. Similarly, only one fetch state machine may have access to the register file address bus at one time. Arbitration is performed by three arbiter blocks (two for the ALU state machines and one for the fetch state machines). The arbiters always favor the higher number state machines, preventing a bunch of half finished jobs from clogging up the register files.

1.2 Data Flow graph



The gray area represents blocks that are replicated 4 times per shader pipe (16 times on the overall chip).

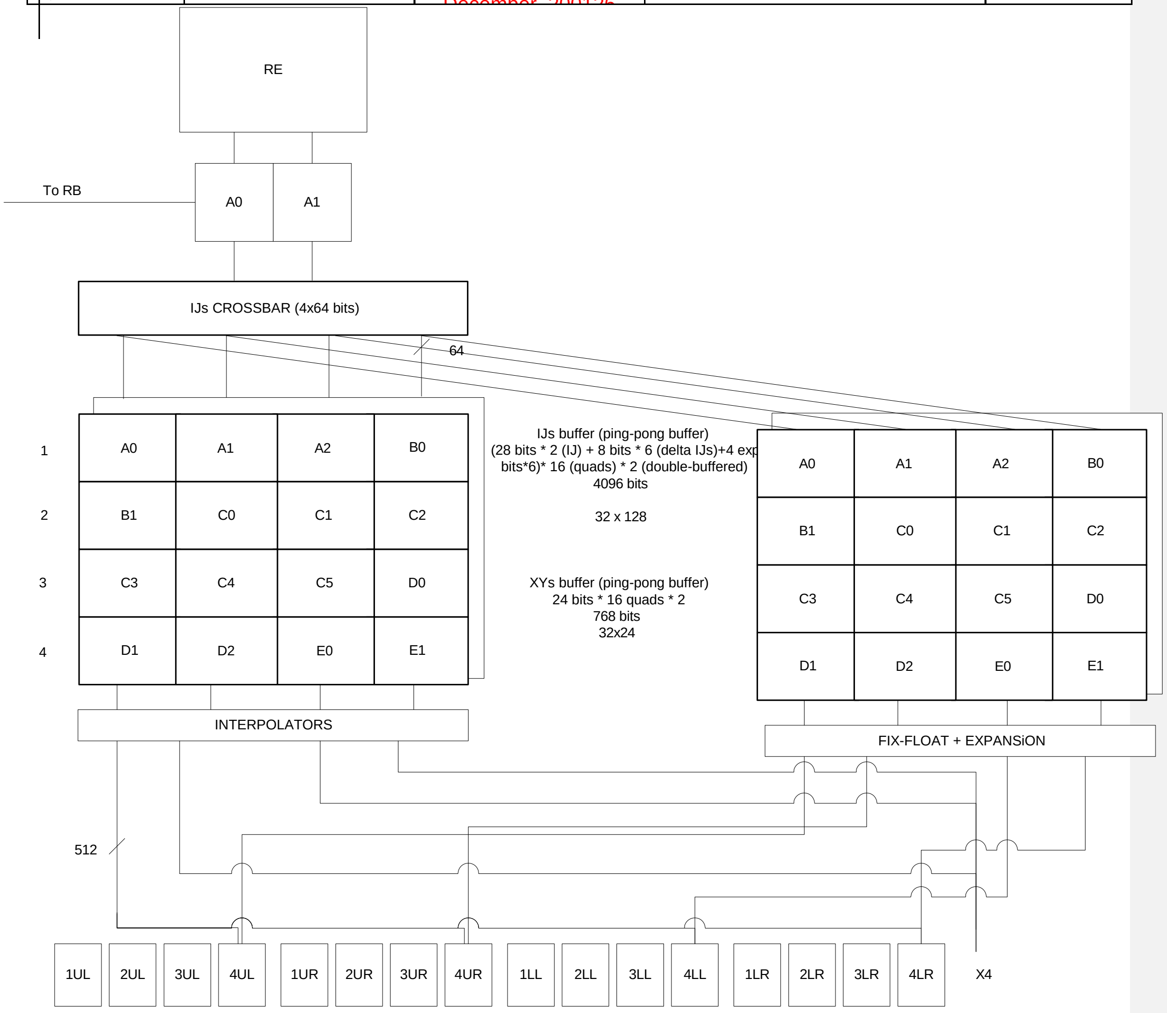
1.3 Control Graph



In green is represented the Fetch control interface, in red the ALU control interface, in blue the Interpolated/Vector control interface and in purple is the output file control interface.

2. Interpolated data bus

The interpolators contain an IJ buffer to pack the information as much as possible before writing it to the register file.



IJs buffer (ping-pong buffer)
(28 bits * 2 (IJ) + 8 bits * 6 (delta IJs)+4 exp
bits*6)* 16 (quads) * 2 (double-buffered)
4096 bits

32 x 128

XYs buffer (ping-pong buffer)
24 bits * 16 quads * 2
768 bits
32x24

	T0	T1	T2	T3	T4	T5	T6	T7	T8	T9	T10	T11	T12	T13	T14	T15	T16	T17	T18	T19	T20	T21	T22	T23
SP 0	XY 0-3	XY 16-19	XY 32-35	XY 48-51	A0	B1	C3	D1					A0	B1	C3	D1					V 0-3	V 16-19	V 32-35	V 48-51

SP 2	XY 8-11	XY 24-27	XY 40-43	XY 56-59	A2		C5			C1		E0	A2		C5			C1		E0	V 8-11	V 24-27	V 40-43	V 56-59
SP 3	XY 12-15	XY 28-31	XY 44-47	XY 60-63					B0	C2	D0	E1					B0	C2	D0	E1	V 12-15	V 28-31	V 44-47	V 60-63
	XY				P1								P2								VTX			

Above is an example of a tile we might receive. The IJ information is packed in the IJ buffer 2 quads at a time. The sequencer allows at any given time as many as four quads to interpolate a parameter. They all have to come from the same primitive. Then the sequencer controls the write mask to the register to write the valid data in.

3. Instruction Store

There is going to be only one instruction store for the whole chip. It will contain 4096 instructions of 96 bits each.

It is likely to be a 1 port memory; we use 1 clock to load the ALU instruction, 1 clocks to load the Fetch instruction, 1 clock to load 2 control flow instructions and 1 clock to write instructions.

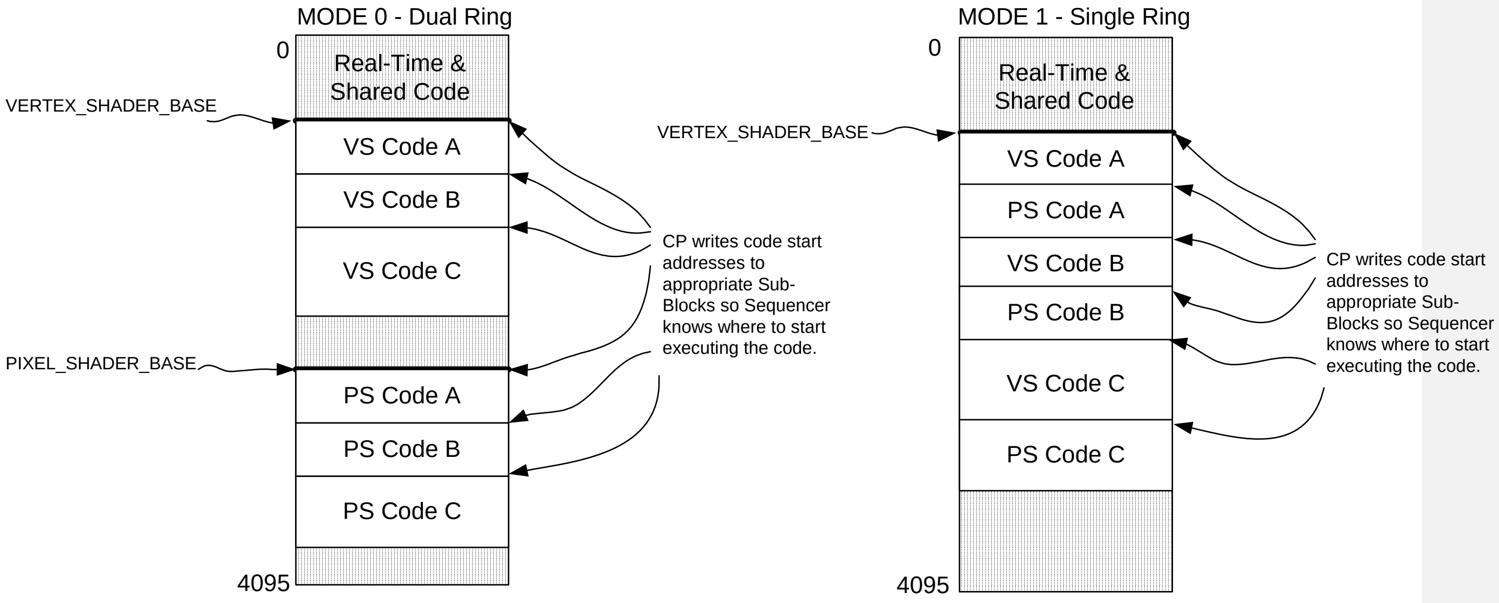
The instruction store is loaded by the CP thru the INST_DATA~~INSTRUCTION_DATA~~, INST_INDEX_PORT ~~INSTRUCTION_INDEX_PORT~~ control registers. The INST_INDEX_PORT~~INSTRUCTION_INDEX_PORT~~ is auto-incremented on both reads and writes to the INST_DATA~~INSTRUCTION_DATA~~ register.

The next picture shows the various modes the CP can load the memory. The Sequencer has to keep track of the loading modes in order to wrap around the correct boundaries. The MSB of the INST_INDEX_PORT ~~INSTRUCTION_INDEX_PORT~~ register contains the packet type for the sequencer to know where it must wrap around. The wrap around points are arbitrary and they are specified in the ~~VERTEX_SHADER~~VS_BASE and PI~~XEL_SHADER~~X_BASE registers.

For the Real time commands the story is quite the same but for some small differences. The CP will use the INST_INDEX_PORT_RT and INST_DATA_RT register pair instead of the regular ones and there are no wrap around points for real time so the driver must be careful not to overwrite regular shader data. The shared code (shared subroutines) uses the same path as real time.

R400 CP's Views of Instruction Memory

Updated: 11/14/2001
John A. Carey



CP writes code start addresses to appropriate Sub-Blocks so Sequencer knows where to start executing the code.

CP writes code start addresses to appropriate Sub-Blocks so Sequencer knows where to start executing the code.

4. Sequencer Instructions

All control flow instructions and move instructions are handled by the sequencer only. The ALUs will perform NOPs during this time (MOV PV,PV, PS,PS).

5. Constant Stores

5.1 Memory organizations

Formatted: Bullets and Numbering

~~The sequencer is aware of where the constants are using a remaping table.~~ A likely size for the ALU constant store is 1024x128 bits. The read BW from the ALU constant store is 128 bits/clock and the write bandwidth is 32 bits/clock (directed by the CP bus size not by memory ports)~~32/4 bits/clock~~.

The maximum logical size of the constant store for a given shader is 256 constants. Or 512 for the pixel/vertex shader pair. The size of the remaping table is 128 lines (each line addresses 4 constants). The write granularity is 4 constants or 512 bits. It takes 16 clocks to write the four constants.

The texture state is also kept in a similar memory. The size of this memory is 192x128. The memory thus holds 128 texture states (192 bits per state). The logical size exposed 32 different states total, which are going to be shared between the pixel and the vertex shader. The size of the remaping table to for the texture state memory is 16 lines (each line addresses 2 texture state lines in the real memory). The write granularity is 2 texture state lines (or 384 bits). The driver sends 512 bits but the CP ignores the top 128 bits. It thus takes 12 clocks to write the two texture states.

The control flow constant memory doesn't sit behind a renaming table. It is register mapped and thus the driver must reload its content each time there is a state change. Its size is 256*32 because it must hold 8 copies of the 32 dwords of control flow constants.

The CP is loading the constant store using the CONST_DATA and CONST_ADDR registers. It does so by writing to the CONST_ADDR register the logical address for the constant block it wants to update and then writes 16 times to the CONST_DATA register. The CONST_ADDR is auto-incremented on both reads and writes to the CONST_DATA register.

5.2 Management of the remaping tables

Formatted: Bullets and Numbering

The sequencer is responsible to manage two remaping tables (one for the constant store and one for the texture state). On a state change (by the driver), the sequencer will broadside copy the contents of its remaping tables to a new one. We have 8 different remaping tables we can use concurrently. More details and a diagram to come….

~~5.1~~5.3 Constant Store Indexing

Formatted: Bullets and Numbering

In order to do constant store indexing, the sequencer must be loaded first with the indexes (that come from the GPRs). There are 144 wires from the exit of the SP to the sequencer (9 bits pointers x 16 vertexes/clock). Since the data must pass thru the Shader pipe for the float to fixed conversion, there is a latency of 4 clocks (1 instruction) between the time the sequencer is loaded and the time one can index into the constant store. The assembly will look like this

```
MOVA  R1.X,R2.X       // Loads the sequencer with the content of R2.X, also copies the content of R2.X into R1.X
NOP                   // latency of the float to fixed conversion
ADD   R3,R4,C0[R2.X]// Uses the state from the sequencer to add R4 to C0[R2.X] into R3
```

Note that we don't really care about what is in the brackets because we use the state from the MOVA instruction. R2.X is just written again for the sake of simplicity and coherency.

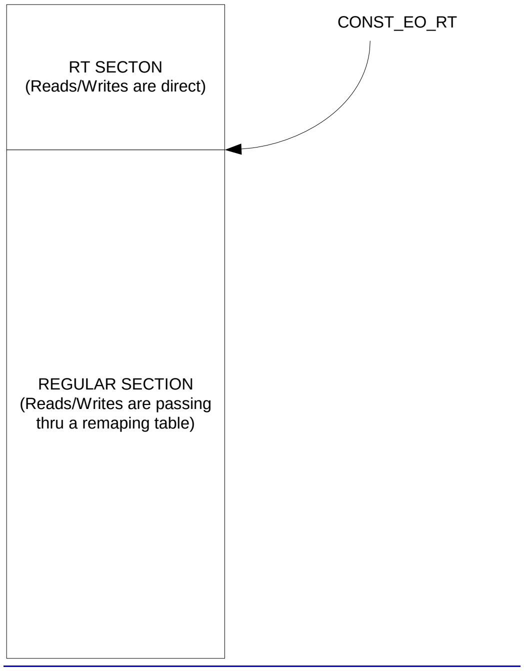
The storage needed in the sequencer in order to support this feature is 2*64*9 bits = 1152 bits.

Formatted: Bullets and Numbering

5.4

5.5 Real Time Commands

The real time commands constants are written by the CP using the CONST_DATA_RT and CONST_ADDR_RT registers. It works is the same way than when dealing with regular constant loads BUT in this case the CP is not sending a logical address but rather a physical address and the reads are not passing thru the remaping table but are directly read from the memory. The boundary between the two zones is defined by the CONST_EO_RT control register.



CONST_EO_RT
RT SECTON
(Reads/Writes are direct)
REGULAR SECTION
(Reads/Writes are passing thru a remaping table)

~~The texture state is also kept in a similar memory. The size of this memory is 192x128. Which lets us load a texture state in 2 clocks. The memory thus holds 96 texture states (2*128 bits per state)~~

~~The control flow constant memory doesn't sit behind a renaming table. It is register mapped and thus the driver must reload its content each time there is a state change. Its size is 192*32 because it must hold 8 copies of the 24 dwords of control flow constants.~~

6. Looping and Branches

Loops and branches are planned to be supported and will have to be dealt with at the sequencer level. We plan on supporting constant loops and branches using a control program.

6.1 The controlling state.

The R400 controling state consists of:
~~As per Dx9 the following state is available for control flow:~~

~~Boolean[15:0]~~
~~loop_count[7:0][7:0]~~
~~In addition:~~

~~loop_start [7:0] [7:0]~~
~~loop_step [7:0] [7:0]~~
~~Exist to give more control to the controlling program.~~

~~We will extend that in the R400 to:~~
Boolean[~~255~~256:0]
Loop_count[7:0][~~31:0~~31:0]
Loop_Start[7:0]~~ ~~[~~[31:0~~31:0]
Loop_Step[7:0]~~ ~~[~~31:~~31:0]
~~Loop_End[7:0] [31:0]~~

That is 256 Booleans and 32 loops.

We have a stack of 4 elements for nested call~~ings~~ of subroutines and 4 loop counters to allow for nested loops.

6.2 The Control Flow Program

~~The R300 uses a match method for control flow: The shader is executed, and at every instruction its address is compared with addresses (or address?) in a control table. The "event" in the control table can redirect operations in the program.~~
The basic model is as follows:

The render state defined the clause boundaries:
Vertex_shader_fetch[7:0][7:0] // eight 8 bit pointers to the location where each clauses control program is located
Vertex_shader_alu[7:0][7:0] // eight 8 bit pointers to the location where each clauses control program is located
Pixel_shader_fetch[7:0][7:0] // eight 8 bit pointers to the location where each clauses control program is located
Pixel_shader_alu[7:0][7:0] // eight 8 bit pointers to the location where each clauses control program is located

A pointer value of FF means that the clause doesn't contain any instructions.

The control program for a given clause is executed to completion before moving to another clause, (with the exception of the pick two nature of the alu execution). The control program is the only program aware of the clause boundaries.

~~The Method chosen for the R400 is a "control program".~~ The control program has ~~ten~~ eleven basic instructions:

Execute
Conditional_execute
Conditional_Execute_Predicates
Conditional_jump
Call
Return
Loop_start
Loop_end
End_of_clause
Conditional_End_of_clause
NOP

Execute, causes the specified number of instructions in instruction store to be executed.
Conditional_execute checks a condition first, and if true, causes the specified number of instructions in instruction store to be executed.
Loop_start resets the corresponding loop counter to the start value on the first pass after it checks for the end condition and if met jumps over to a specified address.
Loop_end increments (decrements?) the loop counter and jumps back the specified number of instructions.
Call jumps to an address and pushes the IP counter on the stack. On the return instruction, the IP is popped from the stack.
Conditional_execute_or_Jump executes a block of instructions or jumps to an address is the condition is not met.
Conditional_execute_Predicates executes a block of instructions if all bits in the predicate vectors meet the condition.
End_of_clause marks the end of a clause.

Conditional_End_of_clause marks the end of a clause if the condition is met.
Conditional_jumps jumps to an address if the condition is met.
NOP is a regular NOP

NOTE THAT ALL JUMPS MUST JUMP TO EVEN CFP ADDRESSES. Thus the compiler must insert NOPs where needed to align the jumps on even CFP addresses.

Also if the jump is logically bigger than pshader_cntl_size (or vshader_cntl_size) we break the program (clause) and set the debug registers. If an execute or conditional_execute is lower than cntl_size or bigger than size we also break the program (clause) and set the debug registers.

We have to fit instructions into 48 bits in order to be able to put two control flow instruction per line in the instruction store.

Note that whenever a field is marked as RESERVED, it is assumed that all the bits of the field are cleared (0).

Formatted

Execute				
47	46… 42	41 … 24	23 … 12	11 … 0
Addressing	00001	RESERVED	Instruction -count	Exec Address

Execute up to 4k instructions at the specified address in the instruction memory.

NOP		
47	46 … 42	41 … 0
Addressing	00010	RESERVED

This is a regular NOP.

Conditionnal_Execute							
47	46 … 42	41~~41 … 34~~	40 … 33	~~33~~32	~~32~~ 31 … 24	23 … 12	11 … 0
Addressing	00011	RESERVED ~~Boolean address~~	Boolean address	Condition	RESERVED	Instruction -count	Exec Address

If the specified boolean (8 bits can address 256 booleans) meets the specified condition then execute the specified instructions (up to 4k instructions)

Conditionnal_Execute_Predicates							
47	46 … 42	41 … 35	~~41~~ 34 … ~~38~~33	~~37~~32	~~36~~ 31 … 24	23 … 12	11 … 0
Addressing	00100	RESERVED	Predicate vector	Condition	RESERVED	Instruction- count	Exec Address

Check the AND/OR of all current predicate bits. If AND/OR matches the condition execute the specified number of instructions. We need to AND/OR this with the kill mask in order not to consider the pixels that aren't valid.

Loop_Start				
47	46 … 42	41 … 17	~~16 … 5~~16 … 12	~~4 … 0~~11 … 0
Addressing	00101	RESERVED	~~Jump address~~loop ID	~~Loop ID~~Jump address

Loop Start. Compares the loop count with the end value. If loop condition not met jump to the address. Forward jump only. Also computes the index value.

Loop_End				
47	46 … 42	41 … 17	16 … ~~5~~12	~~4 … 0~~11 … 0

Addressing	00111	RESERVED	~~Start address~~loop ID	~~Loop ID~~start address

Loop end. Increments the counter by one and jumps BACK only to the start of the loop.

The way this is described does not prevent nested loops, and the inclusion of the loop id make this easy to do.

Call			
47	46 … 42	41…12	11 … 0
Addressing	01000	RESERVED	Jump address~~Address~~

Jumps to the specified address and pushes the IP counter on the stack.

Return		
47	46 … 42	41 … 0
Addressing	01001	RESERVED

Pops the topmost address from the stack and jumps to that address. If nothing is on the stack, the program will just continue to the next instruction.

Conditionnal_Jump							
47	46 … 42	41~~41 … 34~~	40 … 33	~~33~~32	~~32 … 13~~31	~~12~~30 … 12	11 … 0
Addressing	01010	RESERVED ~~Boolean address~~	Boolean address	Condition	FW only~~RESERVED~~	RESERVED~~FW only~~	Jump address~~Address~~

If condition met, jumps to the address. FORWARD jump only allowed if bit ~~12~~ 31 set. Bit ~~12~~ 31 is only an optimization for the compiler and should NOT be exposed to the API.

Conditional_End_of_Clause					
47	46 … 42	41~~41 … 34~~	40 … 33	~~33~~32	~~32~~ 31 … 0
Addressing	01011	RESERVED ~~Boolean address~~	Boolean address	Condition	RESERVED

This is an optimization in the case of very short shaders (where the control flow instruction can't be hidden anymore and thus are not free. In this case, if the condition is met, the clause is ended, else we continue the execution of the clause.

End_of_Clause		
47	46 … 42	41 … 0
Addressing	01011	RESERVED

Marks the end of a clause.

To prevent infinite loops, we will keep 9 bits loop counters instead of 8 (we are only able to loop 256 times). If the counter goes higher than 255 then the loop_end or the loop_start instruction is going to break the loop and set the debug registers.

~~The basic model is as follows:~~

~~The render state defined the clause boundaries:~~
~~Vertex_shader_fetch[7:0][7:0] // eight 8 bit pointers to the location where each clauses control program is located~~
~~Vertex_shader_alu[7:0][7:0] // eight 8 bit pointers to the location where each clauses control program is located~~
~~Pixel_shader_fetch[7:0][7:0] // eight 8 bit pointers to the location where each clauses control program is located~~
~~Pixel_shader_alu[7:0][7:0] // eight 8 bit pointers to the location where each clauses control program is located~~

~~**A pointer value of FF means that the clause doesn't contain any instructions.**~~

~~The control program for a given clause is executed to completion before moving to another clause, (with the exception of the pick two nature of the alu execution). The control program is the only program aware of the clause boundaries.~~

6.3 Data dependant predicate instructions

Data dependant conditionals will be supported in the R400. The only way we plan to support those is by supporting three vector/scalar predicate operations of the form:

PRED_SETE_# - similar to SETE except that the result is 'exported' to the sequencer.
PRED_SETNE_# - similar to SETNE except that the result is 'exported' to the sequencer.
PRED_SETGT_# - similar to SETGT except that the result is 'exported' to the sequencer
PRED_SETGTE_# - similar to SETGTE except that the result is 'exported' to the sequencer

For the scalar operations only we will also support the two following instructions:
PRED_SETE0_# – SETE0
PRED_SETE1_# – SETE1

The export is a single bit - 1 or 0 that is sent using the same data path as the MOVA instruction. The sequencer will maintain 4 sets of 64 bit predicate vectors (in fact 8 sets because we interleave two programs but only 4 will be exposed) and use it to control the write masking. This predicate is not maintained across clause boundaries. The # sign is used to specify which predicate set you want to use 0 thru 3.

Then we have two conditional execute bits. The first bit is a conditional execute "on" bit and the second bit tells us if we execute on 1 or 0. For example, the instruction:

P0_ADD_# R0,R1,R2

Is only going to write the result of the ADD into those GPRs whose predicate bit is 0. Alternatively, P1_ADD_# would only write the results to the GPRs whose predicate bit is set. The use of the P0 or P1 without precharging the sequencer with a PRED instruction is undefined.

{Issue: do we have to have a NOP between PRED and the first instruction that uses a predicate?}

6.4 HW Detection of PV,PS

Because of the control program, the compiler cannot detect statically dependant instructions. In the case of non-masked writes and subsequent reads the sequencer will insert uses of PV,PS as needed. This will be done by comparing the read address and the write address of consecutive instructions. For masked writes, the sequencer will insert NOPs wherever there is a dependant read/write.

The sequencer will also have to insert NOPs between PRED_SET and MOVA instructions and their uses.

6.5 Register file indexing

Because we can have loops in fetch clause, we need to be able to index into the register file in order to retrieve the data created in a fetch clause loop and use it into an ALU clause. The instruction will include the base address for register indexing and the instruction will contain these controls:

Bit7	Bit 6	
0	0	'absolute register'
0	1	'relative register'
1	0	'previous vector'
1	1	'previous scalar'

In the case of an absolute register we just take the address as is. In the case of a relative register read we take the base address and we add to it the loop_index and this becomes our new address that we give to the shader pipe.

The sequencer is going to keep a loop index computed as such:

Index = Loop_counter*Loop_iterator + Loop_init.

The index is going to return 0 if it is out of the range.

6.6 Predicated Instruction support for Texture clauses

For texture clauses, we support the following optimization: we keep 1 bit (thus 4 bits for the four predicate vectors) per predicate vector in the reservation stations. A value of 1 means that one ore more elements in the vector have a value of one (thus we have to do the texture fetches for the whole vector. A value of 0 means that no elements in the vector have his predicate bit set and we can thus skip over the texture fetch. **We have to make sure the invalid pixels aren't considered with this optimization.**

6.7 Debugging the Shaders

In order to be able to debug the pixel/vertex shaders efficiently, we provide 2 methods.

6.7.1 *Method 1: Debugging registers*

Current plans are to expose 2 debugging, or error notification, registers:
1. address register where the first error occurred
2. count of the number of errors

The sequencer will detect the following groups of errors:
- count overflow
- jump error
  relative jump address > size of the control flow program
  relative jump address > length of the shader program
- constant overflow
- register overflow
- call stack
  call with stack full
  return with stack empty

With two of the errors, a jump error or a register overflow will cause the program to break. In this case, a break means that a clause will halt execution, but allowing further clauses to be executed.

With the other errors, program can continue to run, potentially to worst-case limits.

If indexing outside of the constant range, causing an overflow error, the hardware is specified to return the value with an index of 0. This could be exploited to generate error tokens, by reserving and initializing the 0th register (or constant) for errors.

{ISSUE : Interrupt to the driver or not?}

6.7.2 *Method 2: Exporting the values in the GPRs (12)*

The sequencer will have a count register and an address register for this mode and 3 bits per clause specifying the execution mode for each clause. The modes can be :

1) Normal
2) Debug Kill
3) Debug Addr + Count

Under the normal mode execution follows the normal course. Under the kill mode, all control flow instructions are executed but all normal shader instructions of the clause are replaced by NOPs. Only debug_export instructions of clause 7 will be executed under the debug kill setting. Under the other mode, normal execution is done until we reach an address specified by the address register and instruction count (useful for loops) specified by the count register. After we have hit the instruction n times (n=count) we switch the clause to the kill mode.

Under the debug mode (debug kill OR debug Addr + count), it is assumed that clause 7 is always exporting 12 debug vectors and that all other exports to the SX block (position, color, z, ect) will been turned off (changed into NOPs) by the sequencer (even if they occur before the address stated by the ADDR debug register).

7. Pixel Kill Mask

A vector of 64 bits is kept by the sequencer per group of pixels/vertices. Its purpose is to optimize the texture fetch requests and allow the shader pipe to kill pixels using the following instructions:

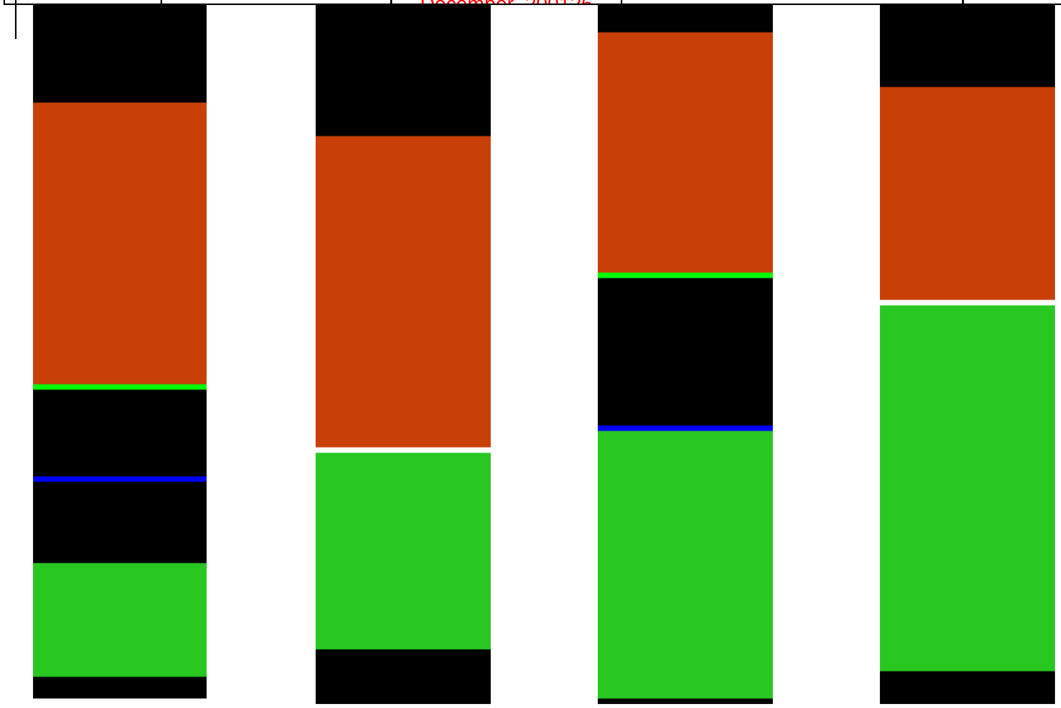
MASK_SETE
MASK_SETNE
MASK_SETGT
MASK_SETGTE

8. ~~HOS surfaces~~Multipass vertex shaders (HOS)

~~HOS~~Multipass vertex shaders~~ surfaces~~ are able to export from the 6 last clauses but to memory ONLY.~~ If they want to export to the parameter cache they have to do it in the last clause (7). They can also export position in clause 3.~~

9. Register file allocation

The register file allocation for vertices and pixels can either be static or dynamic. In both cases, the register file in managed using two round robins (one for pixels and one for vertices). In the dynamic case the boundary between pixels and vertices is allowed to move, in the static case it is fixed to VERTEX_REG_SIZE for vertices and 256-VERTEX_REG_SIZE for pixels.



Above is an example of how the algorithm works. Vertices come in from top to bottom; pixels come in from bottom to top. Vertices are in orange and pixels in green. The blue line is the tail of the vertices and the green line is the tail of the pixels. Thus anything between the two lines is shared. When pixels meets vertices the line turns white and the boundary is static until both vertices and pixels share the same “unallocated bubble”. Then the boundary is allowed to move again.

10. Fetch Arbitration

The fetch arbitration logic chooses one of the 8 potentially pending fetch clauses to be executed. The choice is made by looking at the fifos from 7 to 0 and picking the first one ready to execute. Once chosen, the clause state machine will send one 2x2 fetch per clock (or 4 fetches in one clock every 4 clocks) until all the fetch instructions of the clause are sent. This means that there cannot be any dependencies between two fetches of the same clause.

The arbitrator will not wait for the fetches to return prior to selecting another clause for execution. The fetch pipe will be able to handle up to X(?) in flight fetches and thus there can be a fair number of active clauses waiting for their fetch return data.

11. ALU Arbitration

ALU arbitration proceeds in almost the same way than fetch arbitration. The ALU arbitration logic chooses one of the 8 potentially pending ALU clauses to be executed. The choice is made by looking at the fifos from 7 to 0 and picking the first one ready to execute. There are two ALU arbitrers, one for the even clocks and one for the odd clocks. For exemple, here is the sequencing of two interleaved ALU clauses (E and O stands for Even and Odd sets of 4 clocks):

Einst0 Oinst0 Einst1 Oinst1 Einst2 Oinst2 Einst0 Oinst3 Einst1 Oinst4 Einst2 Oinst0…
Proceeding this way hides the latency of 8 clocks of the ALUs.

12. Handling Stalls

When the output file is full, the sequencer prevents the ALU arbitration logic to select the last clause (this way nothing can exit the shader pipe until there is place in the output file. If the packet is a vertex packet and the position buffer is full (POS_FULL) then the sequencer also prevents a thread to enter the exporting clause (3?). The sequencer will set the OUT_FILE_FULL signal n clocks before the output file is actually full and thus the ALU arbiter will be able read this signal and act accordingly by not preventing exporting clauses to proceed.

13. Content of the reservation station FIFOs

~~21~~ 3 bits of Render State 7 bits for the base address of the GPRs, some bits for LOD correction and coverage mask information in order to fetch fetch for only valid pixels, quad address and 1 bit to specify if the vector is of pixels or vertices. Since pixels and vertices are kept in order in the shader pipe, we only need two fifos (one for vertices and one for pixels) deep enough to cover the shader pipe latency. This size will be determined later when we will know the size of the small fifos between the reservation stations.

14. The Output File

The output file is where pixels are put before they go to the RBs. The write BW to this store is 256 bits/clock. Just before this output file are staging registers with write BW 512 bits/clock and read BW 256 bits/clock. The staging registers are 4x128 (and there are 16 of those on the whole chip).

15. IJ Format

The IJ information sent by the PA is of this format on a per quad basis:

We have a vector of IJ's (one IJ per pixel at the centroid of the fragment or at the center of the pixel depending on the mode bit). The interpolation is done at a different precision across the 2x2. The upper left pixel's parameters are always interpolated at full 20x24 mantissa precision. Then the result of the interpolation along with the difference in IJ in reduced precision is used to interpolate the parameter for the other three pixels of the 2x2. Here is how we do it:

Assuming P0 is the interpolated parameter at Pixel 0 having the barycentric coordinates I(0), J(0) and so on for P1,P2 and P3. Also assuming that A is the parameter value at V0 (interpolated with I), B is the parameter value at V1 (interpolated with J) and C is the parameter value at V2 (interpolated with (1-I-J).

$$\Delta 01I = I(1) - I(0)$$
$$\Delta 01J = J(1) - J(0)$$
$$\Delta 02I = I(2) - I(0)$$
$$\Delta 02J = J(2) - J(0)$$
$$\Delta 03I = I(3) - I(0)$$
$$\Delta 03J = J(3) - J(0)$$

P0	P1
P2	P3

$$P0 = C + I(0) * (A - C) + J(0) * (B - C)$$
$$P1 = P0 + \Delta 01I * (A - C) + \Delta 01J * (B - C)$$
$$P2 = P0 + \Delta 02I * (A - C) + \Delta 02J * (B - C)$$
$$P3 = P0 + \Delta 03I * (A - C) + \Delta 03J * (B - C)$$

P0 is computed at 20x24 mantissa precision and P1 to P3 are computed at 8X24 mantissa precision. So far no visual degradation of the image was seen using this scheme.

Multiplies (Full Precision): 2
Multiplies (Reduced precision): 6

Subtracts 19x24 (Parameters): 2
Adds: 8

FORMAT OF P0's IJ : Mantissa 20 Exp 4 for I + Sign
Mantissa 20 Exp 4 for J + Sign

FORMAT of Deltas (x3):Mantissa 8 Exp 4 for I + Sign
Mantissa 8 Exp 4 for J + Sign

Total number of bits : ~~19~~20*2 + ~~8*6 + 4*8 + 4*2~~8*6 + 4*8 + 4*2 = 128

The Deltas have a leading 1, the Full precision IJs don't. This means that in the case of the deltas we MUST be able to shift 8 right (exponent value of 0 means number = 0, exponent value of 1 means shift right 8~~8~~). This means that the maximum range for the IJs (Full precision) is +/- 63~~4~~ and the range for the Deltas is +/- 12~~8~~7.

15.1 Interpolation of constant attributes

Formatted: Bullets and Numbering

Because of the floating point imprecision, we need to take special provisions if all the interpolated terms are the same or if two of the barycentric coordinates are the same.

We start with the premise that if A = B and B = C and C = A, then P0,1,2,3 = A. Since one or more of the IJ terms may be zero, so we extend this to:

```
if (A=B and B=C and C=A)
   P0,1,2,3 = A;
else if ((I = 0) or (J = 0)) and
          ((J = 0) or (1-I-J = 0)) and
          ((1-J-I = 0) or (I = 0))) {
                if(I != 0) {
                    P0 = A;
                } else if(J != 0) {
                    P0 = B;
                } else {
                    P0 = C;
               }
             //rest of the quad interpolated normally
}
else
{
             normal interpolation
}
```

16. The parameter cache

The parameter cache is where the vertex shaders export their data. It consists of 16 128x128 memories (1R/1W). The reuse engine will make it so that all vertexes of a given primitive will hit different memories.

17. Vertex position exporting

On clause 3 the vertex shader can export to the PA both the vertex position and the point sprite. It can also do so at clause 7 if not done at clause 3. The storage needed to perform the position export is at least 64x128 memories for the position and 64x32 memories for the sprite size. It is going to be taken in the pixel output fifo from the SX blocks. The clause where the position export occurs is specified by the EXPORT_LATE register. If turned on, it means that the export is going to occur at ALU clause 7 if unset position export occurs at clause 3.

18. Exporting Arbitration

Here are the rules for co-issuing exporting ALU clauses.

1) Position exports and position exports cannot be co-issued.
2) Position exports and memory exports cannot be co-issued.
3) Position exports and Z/Color exports cannot be co-issued.
4) Memory exports and Z/Color exports cannot be co-issued.
5) Memory exports and memory exports cannot be co-issued.
6) Z/color exports and Z/color exports cannot be co-issued.
7) Parameter exports and Z/Color exports CAN be co-issued.
8) Parameter exports and parameter exports CAN be co-issued.
9) Parameter exports and memory exports CAN be co-issued.

Formatted: Bullets and Numbering

19. Export Types

The export type (or the location where the data should be put) is specified using the destination address field in the ALU instruction. Here is a list of all possible export modes:

Formatted: Bullets and Numbering

19.1 Vertex Shading

0:15	- 16 parameter cache
16:31	- Empty (Reserved?)
32:43	- 12 vertex exports to the frame buffer and index
44:47	- Empty
48:59	- 12 debug export (interpret as normal vertex export)
60	- export addressing mode
61	- Empty
62	- sprite size export that goes with position export (point_h,point_w,edgeflag,misc)
63	- position

Formatted: Bullets and Numbering

19.2 Pixel Shading

0	- Color for buffer 0 (primary)
1	- Color for buffer 1
2	- Color for buffer 2
3	- Color for buffer 3
4:7	- Empty
8	- Buffer 0 Color/Fog (primary)
9	- Buffer 1 Color/Fog
10	- Buffer 2 Color/Fog
11	- Buffer 3 Color/Fog
12:15	- Empty
16:31	- Empty (Reserved?)
32:43	- 12 exports for multipass pixel shaders.
44:47	- Empty
48:59	- 12 debug exports (interpret as normal pixel export)
60	- export addressing mode
61:62	- Empty
63	- Z for primary buffer (Z exported to 'alpha' component)

Formatted: Bullets and Numbering

~~19.~~20. Special Interpolation modes

~~19.1~~20.1 Real time commands

We are unable to use the parameter memory since there is no way for a command stream to write into it. Instead we need to add three 16x128 memories (one for each of three vertices x 16 interpolants). These will be mapped onto the register bus and written by type 0 packets, and output to the the parameter busses (the sequencer and/or PA need to be able to address the reatime parameter memory as well as the regular parameter store. For higher performance we should be able able to view them as two banks of 16 and do double buffering allowing one to be loaded, while the other is rasterized with. Most overlay shaders will need 2 or 4 scalar coordinates, one option might be to restrict the memory to 16x64 or 32x64 allowing only two interpolated scalars per cycle, the only problem I see with this is, if we view support for 16 vector-4 interpolants important (true only if we map Microsoft's high priority stream to the realtime stream), then the PA/sequencer need to support a realtime-specific mode where we need to address 32 vectors of parameters instead of 16. This mode is triggered by the primitive type: REAL TIME.

~~19.2~~20.2 Sprites/ XY screen coordinates/ FB information

Formatted: Bullets and Numbering

When working with sprites, one may want to overwrite the parameter 0 with SC generated data. Also, XY screen coordinates may be needed in the shader program. This functionality is controlled by the gen_I0 register (in SQ) in conjunction with the SND_XY register (in SC). Also it is possible to send the faceness information (for OGL front/back special operations) to the shader using the same control registers. Here is a list of all the modes and how they interact together:

Gen_st is a bit taken from the interface between the SC and the SQ. This is the MSB of the primitive type. If the bit is set, it means we are dealing with Point AA, Line AA or sprite and in this case the vertex values are going to ~~be read from the GEN_S and GEN_T state registers instead of being read from the parameter cache~~generated between 0 and 1.

Param_Gen_I0 disable, snd_xy disable, no gen_st – I0 = No modification
Param_Gen_I0 disable, snd_xy disable, gen_st – I0 = No modification
Param_Gen_I0 disable, snd_xy enable, no gen_st – I0 = No modification
Param_Gen_I0 disable, snd_xy enable, gen_st – I0 = No modification
Param_Gen_I0 enable, snd_xy disable, no gen_st – I0 = garbage, garbage, garbage, faceness
Param_Gen_I0 enable, snd_xy disable, gen_st – I0 = garbage, garbage, s, t
Param_Gen_I0 enable, snd_xy enable, no gen_st – I0 = screen x, screen y, garbage, faceness
Param_Gen_I0 enable, snd_xy enable, gen_st – I0 = screen x, screen y, s, t

20.3 Auto generated counters

Formatted: Bullets and Numbering

In the cases we are dealing with multipass shaders, the sequencer is going to generate a vector count to be able to both use this count to write the 1st pass data to memory and then use the count to retrieve the data on the 2nd pass. The count is always generated in the same way but it is passed to the shader in a slightly different way depending on the shader type (pixel or vertex). This is toggled on and off using the GEN_INDEX register. While there is only one count broadcast to the registers, the LSB are hardwired to specific values making the index different for all elements in the vector.

Formatted

Formatted

20.3.1 *Vertex shaders*

Formatted: Bullets and Numbering

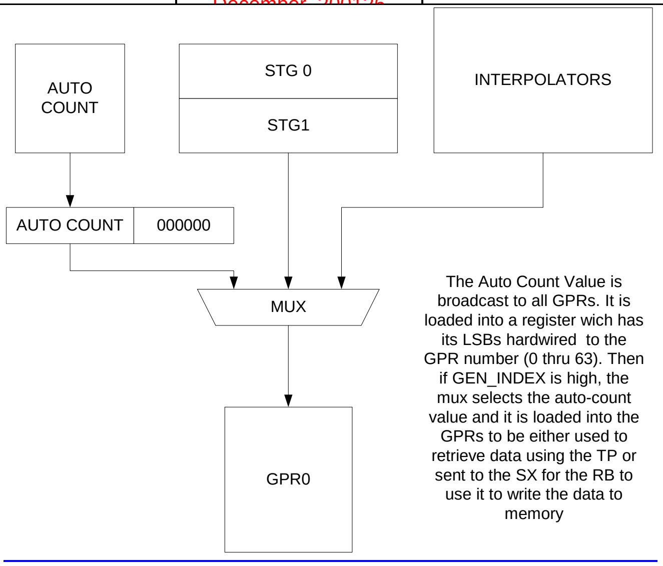
In the case of vertex shaders, if GEN_INDEX is set, the data will be put into the x field of the third register (it means that the compiler must allocate 3 GPRs in all multipass vertex shader modes).

20.3.2 *Pixel shaders*

Formatted: Bullets and Numbering

In the case of pixel shaders, if GEN_INDEX is set, the data will be put in the x field of the 2nd register (I1.x).

Formatted



The Auto Count Value is broadcast to all GPRs. It is loaded into a register wich has its LSBs hardwired to the GPR number (0 thru 63). Then if GEN_INDEX is high, the mux selects the auto-count value and it is loaded into the GPRs to be either used to retrieve data using the TP or sent to the SX for the RB to use it to write the data to memory

Formatted: Bullets and Numbering

~~20.~~21. State management

Every clock, the sequencer will report to the CP the oldest states still in the pipe. These are the states of the programs as they enter the last ALU clause.

Formatted: Bullets and Numbering

~~21.~~22. XY Address imports

The SC will be able to send the XY addresses to the GPRs. It does so by interleaving the writes of the IJs (to the IJ buffer) with XY writes (to the XY buffer). Then when writing the data to the GPRs, the sequencer is going to interpolate the IJ data or pass the XY data thru a Fix→float converter and expander and write the converted values to the GPRs. The Xys are currently SCREEN SPACE COORDINATES. The values in the XY buffers will wrap. See section 20.2~~19.2~~ for details on how to control the interpolation in this mode.

Formatted: Bullets and Numbering

22.1 Vertex indexes imports

In order to import vertex indexes, we have 64x2x96 staging registers. These are loaded one at a time by the VGT block. They are loaded in floating point format and can be transferred in 4 or 8 clocks to the GPRs.

Formatted: Bullets and Numbering

~~22.~~23. Registers

~~22.1~~23.1 Control

~~DYNAMIC_~~REG_DYNAMIC Dynamic allocation (pixel/vertex) of the register file on or off.
~~VERTEX_REG_SIZE What portion of the register file is reserved for vertices (static allocation only)~~
REG_SIZE_PIX~~PIXEL_MIN_SIZE~~ S~~Minimal s~~ize of the register file's pixel portion (minimal size when dynamic allocation turned on) ~~(dynamic only)~~
REG_SIZE_VTX ~~VERTEX_MIN_SIZE Minimal s~~Size of the register file's vertex portion (minimal size when dynamic allocation turned on) ~~(dynamic only)~~
ARBITRATION_~~policy~~POLICY policy of the arbitration between vertexes and pixels
INST_STORE_ALLOC interleaved, separate
~~VERTEX_BASE~~INST_BASE_VTX start point for the vertex instruction store (RT always ends at vertex_base and

Begins at 0)

~~PIXEL_BASE~~INST_BASE_PIX start point for the pixel shader instruction store

~~NO_INTERLEAVE~~ONE_THREAD debug state register. Only allows one program at a time into the GPRs

~~NO_INTERLEAVE_ALU~~ONE_ALU debug state register. Only allows one ALU program at a time to be executed (instead of 2)

INSTRUCTION_INDEX_PORT This is where the CP puts the base address of the instruction writes and type (auto-incremented on reads/writes)

INSTRUCTION_DATA This is where the CP puts the actual data going to the instruction memory

CONSTANT_DATA This is where the CP puts constant data (32 bits)

CONSTANT_ADDR This is where the CP puts the logical constant address (9 bits)

INSTRUCTION_INDEX_PORT_RT This is where the CP puts the base address of the instruction writes and type for Real Time (auto-incremented on reads/writes)

INSTRUCTION_DATA_RT This is where the CP puts the actual data going to the instruction memory for Real Time

CONSTANT_DATA_RT This is where the CP puts constant data for Real Time (32 bits)

CONSTANT_ADDR_RT This is where the CP puts the logical constant address for Real Time (9 bits)

CONSTANT_EO_RT This is the size of the space reserved for real time in the constant store (from 0 to CONSTANT_EO_RT). The remaping table operates on the rest of the memory

EXPORT_LATE Controls whether or not we are exporting position from clause 3. If set, position exports occur at clause 7.

Formatted

~~22.2~~23.2 Context

Formatted: Bullets and Numbering

~~Vshader_fetch[7:0][7:0]~~VS_FETCH_{0…7} eight 8 bit pointers to the location where each clauses control program is located

~~Vshader_alu[7:0][7:0]~~VS_ALU_{0…7} eight 8 bit pointers to the location where each clauses control program is located

PS_FETCH_{0…7} ~~Pshader_fetch[7:0][7:0]~~ eight 8 bit pointers to the location where each clauses control program is located

PS_ALU_{0…7} ~~Pshader_alu[7:0][7:0]~~ eight 8 bit pointers to the location where each clauses control program is located

~~PSHADER~~PS_BASE base pointer for the pixel shader in the instruction store

~~VSHADER~~VS_BASE base pointer for the vertex shader in the instruction store

~~Vshader_cntl_size~~VS_CF_SIZE size of the vertex shader (# of instructions in control program/2)

~~Pshader_cntl_size~~PS_CF_SIZE size of the pixel shader (# of instructions in control program/2)

~~Pshader_size~~PS_SIZE size of the pixel shader (cntl+instructions)

~~Vshader_size~~VS_SIZE size of the vertex shader (cntl+instructions)

~~REG_ALLOC_PIX~~PS_NUM_REG number of registers to allocate for pixel shader programs

~~REG_ALLOC_VERT~~VS_NUM_REG number of registers to allocate for vertex shader programs

~~FLAT_GOUR[0…15]~~PARAM_SHADE One 16 bit register specifying which parameters are to be gouraud shaded (0 = flat, 1 = gouraud)

~~CYL_WRAP[0…63]~~ PARAM_WRAP 64 bits: for which parameters (and channels (xyzw)) do we do the cyl wrapping (0=linear, 1=cylindrical).

~~P_export_mode~~PS_EXPORT_MODE 0xxxx : Normal mode
1xxxx : Multipass mode
If normal, bbbz where bbb is how many colors (0-4) and z is export z or not
If multipass 1-12 exports for color.

~~vshader_export_mask~~VS_EXPORT_MASK which of the last 6 ALU clauses is exporting (multipass only)

~~vshader_export_mode~~VS_EXPORT_MODE 0: position (1 vector), 1: position (2 vectors), 3:multipass

~~vshader_export_count[6]~~VS_EXPORT_COUNT_{0…6} Six 4 bit counters representing the ~~#~~# of interpolated parameters exported in clause 7 (located in VS_EXPORT_COUNT_6) OR
# of exported vectors to memory per clause in multipass mode (per clause)

~~Control_Flow~~ ~~24 Dwords that contain the control flow constants.~~

PARAM_~~GEN_T~~ ~~Max Value interpolated in the T coordinate field (sprites)~~

~~GEN_S~~ ~~Max Value interpolated in the S coordinate field (sprites)~~

GEN_I0 Do we overwrite or not the parameter 0 with XY data and generated T and S values
GEN_INDEX Auto generates an address from 0 to XX. Puts the results into R1 for pixel shaders and R3 for vertex shaders
CONST_BASE_VTX~~VTX_CST_BASE~~ (9 bits) Logical Base address for the constants of the Vertex shader
~~PIX_CST_BASE~~CONST_BASE_PIX (9 bits) Logical Base address for the constants of the Pixel shader
~~PIX_CST_SIZE~~CONST_SIZE_PIX (8 bits) Size of the logical constant store for pixel shaders
~~VTX_CST_SIZE~~CONST_SIZE_VTX (8 bits) Size of the logical constant store for vertex shaders
INST_PRED_OPTIMIZE Turns on the predicate bit optimization (if of, conditional_execute_predicates is always executed).
CF_BOOLEANS 256 boolean bits
CF_LOOP_COUNT 32x8 bit counters (number of times we traverse the loop)
CF_LOOP_START 32x8 bit counters (init value used in index computation)
CF_LOOP_STEP 32x8 bit counters (step value used in index computation)

Formatted: Bullets and Numbering

~~23.~~24. DEBUG registers

~~23.1~~24.1 Context

DB_PROB_ADDR instruction address where the first problem occurred
DB_PROB_COUNT number of problems encountered during the execution of the program
~~Count~~DB_INST_COUNT instruction counter for debug method 2
~~Addr~~DB_BREAK_ADDR break address for method number 2
DB_CLAUSE_MODE_ALU_{0…7}~~Clause_mode[3]~~ clause mode for debug method 2 (0: normal, 1: addr, 2: kill)
DB_CLAUSE_MODE_FETCH_{0…7} clause mode for debug method 2 (0: normal, 1: addr, 2: kill)

~~NO_PRED_OPTIMIZE turns off the predicate bit optimization (conditional_execute_predicates is always executed.~~

Formatted: Bullets and Numbering

~~24.~~25. Interfaces

~~24.1~~25.1 External Interfaces

Whenever an x is used, it means that the bus is broadcast to all units of the same name. For example, if a bus is named SQ→SPx it means that SQ is going to broadcast the same information to all SP instances.

Formatted: Bullets and Numbering

~~24.1.1~~25.1.1 *SC to SP : IJ bus*

This is a bus that sends the IJ information to the IJ fifos on the top of each shader pipe. At the same time the control information goes to the sequencer. There are 4 of these buses over the whole chip (SP0 thru 3)

Name	Direction	Bits	Description
SC_SP0_data	SC→SP0	64	IJ information sent over 2 clocks (or XY info sent over 1 clock in the lower 24 LSBs of the interface)
SC_SP0_q_wr_mask	SC→SP0	1	Write Mask
SC_SP0_dest	SC→SP0	1	Controls the write destination (XY buffer, IJ buffer)
SC_SP1_data	SC→SP1	64	IJ information sent over 2 clocks (or XY info sent over 1 clock in the lower 24 LSBs of the interface)
SC_SP1_q_wr_mask	SC→SP1	1	Write Mask
SC_SP1_dest	SC→SP1	1	Controls the write destination (XY buffer, IJ buffer)
SC_SP2_data	SC→SP2	64	IJ information sent over 2 clocks (or XY info sent over 1 clock in the lower 24 LSBs of the interface)
SC_SP2_q_wr_mask	SC→SP2	1	Write Mask
SC_SP2_dest	SC→SP2	1	Controls the write destination (XY buffer, IJ buffer)
SC_SP3_data	SC→SP3	64	IJ information sent over 2 clocks (or XY info sent over 1 clock in the lower 24 LSBs of the interface)
SC_SP3_q_wr_mask	SC→SP3	1	Write Mask
SC_SP3_dest	SC→SP3	1	Controls the write destination (XY buffer, IJ buffer)

~~24.1.2~~25.1.2 SC to S~~E~~Q : IJ Control bus

Formatted: Bullets and Numbering

This is the control information sent to the sequencer in order to control the IJ fifos and all other information needed to execute a shader program on the sent pixels. This information is sent over 2 clocks, if SENDXY is asserted the next control packet is going to be ignored and XY information is going to be sent on the IJ bus (for the quads that where just sent).

Name	Direction	Bits	Description
SC_SQ_q_wr_mask	SC→SQ	4	Quad Write mask left to right
SC_SQ_lod_correct	SC→SQ	24	LOD correction per quad (6 bits per quad)
SC_SQ_flat_vertex	SC→SQ	2	Provoking vertex for flat shading
SC_SQ_param_ptr0	SC→SQ	11	P Store pointer for vertex 0
SC_SQ_param_ptr1	SC→SQ	11	P Store pointer for vertex 1
SC_SQ_param_ptr2	SC→SQ	11	P Store pointer for vertex 2
SC_SQ_end_of_vect	SC→SQ	1	End of the vector
SC_SQ_store_dealloc	SC→SQ	1	Deallocation token for the P Store
SC_SQ_state	SC→SQ	3	State/constant pointer (6*3+3)
SC_SQ_valid_pixel	SC→SQ	16	Valid bits for all pixels
SC_SQ_null_prim	SC→SQ	1	Null Primitive (for PC deallocation purposes)
SC_SQ_end_of_prim	SC→SQ	1	End Of the primitive
SC_SQ_fbface	SC→SQ	1	Front face = 1, back face = 0
SC_SQ_send_xy	SC→SQ	1	Sending XY information [XY information is going to be sent on the next clock]
SC_SQ_prim_type	SC→SQ	3	Real time command need to load tex cords from alternate buffer. Line AA, Point AA and Sprite reads their parameters from GEN_T and GEN_S registers. 000 : Normal 011 : Real Time 100 : Line AA 101 : Point AA 110 : Sprite
SC_SQ_new_vector	SC→SQ	1	This primitive comes from a new vector of vertices. Make sure that the corresponding vertex shader has finished before starting the group of pixels.
SC_SQ_RTRn	SQ→SC	1	Stalls the PA in n clocks
SC_SQ_RTS	SC→SQ	1	SC ready to send data

~~24.1.3~~25.1.3 SQ to SP: Interpolator bus

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
SQ_SPx_interp_prim_type	SQ→SPx	3	Type of the primitive 000 : Normal 011 : Real Time 100 : Line AA 101 : Point AA 110 : Sprite
SQ_SPx_interp_flat_vtx	SQ→SPx	2	Provoking vertex for flat shading
SQ_SPx_interp_flat_gouraud	SQ→SPx	1	Flat or gouraud shading
SQ_SPx_interp_cyl_wrap	SQ→SPx	4	Wich parameter needs to be cylindrical wrapped
SQ_SPx_interp_ijline	SQ→SPx	2	Line in the IJ/XY buffer to use to interpolate
SQ_SPx_interp_buff_swap	SQ→SPx	1	Swap the IJ/XY buffers at the end of the interpolation
SQ_SPx_interp_gen_I0	SQ→SPx	1	Generate I0 or not. This tells the interpolators not to use the parameter cache but rather overwrite the data with interpolated 1 and 0. Overwrite if gen_I0 is high.

25.1.4 SQ to SP: GPR Input Mux select

Formatted: Bullets and Numbering

This interface is synchronized with the Interpolator bus. This controls the input mux to the GPRs. The three types of data are: generated index, Interpolated data, vertex index data (coming from the staging registers).

Name	Direction	Bits	Description
SQ_SPx_data_type	SQ→SPx	2	00: Interpolated data 01: Staging register data 1x: Count
SQ_SPx_index_count	SQ→SPx	12?	Index count, common for all shader pipes
SQ_SPx_stage_addr	SQ→SPx	1	Staging register address 0: First staging register 1: second staging register

Formatted

Formatted

Formatted

Formatted

25.1.5 SQ to SPx: Parameter cache write control

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
SQ_SPx_pc_wr_addr	SQ→SPx	7	Write address
SQ_SPx_pc_we_addr	SQ→SPx	1	Write Enable
SQ_SPx_pc_phase_mux	SQ→SPx	1	The output selector mux (gpr vs parameter cache)

~~24.1.4~~25.1.6 SQ to SP: Parameter Cache Read control bus

Formatted: Bullets and Numbering

The four following interfaces (SQ→SP, SQ→SX,SP→SX and SX→Interpolators) are all SYNCHRONIZED together.

Name	Direction	Bits	Description
SQ_SPx_ptr0	SQ→SPx	9	Pointer of PC
SQ_SPx_ptr1	SQ→SPx	9	Pointer of PC
SQ_SPx_ptr2	SQ→SPx	9	Pointer of PC
SQ_SP0_read_ena	SQ→SP0	4	Read enables for the 4 memories in the SP0
SQ_SP1_read_ena	SQ→SP1	4	Read enables for the 4 memories in the SP1
SQ_SP2_read_ena	SQ→SP2	4	Read enables for the 4 memories in the SP2
SQ_SP3_read_ena	SQ→SP3	4	Read enables for the 4 memories in the SP3

~~24.1.5~~25.1.7 SQ to SX: Parameter Cache Mux control Bus

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
SQ_SXx_mux0	SQ→SXx	4	Mux control for PC (4 MSbs of Pointer)
SQ_SXx_mux1	SQ→SXx	4	Mux control for PC (4 MSbs of Pointer)
SQ_SXx_mux2	SQ→SXx	4	Mux control for PC (4 MSbs of Pointer)

~~24.1.6~~25.1.8 SP to SX: Parameter data

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
SP0_SX0_data0	SP0→SX0	128	Parameter data 0
SP0_SX0_data1	SP0→SX0	128	Parameter data 1
SP0_SX0_data2	SP0→SX0	128	Parameter data 2
SP0_SX0_data3	SP0→SX0	128	Parameter data 3
SP1_SX1_data0	SP1→SX1	128	Parameter data 0
SP1_SX1_data1	SP1→SX1	128	Parameter data 1
SP1_SX1_data2	SP1→SX1	128	Parameter data 2
SP1_SX1_data3	SP1→SX1	128	Parameter data 3
SP2_SX0_data0	SP2→SX0	128	Parameter data 0
SP2_SX0_data1	SP2→SX0	128	Parameter data 1
SP2_SX0_data2	SP2→SX0	128	Parameter data 2
SP2_SX0_data3	SP2→SX0	128	Parameter data 3
SP3_SX1_data0	SP3→SX1	128	Parameter data 0
SP3_SX1_data1	SP3→SX1	128	Parameter data 1
SP3_SX1_data2	SP3→SX1	128	Parameter data 2

SP3_SX1_data3	SP3→SX1	128	Parameter data 3

~~24.1.7~~25.1.9 *SX to Interpolators: Parameter Cache Return bus*

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
SXx_SPx_vtx_data_0	SXx→SPx	128	Vertex data to interpolate
SXx_SPx_vtx_data_1	SXx→SPx	128	Vertex data to interpolate
SXx_SPx_vtx_data_2	SXx→SPx	128	Vertex data to interpolate

25.1.10 *SQ to SP0: Staging Register Data*

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
SQ_SP0_vgt_vsisr_data	SQ→SP0	96	Pointers of indexes or HOS surface information
SQ_SP0_vgt_vsisr_double	SQ→SP0	1	0: Normal 96 bits per vert 1: double 192 bits per vert
SQ_SP0_data_valid	SQ→SP0	1	Data is valid

25.1.11 *PA to SQ : Vertex interface*

Formatted: Bullets and Numbering

25.1.11.1 Interface Signal Table

The area difference between the two methods is not sufficient to warrant complicating the interface or the state requirements of the VSISRs. **Therefore, the POR for this interface is that the VGT will transmit the data to the VSISRs (via the Shader Sequencer) in full, 32-bit floating-point format.** The VGT can transmit up to six 32-bit floating-point values to each VSISR where four or more values require two transmission clocks. The data bus is 96 bits wide.

Name	Bits	Description
PA_SQ_vgt_vsisr_data	96	Pointers of indexes or HOS surface information
PA_SQ_vgt_vsisr_double	1	0: Normal 96 bits per vert 1: double 192 bits per vert
PA_SQ_vgt_end_of_vector	1	Indicates the last VSISR data set for the current process vector (for double vector data, "end_of_vector" is set on the second vector)
PA_SQ_vgt_state	3	Render State (6*3+3 for constants). This signal is guaranteed to be correct when "PA_SQ_vgt_end_of_vector" is high.
PA_SQ_vgt_send	1	Data on the VGT_SQ is valid receive (see write-up for standard R400 SEND/RTR interface handshaking)
SQ_PA_vgt_rtr	1	Ready to receive (see write-up for standard R400 SEND/RTR interface handshaking)

~~24.1.8 VGT to SP0/SQ : Vertex Bus~~

~~24.1.9~~

Formatted: Bullets and Numbering

~~24.1.10~~25.1.12 S~~E~~Q to CP: State report

Name	Direction	Bits	Description
SQ_CP_vrtx_ state	SEQ→CP	3	Oldest vertex state still in the pipe
SQ_CP_pix_state	SEQ→CP	3	Oldest pixel state still in the pipe

~~24.1.10~~25.1.13 SP to SX : Pixel/Vertex write to SX

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
SP0_SX0_Export_data	SP0→SX0	256	4 pairs of 32 bits channel values
SP0_SX0_Shader_Dest	SP0→SX0	4	Specifies one of the of up to 12 export destinations
SP1_SX1_Export_data	SP1→SX1	256	4 pairs of 32 bits channel values
SP1_SX1_Shader_Dest	SP1→SX1	4	Specifies one of the of up to 12 export destinations
SP2_SX0_Export_data	SP2→SX0	256	4 pairs of 32 bits channel values
SP2_SX0_Shader_Dest	SP2→SX0	4	Specifies one of the of up to 12 export destinations
SP3_SX1_Export_data	SP3→SX1	256	4 pairs of 32 bits channel values
SP3_SX1_Shader_Dest	SP3→SX1	4	Specifies one of the of up to 12 export destinations
SPx_SXx_Shader_Count	SP0→SX0	3	Each set of four pixels or vectors is exported over eight clocks. This field specifies where the SP is in that sequence.
SPx_SXx_Shader_Last	SP0→SX0	1	Asserted on the first shader count of the last export of the clause
SP0_SX0_Shader_PixelValid	SP0→SX0	4	Result of pixel kill in the shader pipe, which must be output for all pixel exports (depth and all color buffers). 4x4 because 16 pixels are computed per clock
SP0_SX0_Shader_WordValid	SP0→SX0	2	Specifies whether to write low and/or high 32-bit word of the 64-bit export data from each of the 16 pixels or vectors
SP1_SX1_Shader_PixelValid	SP1→SX1	4	Result of pixel kill in the shader pipe, which must be output for all pixel exports (depth and all color buffers). 4x4 because 16 pixels are computed per clock
SP1_SX1_Shader_WordValid	SP1→SX1	2	Specifies whether to write low and/or high 32-bit word of the 64-bit export data from each of the 16 pixels or vectors
SP2_SX0_Shader_PixelValid	SP2→SX0	4	Result of pixel kill in the shader pipe, which must be output for all pixel exports (depth and all color buffers). 4x4 because 16 pixels are computed per clock
SP2_SX0_Shader_WordValid	SP2→SX0	2	Specifies whether to write low and/or high 32-bit word of the 64-bit export data from each of the 16 pixels or vectors
SP3_SX1_Shader_PixelValid	SP3→SX1	4	Result of pixel kill in the shader pipe, which must be output for all pixel exports (depth and all color buffers). 4x4 because 16 pixels are computed per clock
SP3_SX1_Shader_WordValid	SP3→SX1	2	Specifies whether to write low and/or high 32-bit word of the 64-bit export data from each of the 16 pixels or vectors

~~24.1.11~~25.1.14 SQ to SX: Control bus

Formatted: Bullets and Numbering

Name	Direction	Bits	Description

SQ_SXx_exp_Pixel	SQ→SXx	1	1: Pixel 0: Vertex
SQ_SXx_exp_start	SQ→SXx	1	Raised to indicate that the SQ is starting an export
SQ_SXx_exp_Clause	SQ→SXx	3	Clause number, which is needed for vertex clauses
SQ_SXx_exp_State	SQ→SXx	3	State ID, which is needed for vertex clauses

These fields are sent synchronously with SP export data, described in SP0→SX0 interface
{ISSUE: Where are the PC pointers}

~~24.1.12~~25.1.15 *SX to SQ : Output file control*

Formatted: Bullets and Numbering

Name	**Direction**	**Bits**	**Description**
SXx_SQ_Export_count_rdy	SXx→SQ	1	Raised by SX0 to indicate that the following two fields reflect the result of the most recent export
SXx_SQ_Export_Position	SXx→SQ	1	Specifies whether there is room for another position.
SXx_SQ_Export_Buffer	SXx→SQ	7	Specifies the space available in the output buffers. 0: buffers are full 1: 2K-bits available (32-bits for each of the 64 pixels in a clause) ... 64: 128K-bits available (16 128-bit entries for each of 64 pixels) 65-127: RESERVED

~~24.1.13~~25.1.16 *Shader Engine to Fetch Unit Bus*

Formatted: Bullets and Numbering

Four quad's worth of addresses is transferred to Fetch Unit every clock. These are sourced from a different pixel within each of the sub-engines repeating every 4 clocks. The register file index to read must precede the data by 2 clocks. The Read address associated with Quad 0 must be sent 1 clock after the Instruction Start signal is sent, so that data is read 3 clocks after the Instruction Start.

Four Quad's worth of Fetch Data may be written to the Register file every clock. These are directed to a different pixel of the sub-engines repeating every 4 clocks. The register file index to write must accompany the data. Data and Index associated with the Quad 0 must be sent 3 clocks after the Instruction Start signal is sent.

Name	**Direction**	**Bits**	**Description**
SP0_TP0_fetch_addr	SP0->TP0	512	4 Fetch Addresses read from the Register file
TP0_SP0_data	TP0→SP0	512	4 texture results
SP1_TP1_fetch_addr	SP1->TP1	512	4 Fetch Addresses read from the Register file
TP1_SP1_data	TP1→SP1	512	4 texture results
SP2_TP2_fetch_addr	SP2->TP2	512	4 Fetch Addresses read from the Register file
TP2_SP2_data	TP2→SP2	512	4 texture results
SP3_TP3_fetch_addr	SP3->TP3	512	4 Fetch Addresses read from the Register file
TP3_SP3_data	TP3→SP3	512	4 texture results
TPx_SPx_gpr_dst	TPx→SPx	7	Write address into the gprs
TPx_SPx_gpr_cmask	TPx→SPx	4	Channel mask

~~24.1.14~~25.1.17 *Sequencer to Fetch Unit bus*

Formatted: Bullets and Numbering

Once every clock, the fetch unit sends to the sequencer on which clause it is now working and if the data in the registers is ready or not. This way the sequencer can update the fetch counters for the reservation station fifos. The sequencer also provides the instruction and constants for the fetch to execute and the address in the register file where to write the fetch return data.

Name	**Direction**	**Bits**	**Description**
TPx_SQ_data_rdy	TPx→ SQ	1	Data ready
TPx_SQ_clause_num	TPx→ SQ	3	Clause number
SQ_TPx_const	SQ→TPx	64	Fetch state sent over 4 clocks
SQ_TPx_instuct	SQ→TPx	24	Fetch instruction sent over 4 clocks
SQ_TPx_end_of_clause	SQ→TPx	1	Last instruction of the clause

SQ_TPx_phase	SQ→TPx	2	Write phase signal
SQ_TP0_lod_correct	SQ→TP0	6	LOD correct 3 bits per comp 2 components per quad
SQ_TP0_pmask	SQ→TP0	4	Pixel mask 1 bit per pixel
SQ_TP1_lod_correct	SQ→TP1	6	LOD correct 3 bits per comp 2 components per quad
SQ_TP1_pmask	SQ→TP1	4	Pixel mask 1 bit per pixel
SQ_TP2_lod_correct	SQ→TP2	6	LOD correct 3 bits per comp 2 components per quad
SQ_TP2_pmask	SQ→TP2	4	Pixel mask 1 bit per pixel
SQ_TP3_lod_correct	SQ→TP3	6	LOD correct 3 bits per comp 2 components per quad
SQ_TP3_pmask	SQ→TP3	4	Pixel mask 1 bit per pixel
SQ_TPx_clause_num	SQ→TPx	3	Clause number
SQ_TPx_write_gpr_index	SQ->TPx	7	Index into Register file for write of returned Fetch Data

~~24.1.15~~25.1.18 *Sequencer to SP: GPR control*

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
SQ_SPx_gpr_wr_addr	SQ→SPx	7	Write address
SQ_SPx_gpr_rd_addr	SQ→SPx	7	Read address
SQ_SPx_gpr_re_addr	SQ→SPx	1	Read Enable
SQ_SPx_gpr_we_addr	SQ→SPx	1	Write Enable
SQ_SPx_gpr_phase_mux	SQ→SPx	2	The phase mux
SQ_SPx_gpr_channel_mask	SQ→SPx	4	The channel mask
SQ_SP0_gpr_pixel_mask	SQ→SP0	4	The pixel mask
SQ_SP1_gpr_pixel_mask	SQ→SP1	4	The pixel mask
SQ_SP2_gpr_pixel_mask	SQ→SP2	4	The pixel mask
SQ_SP3_gpr_pixel_mask	SQ→SP3	4	The pixel mask

~~24.1.16 *Sequencer to SPx: Parameter cache write control*~~

Formatted: Bullets and Numbering

~~24.1.17~~25.1.19 *Sequencer to SPx: Instructions*

Name	Direction	Bits	Description
SQ_SPx_instruct_start	SQ→SPx	1	Instruction start
SQ_SP_instruct	SQ→SPx	20	Instruction sent over 4 clocks
SQ_SPx_stall	SQ→SPx	1	Stall signal
SQ_SPx_Shader_Count	SQ→SPx	3	Each set of four pixels or vectors is exported over eight clocks. This field specifies where the SP is in that sequence.
SQ_SPx_Shader_Last	SQ→SPx	1	Asserted on the first shader count of the last export of the clause
SQ_SP0_Shader_PixelValid	SQ→SP0	4	Result of pixel kill in the shader pipe, which must be output for all pixel exports (depth and all color buffers). 4x4 because 16 pixels are computed per clock
SQ_SP0_Shader_WordValid	SQ→SP0	2	Specifies whether to write low and/or high 32-bit word of the 64-bit export data from each of the 16 pixels or vectors
SQ_SP1_Shader_PixelValid	SQ→SP1	4	Result of pixel kill in the shader pipe, which must be output for all pixel exports (depth and all color buffers). 4x4 because 16 pixels are computed per clock
SQ_SP1_Shader_WordValid	SQ→SP1	2	Specifies whether to write low and/or high 32-bit word of the 64-bit export data from each of the 16 pixels or vectors
SQ_SP2_Shader_PixelValid	SQ→SP2	4	Result of pixel kill in the shader pipe, which must be output for all pixel exports (depth and all color buffers). 4x4 because 16 pixels are computed per clock
SQ_SP2_Shader_WordValid	SQ→SP2	2	Specifies whether to write low and/or high 32-bit word of the 64-bit export data from each of the 16

			pixels or vectors
SQ_SP3_Shader_PixelValid	SQ→SP3	4	Result of pixel kill in the shader pipe, which must be output for all pixel exports (depth and all color buffers). 4x4 because 16 pixels are computed per clock
SQ_SP3_Shader_WordValid	SQ→SP3	2	Specifies whether to write low and/or high 32-bit word of the 64-bit export data from each of the 16 pixels or vectors

~~24.1.18~~25.1.20 *SP to Sequencer: Constant address load*

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
SP0_SQ_const_addr	SP0→SQ	36	Constant address load to the sequencer
SP0_SQ_valid	SP0→SQ	1	Data valid
SP1_SQ_const_addr	SP1→SQ	36	Constant address load to the sequencer
SP1_SQ_valid	SP1→SQ	1	Data valid
SP2_SQ_const_addr	SP2→SQ	36	Constant address load to the sequencer
SP2_SQ_valid	SP2→SQ	1	Data valid
SP3_SQ_const_addr	SP3→SQ	36	Constant address load to the sequencer
SP3_SQ_valid	SP3→SQ	1	Data valid

~~24.1.19~~25.1.21 *Sequencer to SPx: constant broadcast*

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
SQ_SPx_constant	SQ→SPx	128	Constant broadcast

~~24.1.20~~25.1.22 *SP0 to Sequencer: Kill vector load*

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
SP0_SQ_kill_vect	SP0→SQ	4	Kill vector load
SP1_SQ_kill_vect	SP1→SQ	4	Kill vector load
SP2_SQ_kill_vect	SP2→SQ	4	Kill vector load
SP3_SQ_kill_vect	SP3→SQ	4	Kill vector load

~~24.1.21~~25.1.23 *SQ to CP: RBBM bus*

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
SQ_RBB_rs	SQ→CP	1	Read Strobe
SQ_RBB_rd	SQ→CP	32	Read Data
SQ_RBBM_nrtrtr	SQ→CP	1	Optional
SQ_RBBM_rtr	SQ→CP	1	Real-Time (Optional)

~~24.1.22~~25.1.24 *CP to SQ: RBBM bus*

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
rbbm_we	CP→SQ	1	Write Enable
rbbm_a	CP→SQ	18	Address -- Upper Extent is TBD
rbbm_wd	CP→SQ	32	Data
rbbm_be	CP→SQ	4	Byte Enables
rbbm_re	CP→SQ	1	Read Enable
rbb_rs0	CP→SQ	1	Read Return Strobe 0
rbb_rs1	CP→SQ	1	Read Return Strobe 1
rbb_rd0	CP→SQ	32	Read Data 0
rbb_rd1	CP→SQ	32	Read Data 0
RBBM_SQ_soft_reset	CP→SQ	1	Soft Reset

Formatted: Bullets and Numbering

~~25.~~26. Examples of program executions

~~25.1.1~~26.1.1 *Sequencer Control of a Vector of Vertices*

1. PA sends a vector of 64 vertices (actually vertex indices – 32 bits/index for 2048 bit total) to the RE's Vertex FIFO
   - state pointer as well as tag into position cache is sent along with vertices
   - space was allocated in the position cache for transformed position before the vector was sent
   - **also before the vector is sent to the RE, the CP has loaded the global instruction store with the vertex shader program (using the MH?)**
   - The vertex program is assumed to be loaded when we receive the vertex vector.
     - the SEQ then accesses the IS base for this shader using the local state pointer (provided to all sequencers by the RBBM when the CP is done loading the program)
2. SEQ arbitrates between the Pixel FIFO and the Vertex FIFO – basically the Vertex FIFO always has priority
   - at this point the vector is removed from the Vertex FIFO
   - the arbiter is not going to select a vector to be transformed if the parameter cache is full unless the pipe as nothing else to do (ie no pixels are in the pixel fifo).
3. SEQ allocates space in the SP register file for index data plus GPRs used by the program
   - the number of GPRs required by the program is stored in a local state register, which is accessed using the state pointer that came down with the vertices
   - SEQ will not send vertex data until space in the register file has been allocated
4. SEQ sends the vector to the SP register file over the RE_SP interface (which has a bandwidth of 2048 bits/cycle)
   - the 64 vertex indices are sent to the 64 register files over 4 cycles
     - RF0 of SU0, SU1, SU2, and SU3 is written the first cycle
     - RF1 of SU0, SU1, SU2, and SU3 is written the second cycle
     - RF2 of SU0, SU1, SU2, and SU3 is written the third cycle
     - RF3 of SU0, SU1, SU2, and SU3 is written the fourth cycle
   - the index is written to the least significant 32 bits **(floating point format?) (what about compound indices)** of the 128-bit location within the register file (w); the remaining data bits are set to zero (x, y, z)
5. SEQ constructs a control packet for the vector and sends it to the first reservation station (the FIFO in front of fetch state machine 0, or TSM0 FIFO)
   - the control packet contains the state pointer, the tag to the position cache and a register file base pointer.
6. TSM0 accepts the control packet and fetches the instructions for fetch clause 0 from the global instruction store
   - TSM0 was first selected by the TSM arbiter before it could start
7. all instructions of fetch clause 0 are issued by TSM0
8. the control packet is passed to the next reservation station (the FIFO in front of ALU state machine 0, or ASM0 FIFO)
   - TSM0 does not wait for requests made to the Fetch Unit to complete; it passes the register file write index for the fetch data to the TU, which will write the data to the RF as it is received
   - once the TU has written all the data to the register files, it increments a counter that is associated with ASM0 FIFO; a count greater than zero indicates that the ALU state machine can go ahead start to execute the ALU clause
9. ASM0 accepts the control packet (after being selected by the ASM arbiter) and gets the instructions for ALU clause 0 from the global instruction store
10. all instructions of ALU clause 0 are issued by ASM0, then the control packet is passed to the next reservation station (the FIFO in front of fetch state machine 1, or TSM1 FIFO)
11. the control packet continues to travel down the path of reservation stations until all clauses have been executed
    - position can be exported in ALU clause 3 (or 4?); the data (and the tag) is sent over a position bus (which is shared with all four shader pipes) back to the PA's position cache
    - A parameter cache pointer is also sent along with the position data. This tells to the PA where the data is going to be in the parameter cache.
      - there is a position export FIFO in the SP that buffers position data before it gets sent back to the PA

    - the ASM arbiter will prevent a packet from starting an exporting clause if the position export FIFO is full
- parameter data is exported in clause 7 (as well as position data if it was not exported earlier)
    - parameter data is sent to the Parameter Cache over a dedicated bus
    - the SEQ allocates storage in the Parameter Cache, and the SEQ deallocates that space when there is no longer a need for the parameters (it is told by the PA when using a token).
    - the ASM arbiter will prevent a packet from starting on ASM7 if the parameter cache (or the position buffer if position is being exported) is full

12. after the shader program has completed, the SEQ will free up the GPRs so that they can be used by another shader program

~~25.1.2~~26.1.2 *Sequencer Control of a Vector of Pixels*

Formatted: Bullets and Numbering

1. **As with vertex shader programs, pixel shaders are loaded into the global instruction store by the CP**
    - At this point it is assumed that the pixel program is loaded into the instruction store and thus ready to be read.
2. the RE's Pixel FIFO is loaded with the barycentric coordinates for pixel quads by the detailed walker
    - the state pointer and the LOD correction bits are also placed in the Pixel FIF0
    - the Pixel FIFO is wide enough to source four quad's worth of barycentrics per cycle
3. SEQ arbitrates between Pixel FIFO and Vertex FIFO – when there are no vertices pending OR there is no space left in the register files for vertices, the Pixel FIFO is selected
4. SEQ allocates space in the SP register file for all the GPRs used by the program
    - the number of GPRs required by the program is stored in a local state register, which is accessed using the state pointer
    - SEQ will not allow interpolated data to be sent to the shader until space in the register file has been allocated
5. SEQ controls the transfer of interpolated data to the SP register file over the RE_SP interface (which has a bandwidth of 2048 bits/cycle). See interpolated data bus diagrams for details.
6. SEQ constructs a control packet for the vector and sends it to the first reservation station (the FIFO in front of fetch state machine 0, or TSM0 FIFO)
    - note that there is a separate set of reservation stations/arbiters/state machines for vertices and for pixels
    - the control packet contains the state pointer, the register file base pointer, and the LOD correction bits
    - all other information (such as quad address for example) travels in a separate FIFO
7. TSM0 accepts the control packet and fetches the instructions for fetch clause 0 from the global instruction store
    - TSM0 was first selected by the TSM arbiter before it could start
8. all instructions of fetch clause 0 are issued by TSM0
9. the control packet is passed to the next reservation station (the FIFO in front of ALU state machine 0, or ASM0 FIFO)
    - TSM0 does not wait for fetch requests made to the Fetch Unit to complete; it passes the register file write index for the fetch data to the TU, which will write the data to the RF as it is received
    - once the TU has written all the data for a particular clause to the register files, it increments a counter that is associated with the ASM0 FIFO; a count greater than zero indicates that the ALU state machine can go ahead and pop the FIFO and start to execute the ALU clause
10. ASM0 accepts the control packet (after being selected by the ASM arbiter) and gets the instructions for ALU clause 0 from the global instruction store
11. all instructions of ALU clause 0 are issued by ASM0, then the control packet is passed to the next reservation station (the FIFO in front of fetch state machine 1, or TSM1 FIFO)
12. the control packet continues to travel down the path of reservation stations until all clauses have been executed
    - pixel data is exported in the last ALU clause (clause 7)
        - it is sent to an output FIFO where it will be picked up by the render backend
        - the ASM arbiter will prevent a packet from starting on ASM7 if the output FIFO is full
13. after the shader program has completed, the SEQ will free up the GPRs so that they can be used by another shader program

~~25.1.3~~26.1.3 *Notes*

Formatted: Bullets and Numbering

14. The state machines and arbiters will operate ahead of time so that they will be able to immediately start the real threads or stall.

15. The register file base pointer for a vector needs to travel with the vector through the reservation stations, but the instruction store base pointer does not – this is because the RF pointer is different for all threads, but the IS pointer is only different for each state and thus can be accessed via the state pointer

16. Waterfalling still needs to be specked out.

~~26.~~27. Open issues

Formatted: Bullets and Numbering

There is currently an issue with constants. If the constants are not the same for the whole vector of vertices, we don't have the bandwidth from the fetch store to feed the ALUs. Two solutions exists for this problem:

1) Let the compiler handle the case and put those instructions in a fetch clause so we can use the bandwidth there to operate. This requires a significant amount of temporary storage in the register store.
2) Waterfall down the pipe allowing only at a given time the vertices having the same constants to operate in parallel. This might in the worst case slow us down by a factor of 16.

Need to do some testing on the size of the register file as well as on the register file allocation method (dynamic VS static).

Saving power?

R400 Sequencer Specification

SQ

Version 1.54

Overview: This is an architectural specification for the R400 Sequencer block (SEQ). It provides an overview of the required capabilities and expected uses of the block. It also describes the block interfaces, internal sub-blocks, and provides internal state diagrams.

AUTOMATICALLY UPDATED FIELDS:

Document Location: C:\perforce\r400\doc_lib\design\blocks\sq\R400_Sequencer.doc

Revision Changes:

Rev 0.1 (Laurent Lefebvre) Date: May 7, 2001	First draft.
Rev 0.2 (Laurent Lefebvre) Date : July 9, 2001	Changed the interfaces to reflect the changes in the SP. Added some details in the arbitration section.
Rev 0.3 (Laurent Lefebvre) Date : August 6, 2001	Reviewed the Sequencer spec after the meeting on August 3, 2001.
Rev 0.4 (Laurent Lefebvre) Date : August 24, 2001	Added the dynamic allocation method for register file and an example (written in part by Vic) of the flow of pixels/vertices in the sequencer.
Rev 0.5 (Laurent Lefebvre) Date : September 7, 2001	Added timing diagrams (Vic)
Rev 0.6 (Laurent Lefebvre) Date : September 24, 2001	Changed the spec to reflect the new R400 architecture. Added interfaces.
Rev 0.7 (Laurent Lefebvre) Date : October 5, 2001	Added constant store management, instruction store management, control flow management and data dependant predication.
Rev 0.8 (Laurent Lefebvre) Date : October 8, 2001	Changed the control flow method to be more flexible. Also updated the external interfaces.
Rev 0.9 (Laurent Lefebvre) Date : October 17, 2001	Incorporated changes made in the 10/18/01 control flow meeting. Added a NOP instruction, removed the conditional_execute_or_jump. Added debug ~~registers~~registers.
Rev 1.0 (Laurent Lefebvre) Date : October 19, 2001	Refined interfaces to RB. Added state ~~registers~~registers.
Rev 1.1 (Laurent Lefebvre) Date : October 26, 2001	Added SEQ→SP0 interfaces. Changed delta precision. Changed VGT→SP0 interface. Debug Methods added.
Rev 1.2 (Laurent Lefebvre) Date : November 16, 2001	Interfaces greatly refined. Cleaned up the spec.
Rev 1.3 (Laurent Lefebvre) Date : November 26, 2001	Added the different interpolation modes.
Rev 1.4 (Laurent Lefebvre) Date : December 6, 2001	Added the auto incrementing counters. Changed the VGT→SQ interface. Added content on constant management. Updated ~~registers~~GPRs.
Rev 1.5 (Laurent Lefebvre) Date : December 11, 2001	Removed from the spec all interfaces that weren't directly tied to the SQ. Added explanations on constant management. Added PA→SQ synchronization fields and explanation.

1. Overview

The sequencer is based on the R300 design. It chooses two ALU clauses and a fetch clause to execute, and executes all of the instructions in a clause before looking for a new clause of the same type. Two ALU clauses are executed interleaved to hide the ALU latency. Each vector will have eight fetch and eight ALU clauses, but clauses do not need to contain instructions. A vector of pixels or vertices ping-pongs along the sequencer FIFO, bouncing from fetch reservation station to alu reservation station. A FIFO exists between each reservation stage, holding up vectors until the vector currently occupying a reservation station has left. A vector at a reservation station can be chosen to execute. The sequencer looks at all eight alu reservation stations to choose an alu clause to execute and all eight fetch stations to choose a fetch clause to execute. The arbitrator will give priority to clauses/reservation stations closer to the bottom of the pipeline. It will not execute an alu clause until the fetch fetches initiated by the previous fetch clause have completed. There are two separate sets of reservation stations, one for pixel vectors and one for vertices vectors. This way a pixel can pass a vertex and a vertex can pass a pixel.

To support the shader pipe the sequencer also contains the shader instruction cache, constant store, control flow constants and texture state. The four shader pipes also execute the same instruction thus there is only one sequencer for the whole chip.

The sequencer first arbitrates between vectors of 64 vertices that arrive directly from primitive assembly and vectors of 16 quads (64 pixels) that are generated in the scan converter.

The vertex or pixel program specifies how many GPRs it needs to execute. The sequencer will not start the next vector until the needed space is available in the GPRs.

There are two sets of the above figure, one for vertices and one for pixels.

Depending on the arbitration state, the sequencer will either choose a vertex or a pixel packet. The control packet consists of 3 bits of state, 7 bits for the base address of the Shader program and some information on the coverage to determine fetch LOD plus other various small state bits.

On receipt of a packet, the input state machine (not pictured but just before the first FIFO) allocated enough space in the ~~registers~~GPRs to store the interpolated values and temporaries. Following this, the barycentric coordinates (and

XY screen position if needed) are sent to the interpolator ~~buffers~~ which ~~are going to~~will use ~~these barycentric coordinates~~them to interpolate the parameters and place the ~~interpolated value~~results into the GPRs. Then, the input state machine stacks the packet in the first FIFO.

On receipt of a command, the level 0 fetch machine issues a ~~texture~~ fetch request to the TP and corresponding ~~register~~ GPR address for the fetch address (ta). A small command (tcmd) is passed to the fetch system identifying the current level number (0) as well as the ~~register~~ GPR write address for the fetch return data. One fetch request is sent every 4 clocks causing the texturing of sixteen 2x2s worth of data (or 64 vertices). Once all the requests are sent the packet is put in FIFO 1.

Upon receipt of the return data, the fetch unit writes the data to the register file using the write address that was provided by the level 0 fetch machine and sends the clause number (0) to the level 0 fetch state machine to signify that the write is done and thus the data is ready. Then, the level 0 fetch machine increments the counter of FIFO 1 to signify to the ALU ~~1~~ 0 that the data is ready to be processed.

On receipt of a command, the level 0 ALU machine first decrements the input FIFO 1 counter and then issues a complete set of level 0 shader instructions. For each instruction, the ALU state machine generates 3 source addresses, one destination address ~~(3 cycles later)~~ and an instruction. Once the last instruction has been issued, the packet is put into FIFO 2.

There will always be two active ALU clauses at any given time (and two arbiters). One arbiter will arbitrate over the odd instructions (4 clocks cycles) and the other one will arbitrate over the even instructions (4 clocks cycles). The only constraints between the two arbiters is that they are not allowed to pick the same clause number as the other one is currently working on if the packet is not of the same type (render state).

If the packet is a vertex packet, upon reaching ALU clause 3, it can export the position if the position is ready. So the arbiter must prevent ALU clause 3 to be selected if the positional buffer is full (or can't be accessed). Along with the positional data, if needed the sprite size and/or edge flags can also be sent.

{ISSUE: How do we handle parameter cache pointers (computed, semi-computed or not computed)?}

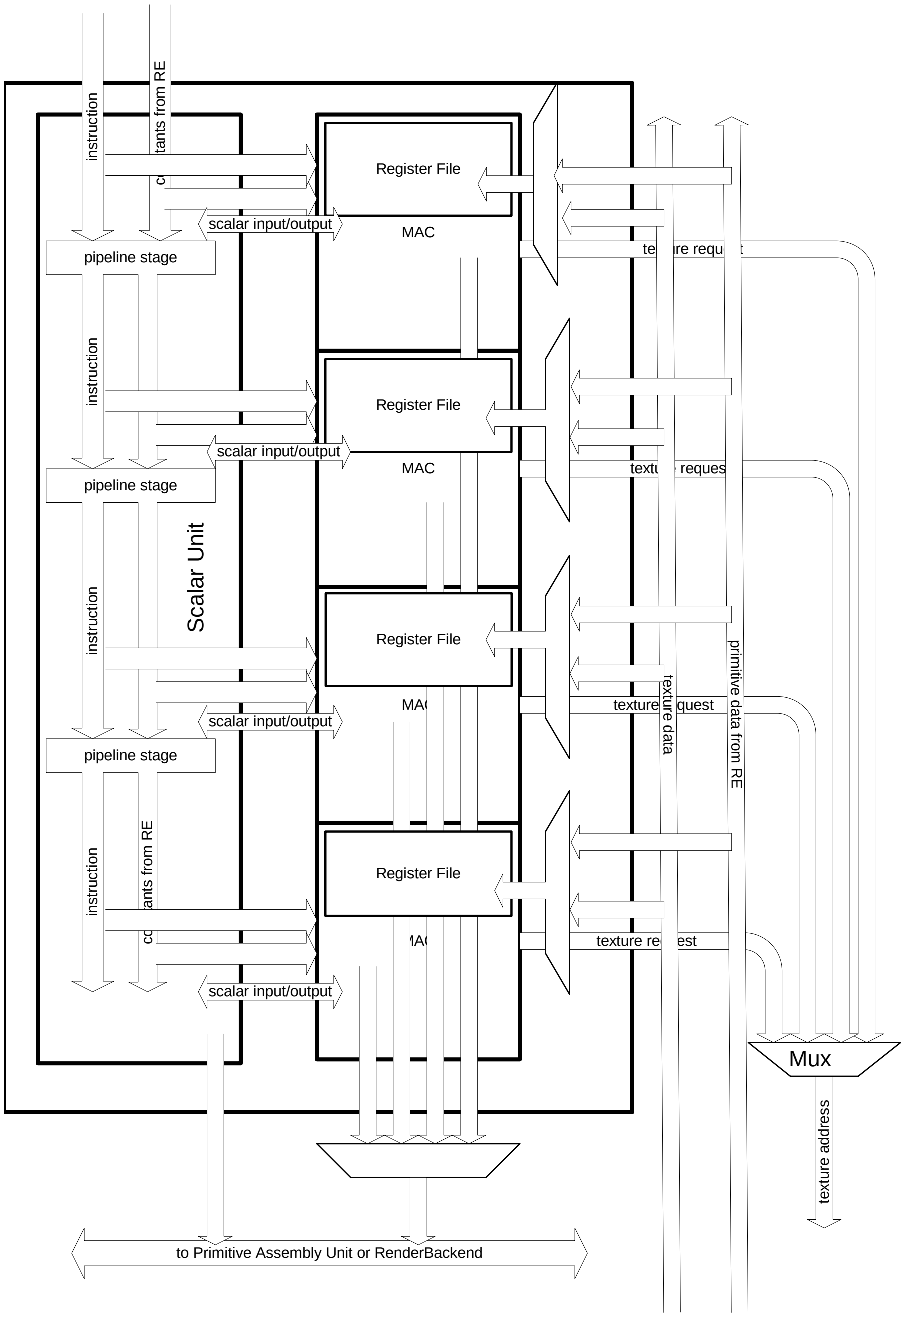
A special case is for multipass vertex shaders, which can export 12 parameters per last 6 clauses to the output buffer. If the output buffer is full or doesn't have enough space the sequencer will prevent such a vertex group to enter an exporting clause.

Multipass pixel shaders can export 12 parameters to memory from the last clause only (7).

All other clauses~~level~~ process in the same way until the packet finally reaches the last ALU machine (7).

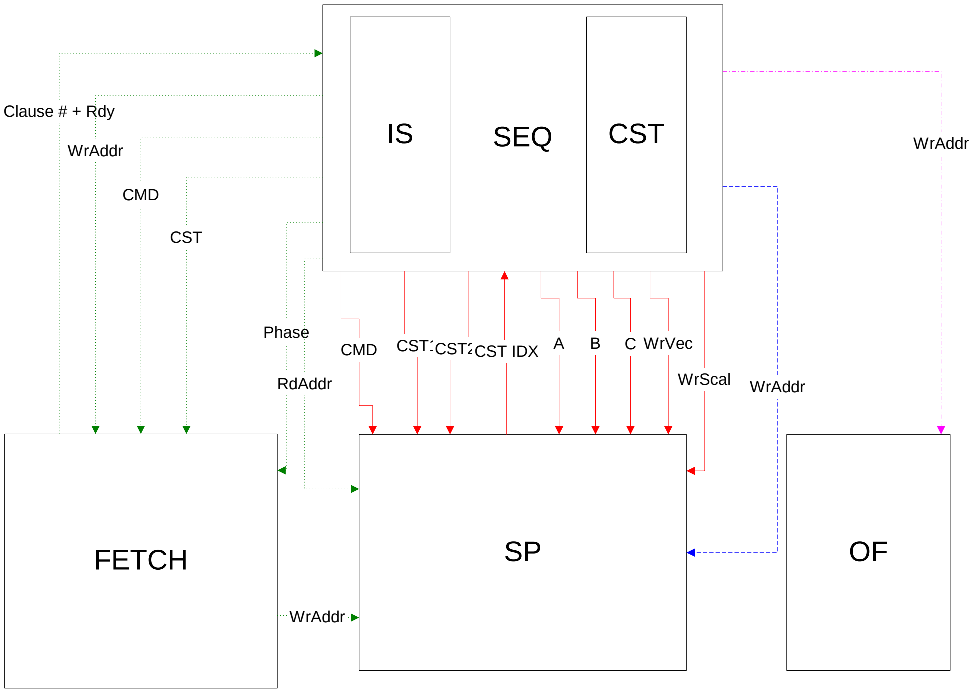
Only ~~two~~ one pair of interleaved ALU state machines may have access to the register file address bus or the instruction decode bus at one time. Similarly, only one fetch state machine may have access to the register file address bus at one time. Arbitration is performed by three arbiter blocks (two for the ALU state machines and one for the fetch state machines). The arbiters always favor the higher number state machines, preventing a bunch of half finished jobs from clogging up the register files.

1.2 Data Flow graph



The gray area represents blocks that are replicated 4 times per shader pipe (16 times on the overall chip).

1.3 Control Graph



In green is represented the Fetch control interface, in red the ALU control interface, in blue the Interpolated/Vector control interface and in purple is the output file control interface.

2. Interpolated data bus

The interpolators contain an IJ buffer to pack the information as much as possible before writing it to the register file.

	XY				P1								P2								VTX			

Above is an example of a tile ~~we~~ the sequencer might receive from the SC. The write side is how the data get stacked into the XY and IJ buffers, the read side is how the data is passed to the GPRs. The IJ information is packed in the IJ buffer ~~2~~4 quads at a time or two clocks. The sequencer allows at any given time as many as four quads to interpolate a parameter. They all have to come from the same primitive. Then the sequencer controls the write mask to the ~~register~~ GPRs to write the valid data in.

3. Instruction Store

There is going to be only one instruction store for the whole chip. It will contain 4096 instructions of 96 bits each.

It is likely to be a 1 port memory; we use 1 clock to load the ALU instruction, 1 clocks to load the Fetch instruction, 1 clock to load 2 control flow instructions and 1 clock to write instructions.

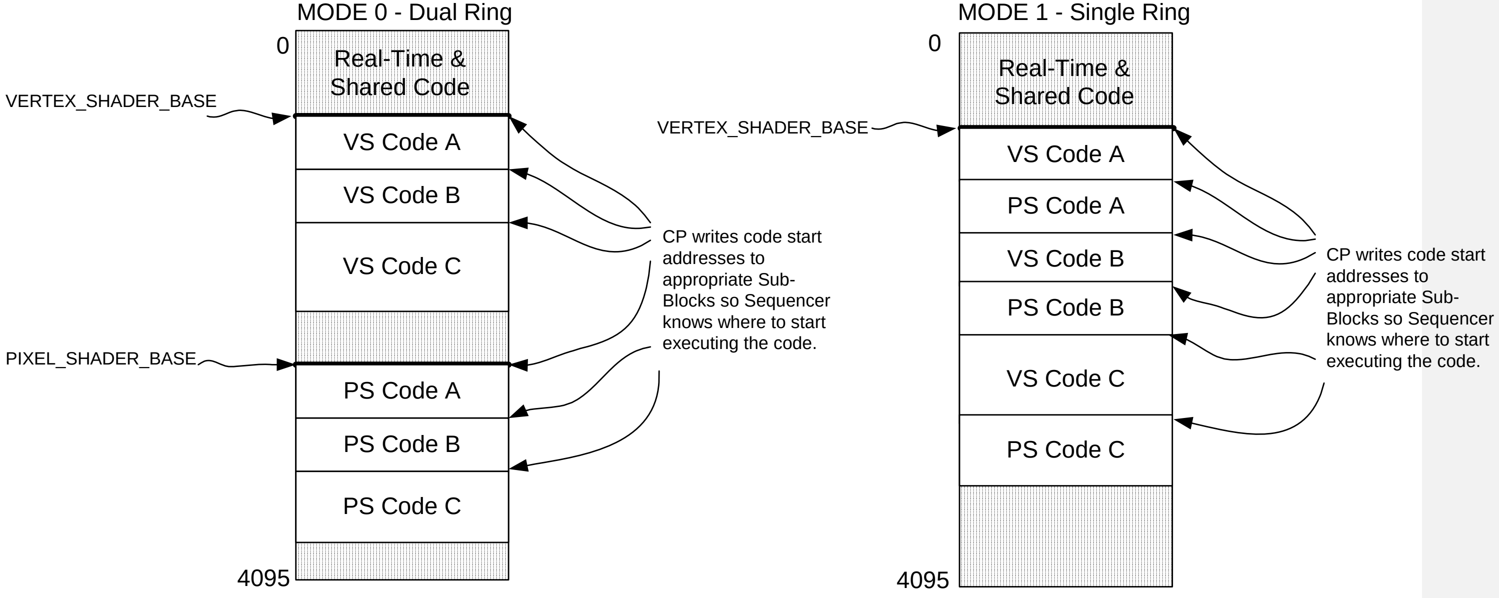
The instruction store is loaded by the CP thru the INST_DATA, INST_INDEX_PORT control ~~registers~~register. The INST_INDEX_PORT is auto-incremented on both reads and writes to the INST_DATA register.

The next picture shows the various modes the CP can load the memory. The Sequencer has to keep track of the loading modes in order to wrap around the correct boundaries. The MSB of the INST_INDEX_PORT register contains the packet type for the sequencer to know where it must wrap around. The wrap around points are arbitrary and they are specified in the VS_BASE and PIX_BASE ~~registers~~registers.

For the Real time commands the story is quite the same but for some small differences. The CP will use the INST_INDEX_PORT_RT and INST_DATA_RT register pair instead of the regular ones and there are no wrap around points for real time so the driver must be careful not to overwrite regular shader data. The shared code (shared subroutines) uses the same path as real time.

R400 CP's Views of Instruction Memory

Updated: 11/14/2001
John A. Carey



CP writes code start addresses to appropriate Sub-Blocks so Sequencer knows where to start executing the code.

CP writes code start addresses to appropriate Sub-Blocks so Sequencer knows where to start executing the code.

4. Sequencer Instructions

All control flow instructions and move instructions are handled by the sequencer only. The ALUs will perform NOPs during this time (MOV PV,PV, PS,PS).

5. Constant Stores

5.1 Memory organizations

A likely size for the ALU constant store is 1024x128 bits. The read BW from the ALU constant store is 128 bits/clock and the write bandwidth is 32 bits/clock (directed by the CP bus size not by memory ports).

The maximum logical size of the constant store for a given shader is 256 constants. Or 512 for the pixel/vertex shader pair. The size of the ~~remaping~~re-mapping table is 128 lines (each line addresses 4 constants). The write granularity is 4 constants or 512 bits. It takes 16 clocks to write the four constants.

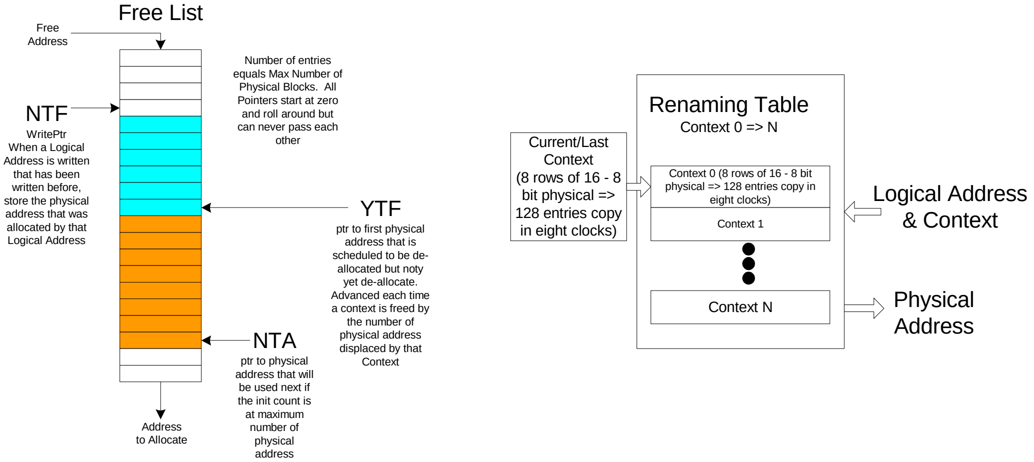
The texture state is also kept in a similar memory. The size of this memory is 192x128. The memory thus holds 128 texture states (192 bits per state). The logical size ~~exposed~~ exposes 32 different states total, which are going to be shared between the pixel and the vertex shader. The size of the ~~remaping~~re-mapping table to for the texture state memory is 16 lines (each line addresses 2 texture state lines in the real memory). The write granularity is 2 texture state lines (or 384 bits). The driver sends 512 bits but the CP ignores the top 128 bits. It thus takes 12 clocks to write the two texture states.

The control flow constant memory doesn't sit behind a renaming table. It is register mapped and thus the driver must reload its content each time there is a state change. Its size is ~~256~~320*32 because it must hold 8 copies of the 32 dwords of control flow constants and the loop construct constants must be aligned.

The CP is loading the constant store using the CONST_DATA and CONST_ADDR ~~registers~~registers. It does so by writing to the CONST_ADDR register the logical address for the constant block it wants to update and then writes 16 times to the CONST_DATA register. The CONST_ADDR is auto-incremented on both reads and writes to the CONST_DATA register.

5.2 Management of the ~~remaping~~re-mapping tables

The sequencer is responsible to manage two ~~remaping~~re-mapping tables (one for the constant store and one for the texture state). On a state change (by the driver), the sequencer will broadside copy the contents of its ~~remaping~~re-mapping tables to a new one. We have 8 different ~~remaping~~re-mapping tables we can use concurrently. ~~More details and a diagram to come….~~



Free List
Free Address
Number of entries equals Max Number of Physical Blocks. All Pointers start at zero and roll around but can never pass each other
NTF
WritePtr When a Logical Address is written that has been written before, store the physical address that was allocated by that Logical Address
YTF
ptr to first physical address that is scheduled to be de-allocated but noty yet de-allocate. Advanced each time a context is freed by the number of physical address displaced by that Context
NTA
ptr to physical address that will be used next if the init count is at maximum number of physical address
Address to Allocate
Current/Last Context (8 rows of 16 - 8 bit physical => 128 entries copy in eight clocks)

Renaming table N-Contexts
Copy Last held above to Current Context on reciept of Set Constant for a new context (Hide loading behind Set State load - 16 clocks) all other Set States just write one entry to current state.

5.2.1 *Dirty bits*

Formatted: Bullets and Numbering

Two sets of dirty bits will be maintained per logical address. The first one will be set to zero on reset and set when the logical address is addressed. The second one will be set to zero when ever a new context is written and set for each address written while in this context. The reset dirty is not set, then writing to that logical address will not require de-allocation of whatever address stored in the renaming table. If it is set and the context dirty is not set, then the physical address store needs to be de-allocated and a new physical address is necessary to store the incoming data. If they are both set, then the data will be written into the physical address held in the renaming for the current logical address. No de-allocation or allocation takes place. This will happen when the driver does a set constant twice to the same logical address between context changes. NOTE: It is important to detect and prevent this, failure to do it will allow multiple writes to allocate all physical memory and thus hang because a context will not fit for rendering to start and thus free up space.

5.2.2 *Free List Block*

Formatted: Bullets and Numbering

A free list block that would consist of a counter (called the IFC or Initial Free Counter) that would reset to zero and incremented every time a chunk of physical memory is used until they have all been used once. This counter would be checked each time a physical block is needed, and if the original ones have not been used up, us a new one, else check the free list for an available physical block address. The count is the physical address for when getting a chunk from the counter.

Storage of a free list big enough to store all physical block addresses.

Maintain three pointers for the free list that are reset to zero. The first one we will call NTF (Next To Free). This pointer will identify the next location to write the physical address of a block to be de-allocated. Note: we can never free more physical memory locations than we have. Once recording address the pointer will be incremented to walk the free list like a ring.

The second pointer will be called YTF (Yet To Free). The YTF pointer will be advanced by the number of address chunks de-allocates when a context finishes. The address between the YTF and NTF cannot be reused because they are still in use. But as soon as the context using then is dismissed the YTF will be advanced.

The third pointer will be called NTA (Next To Allocate). This pointer will point will point to the next address that can be used for allocation as long as the NTA does not equal the YTF and the IFC is at its maximum count.

5.2.3 *De-allocate Block*

Formatted: Bullets and Numbering

This block will maintain a free physical address block count for each context. While in current context, a count shall be maintained specifying how many blocks were written into the free list at the NTF pointer. This count will be reset upon reset or when this context is active on the back and different than the previous context. It is actually a count of blocks in the previous context that will no longer be used. This count will be used to advance the NTF pointer to make available the set of physical blocks freed when the previous context was done. This allows the discard or de-allocation of any number of blocks in one clock.

5.2.4 *Operation of Incremental model*

Formatted: Bullets and Numbering

The basic operation of the model would start with the NTF, YTF, NTA pointers in the free list set to zero and the free list counter is set to zero. Also all the dirty bits and the previous context will be initialized to zero. When the first set constants happen, the reset dirty bit will not be set, so we will allocate a physical location from the free list counter because its not at the max value. The data will be written into physical address zero. Both the additional copy of the renaming table and the context zeros of the big renaming table will be updated for the logical address that was written by set start with physical address of 0. This process will be repeated for any logical address that are not dirty until the context changes. If a logical address is hit that has its dirty bits set while in the same context, both dirty bits would be set, so the new data will be over-written to the last physical address assigned for this logical address. When a set constant comes with a different than last context, the previous context stored in the additional renaming table will be copied to the larger renaming table in the current (new) context location. Then the set constant logical address with be loaded with a new physical address during the copy and if the reset dirty was set, the physical address it replaced in the renaming table would be entered at the NTF pointer location on the free list and the NTF will be incremented. The de-allocation counter for the previous context (zero) will be incremented. This as set states come in for this context one of the following will happen:

1.) No dirty bits are set for the logical address being updated. A line will be allocated of the free-list counter or the free list at NTA pointer if NTA != to YTF .

Formatted: Bullets and Numbering

2.) Reset dirty set and Context dirty not set. A new physical address is allocated, the physical address in the renaming table is put on the free list at NTF and it is incremented along with the de-allocate counter for the last context.
3.) Context dirty is set then the data will be written into the physical address specified by the logical address.

This process will continue as long as set states arrive. This block will provide back pressure to the CP when ever he has not free list entries available (counter at max and YTF == NTA). The command stream will keep a count of contexts of constants in use and prevent more than max constants contexts from being sent.
Now preferable when the constant context leaves the last ALU clause it will be sent to this block and compared with the previous context that left. (Init to zero) If they differ than the older context will no longer be referenced and thus can be de-allocated in the physical memory. This is accomplished by adding the number of blocks freed this context to the YTF pointer. This will make all the physical addresses used by this context available to the NTA allocate pointer for future allocation.

This device allows representation of multiple contexts of constants data with N copies of the logical address space. It also allows the second context to be represented as the first set plus some new additional data by just storing the delta's. It allows memory to be efficiently used and when the constants updates are small it can store multiple context. However, if the updates are large, less contexts will be stored and potentially performance will be degraded. Although it will still perform as well as a ring could in this case.

5.3 Constant Store Indexing

In order to do constant store indexing, the sequencer must be loaded first with the indexes (that come from the GPRs). There are 144 wires from the exit of the SP to the sequencer (9 bits pointers x 16 vertexes/clock). Since the data must pass thru the Shader pipe for the float to fixed conversion, there is a latency of 4 clocks (1 instruction) between the time the sequencer is loaded and the time one can index into the constant store. The assembly will look like this

```
MOVA  R1.X,R2.X        // Loads the sequencer with the content of R2.X, also copies the content of R2.X into R1.X
NOP                    // latency of the float to fixed conversion
ADD   R3,R4,C0[R2.X]// Uses the state from the sequencer to add R4 to C0[R2.X] into R3
```

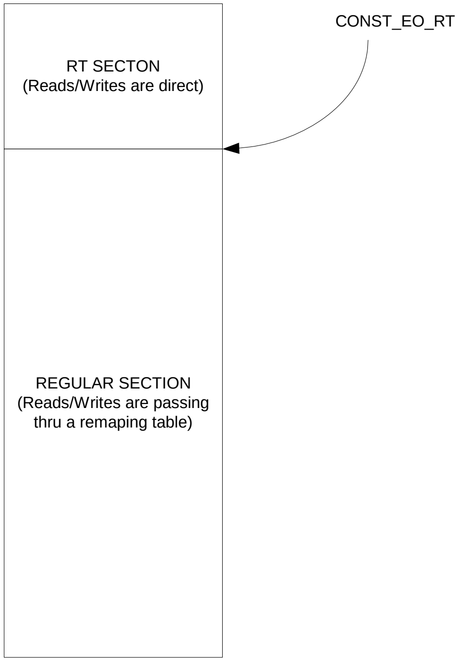
Note that we don't really care about what is in the brackets because we use the state from the MOVA instruction. R2.X is just written again for the sake of simplicity and coherency.

~~5.4~~The storage needed in the sequencer in order to support this feature is 2*64*9 bits = 1152 bits.

Formatted: Bullets and Numbering

~~5.5~~5.4 Real Time Commands

The real time commands constants are written by the CP using the CONST_DATA_RT and CONST_ADDR_RT ~~registers~~GPRs. It works is the same way than when dealing with regular constant loads BUT in this case the CP is not sending a logical address but rather a physical address and the reads are not passing thru the ~~remaping~~re-mapping table but are directly read from the memory. The boundary between the two zones is defined by the CONST_EO_RT control register.



6. Looping and Branches

Loops and branches are planned to be supported and will have to be dealt with at the sequencer level. We plan on supporting constant loops and branches using a control program.

6.1 The controlling state.

The R400 controling state consists of:

Boolean[256:0]
Loop_count[7:0][31:0]
Loop_Start[7:0][31:0]
Loop_Step[7:0][31:0]

That is 256 Booleans and 32 loops.

We have a stack of 4 elements for nested calls of subroutines and 4 loop counters to allow for nested loops.

This state is available on a per shader program basis.

6.2 The Control Flow Program

Examples of control flow programs are located in the R400 programming guide document.

The basic model is as follows:

The render state defined the clause boundaries:
Vertex_shader_fetch[7:0][7:0]   // eight 8 bit pointers to the location where each clauses control program is located
Vertex_shader_alu[7:0][7:0]   // eight 8 bit pointers to the location where each clauses control program is located

Pixel_shader_fetch[7:0][7:0]   // eight 8 bit pointers to the location where each clauses control program is located
Pixel_shader_alu[7:0][7:0]   // eight 8 bit pointers to the location where each clauses control program is located

A pointer value of FF means that the clause doesn't contain any instructions.

The control program for a given clause is executed to completion before moving to another clause, (with the exception of the pick two nature of the alu execution). The control program is the only program aware of the clause boundaries.

The control program has eleven basic instructions:

Execute
Conditional_execute
Conditional_Execute_Predicates
Conditional_jump
Call
Return
Loop_start
Loop_end
End_of_clause
Conditional_End_of_clause
NOP

Execute, causes the specified number of instructions in instruction store to be executed.
Conditional_execute checks a condition first, and if true, causes the specified number of instructions in instruction store to be executed.
Loop_start resets the corresponding loop counter to the start value on the first pass after it checks for the end condition and if met jumps over to a specified address.
Loop_end increments (decrements?) the loop counter and jumps back the specified number of instructions.
Call jumps to an address and pushes the IP counter on the stack. On the return instruction, the IP is popped from the stack.
Conditional_execute_or_Jump executes a block of instructions or jumps to an address is the condition is not met.
Conditional_execute_Predicates executes a block of instructions if all bits in the predicate vectors meet the condition.
End_of_clause marks the end of a clause.
Conditional_End_of_clause marks the end of a clause if the condition is met.
Conditional_jumps jumps to an address if the condition is met.
NOP is a regular NOP

NOTE THAT ALL JUMPS MUST JUMP TO EVEN CFP ADDRESSES since there are two control flow instructions per memory line. Thus the compiler must insert NOPs where needed to align the jumps on even CFP addresses.

Also if the jump is logically bigger than pshader_cntl_size (or vshader_cntl_size) we break the program (clause) and set the debug ~~registers~~registers. If an execute or conditional_execute is lower than cntl_size or bigger than size we also break the program (clause) and set the debug ~~registers~~registers.

We have to fit instructions into 48 bits in order to be able to put two control flow instruction per line in the instruction store.

Note that whenever a field is marked as RESERVED, it is assumed that all the bits of the field are cleared (0).

Execute				
47	46… 42	41 … 24	23 … 12	11 … 0
Addressing	00001	RESERVED	Instruction count	Exec Address

Execute up to 4k instructions at the specified address in the instruction memory.

NOP		
47	46 … 42	41 … 0

Addressing	00010	RESERVED

This is a regular NOP.

Conditio~~n~~nal_Execute							
47	46 … 42	41	40 … 33	32	31 … 24	23 … 12	11 … 0
Addressing	00011	RESERVED	Boolean address	Condition	RESERVED	Instruction count	Exec Address

If the specified ~~boolean~~Boolean (8 bits can address 256 ~~booleans~~Booleans) meets the specified condition then execute the specified instructions (up to 4k instructions)

Conditio~~n~~nal_Execute_Predicates							
47	46 … 42	41 … 35	34 … 33	32	31 … 24	23 … 12	11 … 0
Addressing	00100	RESERVED	Predicate vector	Condition	RESERVED	Instruction count	Exec Address

Check the AND/OR of all current predicate bits. If AND/OR matches the condition execute the specified number of instructions. We need to AND/OR this with the kill mask in order not to consider the pixels that aren't valid.

Loop_Start				
47	46 … 42	41 … 17	16 … 12	11 … 0
Addressing	00101	RESERVED	loop ID	Jump address

Loop Start. Compares the loop ~~count~~iterator with the end value. If loop condition not met jump to the address. Forward jump only. Also computes the index ~~value.~~value. The loop id must match between the start to end, and also indicates which control flow constants should be used with the loop.

Loop_End				
47	46 … 42	41 … 17	16 … 12	11 … 0
Addressing	00111	RESERVED	loop ID	start address

Loop end. Increments the counter by one, compares the loop count with the end value. If loop condition met, continue, else, ~~and~~ jump~~s~~ BACK ~~only~~ to the start of the loop.

The way this is described does not prevent nested loops, and the inclusion of the loop id make this easy to do.

Call			
47	46 … 42	41…12	11 … 0
Addressing	01000	RESERVED	Jump address

Jumps to the specified address and pushes the ~~IP~~ control flow program counter on the stack.

Return		
47	46 … 42	41 … 0
Addressing	01001	RESERVED

Pops the topmost address from the stack and jumps to that address. If nothing is on the stack, the program will just continue to the next instruction.

Conditionnal_Jump							
47	46 … 42	41	40 … 33	32	31	30 … 12	11 … 0
Addressing	01010	RESERVED	Boolean address	Condition	FW only	RESERVED	Jump address

If condition met, jumps to the address. FORWARD jump only allowed if bit 31 set. Bit 31 is only an optimization for the compiler and should NOT be exposed to the API.

Conditional_End_of_Clause					
47	46 … 42	41	40 … 33	32	31 … 0
Addressing	01011	RESERVED	Boolean address	Condition	RESERVED

This is an optimization in the case of very short shaders (where the control flow instruction can't be hidden anymore and thus are not free. In this case, if the condition is met, the clause is ended, else we continue the execution of the clause.

End_of_Clause		
47	46 … 42	41 … 0
Addressing	01011	RESERVED

Marks the end of a clause.

To prevent infinite loops, we will keep 9 bits loop counters instead of 8 (we are only able to loop 256 times). If the counter goes higher than 255 then the loop_end or the loop_start instruction is going to break the loop and set the debug ~~registers~~GPRs.

6.3 Data dependant predicate instructions

Data dependant conditionals will be supported in the R400. The only way we plan to support those is by supporting three vector/scalar predicate operations of the form:

PRED_SETE_# - similar to SETE except that the result is 'exported' to the sequencer.
PRED_SETNE_# - similar to SETNE except that the result is 'exported' to the sequencer.
PRED_SETGT_# - similar to SETGT except that the result is 'exported' to the sequencer
PRED_SETGTE_# - similar to SETGTE except that the result is 'exported' to the sequencer

For the scalar operations only we will also support the two following instructions:
PRED_SETE0_# – SETE0
PRED_SETE1_# – SETE1

The export is a single bit - 1 or 0 that is sent using the same data path as the MOVA instruction. The sequencer will maintain 4 sets of 64 bit predicate vectors (in fact 8 sets because we interleave two programs but only 4 will be exposed) and use it to control the write masking. This predicate is not maintained across clause boundaries. The # sign is used to specify which predicate set you want to use 0 thru 3.

Then we have two conditional execute bits. The first bit is a conditional execute "on" bit and the second bit tells us if we execute on 1 or 0. For example, the instruction:

P0_ADD_# R0,R1,R2

Is only going to write the result of the ADD into those GPRs whose predicate bit is 0. Alternatively, P1_ADD_# would only write the results to the GPRs whose predicate bit is set. The use of the P0 or P1 without precharging the sequencer with a PRED instruction is undefined.

{Issue: do we have to have a NOP between PRED and the first instruction that uses a predicate?}

6.4 HW Detection of PV,PS

Because of the control program, the compiler cannot detect statically dependant instructions. In the case of non-masked writes and subsequent reads the sequencer will insert uses of PV,PS as needed. This will be done by comparing the read address and the write address of consecutive instructions. For masked writes, the sequencer will insert NOPs wherever there is a dependant read/write.

The sequencer will also have to insert NOPs between PRED_SET and MOVA instructions and their uses.

6.5 Register file indexing

Because we can have loops in fetch clause, we need to be able to index into the register file in order to retrieve the data created in a fetch clause loop and use it into an ALU clause. The instruction will include the base address for register indexing and the instruction will contain these controls:

Bit7	Bit 6	
0	0	'absolute register'
0	1	'relative register'
1	0	'previous vector'
1	1	'previous scalar'

In the case of an absolute register we just take the address as is. In the case of a relative register read we take the base address and we add to it the loop_index and this becomes our new address that we give to the shader pipe.

The sequencer is going to keep a loop index computed as such:

Index = Loop_~~counter~~iterator*Loop_~~iterator~~step + Loop_~~init~~start.

The index is going to return 0 if it is out of the range. We loop until loop_iterator = loop_count. Loop_step is a signed value [-128…127].

6.6 Predicated Instruction support for Texture clauses

For texture clauses, we support the following optimization: we keep 1 bit (thus 4 bits for the four predicate vectors) per predicate vector in the reservation stations. A value of 1 means that one ore more elements in the vector have a value of one (thus we have to do the texture fetches for the whole vector. A value of 0 means that no elements in the vector have his predicate bit set and we can thus skip over the texture fetch. **We have to make sure the invalid pixels aren't considered with this optimization.**

6.7 Debugging the Shaders

In order to be able to debug the pixel/vertex shaders efficiently, we provide 2 methods.

6.7.1 *Method 1: Debugging ~~registers~~registers*

Current plans are to expose 2 debugging, or error notification, ~~registers~~registers:
1. address register where the first error occurred
2. count of the number of errors

The sequencer will detect the following groups of errors:
- count overflow
- jump error
  relative jump address > size of the control flow program
  relative jump address > length of the shader program
- constant overflow
- register overflow
- call stack
  call with stack full
  return with stack empty

With two of the errors, a jump error or a register overflow will cause the program to break. In this case, a break means that a clause will halt execution, but allowing further clauses to be executed.

With the other errors, program can continue to run, potentially to worst-case limits.

If indexing outside of the constant range, causing an overflow error, the hardware is specified to return the value with an index of 0. This could be exploited to generate error tokens, by reserving and initializing the 0th register (or constant) for errors.

{ISSUE : Interrupt to the driver or not?}

6.7.2 *Method 2: Exporting the values in the GPRs (12)*

The sequencer will have a count register and an address register for this mode and 3 bits per clause specifying the execution mode for each clause. The modes can be :

1) Normal
2) Debug Kill
3) Debug Addr + Count

Under the normal mode execution follows the normal course. Under the kill mode, all control flow instructions are executed but all normal shader instructions of the clause are replaced by NOPs. Only debug_export instructions of clause 7 will be executed under the debug kill setting. Under the other mode, normal execution is done until we reach an address specified by the address register and instruction count (useful for loops) specified by the count register. After we have hit the instruction n times (n=count) we switch the clause to the kill mode.

Under the debug mode (debug kill OR debug Addr + count), it is assumed that clause 7 is always exporting 12 debug vectors and that all other exports to the SX block (position, color, z, ect) will been turned off (changed into NOPs) by the sequencer (even if they occur before the address stated by the ADDR debug register).

7. Pixel Kill Mask

A vector of 64 bits is kept by the sequencer per group of pixels/vertices. Its purpose is to optimize the texture fetch requests and allow the shader pipe to kill pixels using the following instructions:

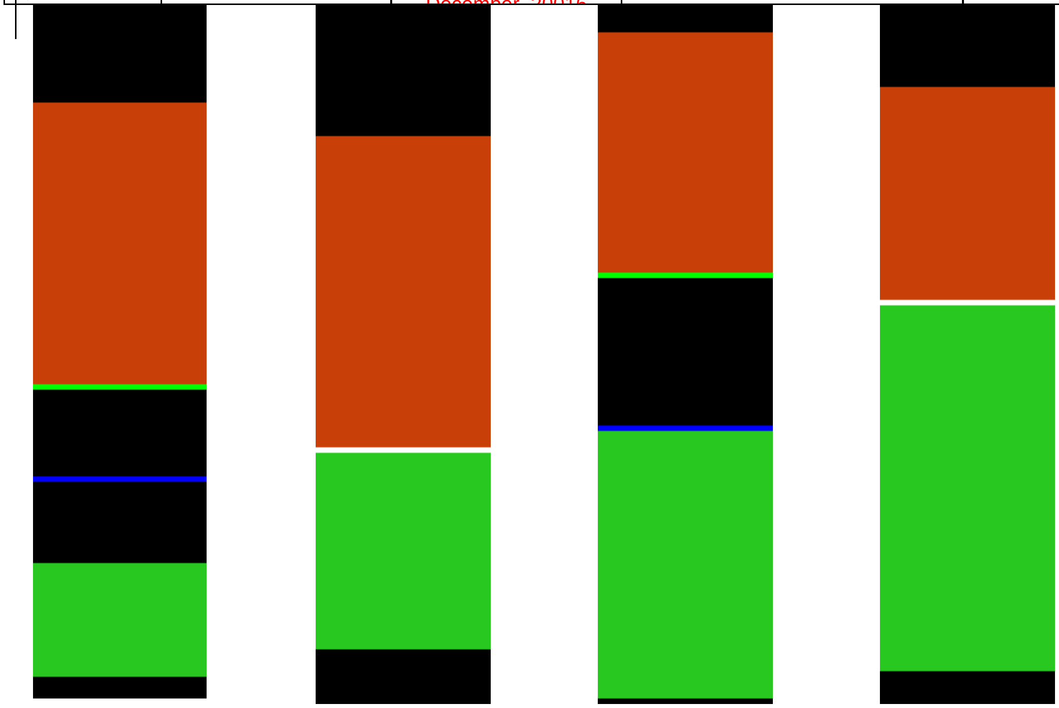
MASK_SETE
MASK_SETNE
MASK_SETGT
MASK_SETGTE

8. Multipass vertex shaders (HOS)

Multipass vertex shaders are able to export from the 6 last clauses but to memory ONLY.

9. Register file allocation

The register file allocation for vertices and pixels can either be static or dynamic. In both cases, the register file in managed using two round robins (one for pixels and one for vertices). In the dynamic case the boundary between pixels and vertices is allowed to move, in the static case it is fixed to VERTEX_REG_SIZE for vertices and 256-VERTEX_REG_SIZE for pixels.



Above is an example of how the algorithm works. Vertices come in from top to bottom; pixels come in from bottom to top. Vertices are in orange and pixels in green. The blue line is the tail of the vertices and the green line is the tail of the pixels. Thus anything between the two lines is shared. When pixels meets vertices the line turns white and the boundary is static until both vertices and pixels share the same “unallocated bubble”. Then the boundary is allowed to move again.

10. Fetch Arbitration

The fetch arbitration logic chooses one of the 8 potentially pending fetch clauses to be executed. The choice is made by looking at the fifos from 7 to 0 and picking the first one ready to execute. Once chosen, the clause state machine will send one 2x2 fetch per clock (or 4 fetches in one clock every 4 clocks) until all the fetch instructions of the clause are sent. This means that there cannot be any dependencies between two fetches of the same clause.

The arbitrator will not wait for the fetches to return prior to selecting another clause for execution. The fetch pipe will be able to handle up to X(?) in flight fetches and thus there can be a fair number of active clauses waiting for their fetch return data.

11. ALU Arbitration

ALU arbitration proceeds in almost the same way than fetch arbitration. The ALU arbitration logic chooses one of the 8 potentially pending ALU clauses to be executed. The choice is made by looking at the fifos from 7 to 0 and picking the first one ready to execute. There are two ALU ~~arbitrers~~arbiters, one for the even clocks and one for the odd clocks. For exa~~e~~mple, here is the sequencing of two interleaved ALU clauses (E and O stands for Even and Odd sets of 4 clocks):

Einst0 Oinst0 Einst1 Oinst1 Einst2 Oinst2 Einst0 Oinst3 Einst1 Oinst4 Einst2 Oinst0…
Proceeding this way hides the latency of 8 clocks of the ALUs. Also note that the interleaving also occurs across clause boundaries.

12. Handling Stalls

When the output file is full, the sequencer prevents the ALU arbitration logic ~~to select~~from selecting the last clause (this way nothing can exit the shader pipe until there is place in the output file. If the packet is a vertex packet and the position buffer is full (POS_FULL) then the sequencer also prevents a thread ~~to enter~~from entering the exporting clause (3?). The sequencer will set the OUT_FILE_FULL signal n clocks before the output file is actually full and thus the ALU arbiter will be able read this signal and act accordingly by not preventing exporting clauses to proceed.

13. Content of the reservation station FIFOs

The reservation FIFOs contain the state of the vector of pixels and vertices. We have two sets of those: one for pixels, and one for vertices. They contain 3 bits of Render State 7 bits for the base address of the GPRs, some bits for LOD correction and coverage mask information in order to fetch fetch for only valid pixels, the quad address~~ and 1 bit to specify if the vector is of pixels or vertices~~. ~~Since pixels and vertices are kept in order in the shader pipe, we only need two fifos (one for vertices and one for pixels) deep enough to cover the shader pipe latency. This size will be determined later when we will know the size of the small fifos between the reservation stations.~~

14. The Output File

The output file is where pixels are put before they go to the RBs. The write BW to this store is 256 bits/clock. Just before this output file are staging ~~registers~~registers with write BW 512 bits/clock and read BW 256 bits/clock. The staging ~~registers~~registers are 4x128 (and there are 16 of those on the whole chip).

15. IJ Format

The IJ information sent by the PA is of this format on a per quad basis:

We have a vector of IJ's (one IJ per pixel at the centroid of the fragment or at the center of the pixel depending on the mode bit). The interpolation is done at a different precision across the 2x2. The upper left pixel's parameters are always interpolated at full 20x24 mantissa precision. Then the result of the interpolation along with the difference in IJ in reduced precision is used to interpolate the parameter for the other three pixels of the 2x2. Here is how we do it:

Assuming P0 is the interpolated parameter at Pixel 0 having the barycentric coordinates I(0), J(0) and so on for P1,P2 and P3. Also assuming that A is the parameter value at V0 (interpolated with I), B is the parameter value at V1 (interpolated with J) and C is the parameter value at V2 (interpolated with (1-I-J).

$$\Delta 01I = I(1) - I(0)$$
$$\Delta 01J = J(1) - J(0)$$
$$\Delta 02I = I(2) - I(0)$$
$$\Delta 02J = J(2) - J(0)$$
$$\Delta 03I = I(3) - I(0)$$
$$\Delta 03J = J(3) - J(0)$$

P0	P1
P2	P3

$$P0 = C + I(0)*(A - C) + J(0)*(B - C)$$
$$P1 = P0 + \Delta 01I*(A - C) + \Delta 01J*(B - C)$$
$$P2 = P0 + \Delta 02I*(A - C) + \Delta 02J*(B - C)$$
$$P3 = P0 + \Delta 03I*(A - C) + \Delta 03J*(B - C)$$

P0 is computed at 20x24 mantissa precision and P1 to P3 are computed at 8X24 mantissa precision. So far no visual degradation of the image was seen using this scheme.

Multiplies (Full Precision): 2
Multiplies (Reduced precision): 6
Subtracts 19x24 (Parameters): 2
Adds: 8

FORMAT OF P0's IJ : Mantissa 20 Exp 4 for I + Sign
Mantissa 20 Exp 4 for J + Sign

FORMAT of Deltas (x3): Mantissa 8 Exp 4 for I + Sign
Mantissa 8 Exp 4 for J + Sign

Total number of bits : 20*2 + 8*6 + 4*8 + 4*2 = 128

~~The Deltas have a leading 1, the Full precision IJs don't. This means that in the case of the deltas we MUST be able to shift 8 right (exponent value of 0 means number = 0, exponent value of 1 means shift right 8).~~All numbers are kept using the un-normalized floating point convention: if exponent is different than 0 the number is normalized if not, then the number is un-normalized. ~~This means that t~~The maximum range for the IJs (Full precision) is +/- 63 and the range for the Deltas is +/- 127.

15.1 Interpolation of constant attributes

Because of the floating point imprecision, we need to take special provisions if all the interpolated terms are the same or if two of the barycentric coordinates are the same.

We start with the premise that if A = B and B = C and C = A, then P0,1,2,3 = A. Since one or more of the IJ terms may be zero, so we extend this to:

```
if (A=B and B=C and C=A)
   P0,1,2,3 = A;
else if ((I = 0) or (J = 0)) and
         ((J = 0) or (1-I-J = 0)) and
         ((1-J-I = 0) or (I = 0))) {
              if(I != 0) {
                 P0 = A;
              } else if(J != 0) {
                 P0 = B;
              } else {
                 P0 = C;
             }
           //rest of the quad interpolated normally
}
else
{
           normal interpolation
}
```

16. The parameter cache

The parameter cache is where the vertex shaders export their data. It consists of 16 128x128 memories (1R/1W). The reuse engine will make it so that all vertexes of a given primitive will hit different memories.

17. Vertex position exporting

On clause 3 the vertex shader can export to the PA both the vertex position and the point sprite. It can also do so at clause 7 if not done at clause 3. The storage needed to perform the position export is at least 64x128 memories for the position and 64x32 memories for the sprite size. It is going to be taken in the pixel output fifo from the SX blocks. The clause where the position export occurs is specified by the EXPORT_LATE register. If turned on, it means that the export is going to occur at ALU clause 7 if unset position export occurs at clause 3.

18. Exporting Arbitration

Here are the rules for co-issuing exporting ALU clauses.

1) Position exports and position exports cannot be co-issued.
2) Position exports and memory exports cannot be co-issued.
3) Position exports and Z/Color exports cannot be co-issued.
4) Memory exports and Z/Color exports cannot be co-issued.
5) Memory exports and memory exports cannot be co-issued.
6) Z/color exports and Z/color exports cannot be co-issued.
7) Parameter exports and Z/Color exports CAN be co-issued.
8) Parameter exports and parameter exports CAN be co-issued.
9) Parameter exports and memory exports CAN be co-issued.

19. Export Types

The export type (or the location where the data should be put) is specified using the destination address field in the ALU instruction. Here is a list of all possible export modes:

19.1 Vertex Shading

0:15	- 16 parameter cache
16:31	- Empty (Reserved?)
32:43	- 12 vertex exports to the frame buffer and index
44:47	- Empty
48:59	- 12 debug export (interpret as normal vertex export)
60	- export addressing mode
61	- Empty
62	- sprite size export that goes with position export (point_h,point_w,edgeflag,misc)
63	- position

19.2 Pixel Shading

0	- Color for buffer 0 (primary)
1	- Color for buffer 1
2	- Color for buffer 2
3	- Color for buffer 3
4:7	- Empty
8	- Buffer 0 Color/Fog (primary)
9	- Buffer 1 Color/Fog
10	- Buffer 2 Color/Fog
11	- Buffer 3 Color/Fog
12:15	- Empty
16:31	- Empty (Reserved?)
32:43	- 12 exports for multipass pixel shaders.
44:47	- Empty
48:59	- 12 debug exports (interpret as normal pixel export)
60	- export addressing mode
61:62	- Empty
63	- Z for primary buffer (Z exported to 'alpha' component)

20. Special Interpolation modes

20.1 Real time commands

We are unable to use the parameter memory since there is no way for a command stream to write into it. Instead we need to add three 16x128 memories (one for each of three vertices x 16 interpolants). These will be mapped onto the register bus and written by type 0 packets, and output to the the parameter busses (the sequencer and/or PA need to be able to address the realtime parameter memory as well as the regular parameter store. For higher performance we should be able able to view them as two banks of 16 and do double buffering allowing one to be loaded, while the other is rasterized with. Most overlay shaders will need 2 or 4 scalar coordinates, one option might be to restrict the memory to 16x64 or 32x64 allowing only two interpolated scalars per cycle, the only problem I see with this is, if we view support for 16 vector-4 interpolants important (true only if we map Microsoft's high priority stream to the realtime stream), then the PA/sequencer need to support a realtime-specific mode where we need to address 32 vectors of parameters instead of 16. This mode is triggered by the primitive type: REAL TIME.

20.2 Sprites/ XY screen coordinates/ FB information

When working with sprites, one may want to overwrite the parameter 0 with SC generated data. Also, XY screen coordinates may be needed in the shader program. This functionality is controlled by the gen_I0 register (in SQ) in conjunction with the SND_XY register (in SC). Also it is possible to send the faceness information (for OGL front/back special operations) to the shader using the same control ~~registers~~register. Here is a list of all the modes and how they interact together:

Gen_st is a bit taken from the interface between the SC and the SQ. This is the MSB of the primitive type. If the bit is set, it means we are dealing with Point AA, Line AA or sprite and in this case the vertex values are going to generated between 0 and 1.

Param_Gen_I0 disable, snd_xy disable, no gen_st – I0 = No modification
Param_Gen_I0 disable, snd_xy disable, gen_st – I0 = No modification
Param_Gen_I0 disable, snd_xy enable, no gen_st – I0 = No modification
Param_Gen_I0 disable, snd_xy enable, gen_st – I0 = No modification
Param_Gen_I0 enable, snd_xy disable, no gen_st – I0 = garbage, garbage, garbage, faceness
Param_Gen_I0 enable, snd_xy disable, gen_st – I0 = garbage, garbage, s, t
Param_Gen_I0 enable, snd_xy enable, no gen_st – I0 = screen x, screen y, garbage, faceness
Param_Gen_I0 enable, snd_xy enable, gen_st – I0 = screen x, screen y, s, t

20.3 Auto generated counters

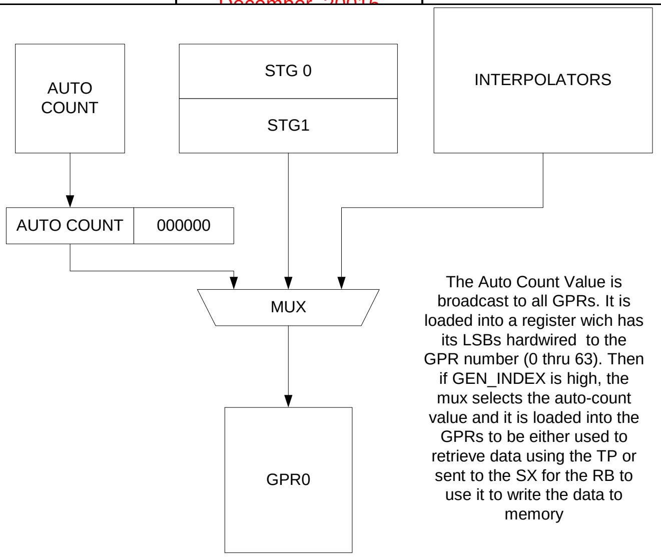
In the cases we are dealing with multipass shaders, the sequencer is going to generate a vector count to be able to both use this count to write the 1st pass data to memory and then use the count to retrieve the data on the 2nd pass. The count is always generated in the same way but it is passed to the shader in a slightly different way depending on the shader type (pixel or vertex). This is toggled on and off using the GEN_INDEX register. While there is only one count broadcast to the ~~registers~~GPRs, the LSB are hardwired to specific values making the index different for all elements in the vector.

20.3.1 *Vertex shaders*

In the case of vertex shaders, if GEN_INDEX is set, the data will be put into the x field of the third register (it means that the compiler must allocate 3 GPRs in all multipass vertex shader modes).

20.3.2 *Pixel shaders*

In the case of pixel shaders, if GEN_INDEX is set, the data will be put in the x field of the 2nd register (I1.x).



The Auto Count Value is broadcast to all GPRs. It is loaded into a register wich has its LSBs hardwired to the GPR number (0 thru 63). Then if GEN_INDEX is high, the mux selects the auto-count value and it is loaded into the GPRs to be either used to retrieve data using the TP or sent to the SX for the RB to use it to write the data to memory

21. State management

Every clock, the sequencer will report to the CP the oldest states still in the pipe. These are the states of the programs as they enter the last ALU clause.

21.1 Parameter cache synchronization

Formatted: Bullets and Numbering

In order for the sequencer not to begin a group of pixels before the associated group of vertices has finished, the sequencer will keep a 6 bit count per state (for a total of 8 counters). These counters are initialized to 0 and every time a vertex shader exports its data TO THE PARAMETER CACHE, the corresponding pointer is incremented. When the SC sends a new vector of pixels with the SC_SQ_new_vector bit asserted, the sequencer will first check if the count is greater than 0 before accepting the transmission (it will in fact accept the transmission but then lower its ready to receive). Then the sequencer waits for the count to go to one and decrements it. The sequencer can then issue the group of pixels to the interpolators. Every time the state changes, the new state counter is initialized to 0.

22. XY Address imports

The SC will be able to send the XY addresses to the GPRs. It does so by interleaving the writes of the IJs (to the IJ buffer) with XY writes (to the XY buffer). Then when writing the data to the GPRs, the sequencer is going to interpolate the IJ data or pass the XY data thru a Fix→float converter and expander and write the converted values to the GPRs. The Xys are currently SCREEN SPACE COORDINATES. The values in the XY buffers will wrap. See section 20.2 for details on how to control the interpolation in this mode.

22.1 Vertex indexes imports

In order to import vertex indexes, we have 64x2x96 staging ~~registers~~registers. These are loaded one at a time by the VGT block. They are loaded in floating point format and can be transferred in 4 or 8 clocks to the GPRs.

23. ~~Registers~~Registers

23.1 Control

REG_DYNAMIC Dynamic allocation (pixel/vertex) of the register file on or off.

REG_SIZE_PIX Size of the register file's pixel portion (minimal size when dynamic allocation turned on)

REG_SIZE_VTX Size of the register file's vertex portion (minimal size when dynamic allocation turned on)

ARBITRATION_POLICY policy of the arbitration between vertexes and pixels

INST_STORE_ALLOC interleaved, separate

INST_BASE_VTX start point for the vertex instruction store (RT always ends at vertex_base and Begins at 0)

INST_BASE_PIX start point for the pixel shader instruction store

ONE_THREAD debug state register. Only allows one program at a time into the GPRs

ONE_ALU debug state register. Only allows one ALU program at a time to be executed (instead of 2)

INSTRUCTION_~~INDEX~~ ~~_PORT~~ADDR This is where the CP puts the base address of the instruction writes and type (auto-incremented on reads/writes)

INSTRUCTION_DATA This is where the CP puts the actual data going to the instruction memory

CONSTANT_DATA This is where the CP puts constant data (32 bits)

CONSTANT_ADDR This is where the CP puts the logical constant address (9 bits)

INSTRUCTION_~~INDEX~~ ~~PORT~~ADDR_RT This is where the CP puts the base address of the instruction writes and type for Real Time (auto-incremented on reads/writes)

INSTRUCTION_DATA_RT This is where the CP puts the actual data going to the instruction memory for Real Time

CONSTANT_DATA_RT This is where the CP puts constant data for Real Time (32 bits)

CONSTANT_ADDR_RT This is where the CP puts the logical constant address for Real Time (9 bits)

CONSTANT_EO_RT This is the size of the space reserved for real time in the constant store (from 0 to CONSTANT_EO_RT). The ~~remaping~~re-mapping table operates on the rest of the memory

EXPORT_LATE Controls whether or not we are exporting position from clause 3. If set, position exports occur at clause 7.

23.2 Context

VS_FETCH_{0…7} eight 8 bit pointers to the location where each clauses control program is located

VS_ALU_{0…7} eight 8 bit pointers to the location where each clauses control program is located

PS_FETCH_{0…7} eight 8 bit pointers to the location where each clauses control program is located

PS_ALU_{0…7} eight 8 bit pointers to the location where each clauses control program is located

PS_BASE base pointer for the pixel shader in the instruction store

VS_BASE base pointer for the vertex shader in the instruction store

VS_CF_SIZE size of the vertex shader (# of instructions in control program/2)

PS_CF_SIZE size of the pixel shader (# of instructions in control program/2)

PS_SIZE size of the pixel shader (cntl+instructions)

VS_SIZE size of the vertex shader (cntl+instructions)

PS_NUM_REG number of ~~registers~~GPRs to allocate for pixel shader programs

VS_NUM_REG number of ~~registers~~GPRs to allocate for vertex shader programs

PARAM_SHADE One 16 bit register specifying which parameters are to be gouraud shaded (0 = flat, 1 = gouraud)

PARAM_WRAP 64 bits: for which parameters (and channels (xyzw)) do we do the cyl wrapping (0=linear, 1=cylindrical).

PS_EXPORT_MODE 0xxxx : Normal mode
1xxxx : Multipass mode
If normal, bbbz where bbb is how many colors (0-4) and z is export z or not
If multipass 1-12 exports for color.

VS_EXPORT_MASK which of the last 6 ALU clauses is exporting (multipass only)

VS_EXPORT_MODE 0: position (1 vector), 1: position (2 vectors), 3:multipass

VS_EXPORT _COUNT_{0…6} Six 4 bit counters representing the # of interpolated parameters exported in clause 7 (located in VS_EXPORT_COUNT_6) OR
# of exported vectors to memory per clause in multipass mode (per clause)

PARAM_GEN_I0	Do we overwrite or not the parameter 0 with XY data and generated T and S values
GEN_INDEX	Auto generates an address from 0 to XX. Puts the results into R1 for pixel shaders and R3 for vertex shaders
CONST_BASE_VTX (9 bits)	Logical Base address for the constants of the Vertex shader
CONST_BASE_PIX (9 bits)	Logical Base address for the constants of the Pixel shader
CONST_SIZE_PIX (8 bits)	Size of the logical constant store for pixel shaders
CONST_SIZE_VTX (8 bits)	Size of the logical constant store for vertex shaders
INST_PRED_OPTIMIZE	Turns on the predicate bit optimization (if of, conditional_execute_predicates is always executed).
CF_BOOLEANS	256 boolean bits
CF_LOOP_COUNT	32x8 bit counters (number of times we traverse the loop)
CF_LOOP_START	32x8 bit counters (init value used in index computation)
CF_LOOP_STEP	32x8 bit counters (step value used in index computation)

24. DEBUG ~~registers~~Registers

24.1 Context

DB_PROB_ADDR	instruction address where the first problem occurred
DB_PROB_COUNT	number of problems encountered during the execution of the program
DB_INST_COUNT	instruction counter for debug method 2
DB_BREAK_ADDR	break address for method number 2
DB_CLAUSE _MODE_ALU_{0…7}	clause mode for debug method 2 (0: normal, 1: addr, 2: kill)
DB_CLAUSE _MODE_FETCH_{0…7}	clause mode for debug method 2 (0: normal, 1: addr, 2: kill)

25. Interfaces

25.1 External Interfaces

Whenever an x is used, it means that the bus is broadcast to all units of the same name. For example, if a bus is named SQ→SPx it means that SQ is going to broadcast the same information to all SP instances.

~~25.1.1 SC to SP : IJ bus~~

Formatted: Bullets and Numbering

~~This is a bus that sends the IJ information to the IJ fifos on the top of each shader pipe. At the same time the control information goes to the sequencer. There are 4 of these buses over the whole chip (SP0 thru 3)~~

~~25.1.2~~25.1.1 *SC to SQ : IJ Control bus*

Formatted: Bullets and Numbering

This is the control information sent to the sequencer in order to control the IJ fifos and all other information needed to execute a shader program on the sent pixels. This information is sent over 2 clocks, if SENDXY is asserted the next control packet is going to be ignored and XY information is going to be sent on the IJ bus (for the quads that where just sent). All pixels from the group of quads are from the same primitive, all quads of a vector are from the same render state.

Name	Direction	Bits	Description
SC_SQ_q_wr_mask	SC→SQ	4	Quad Write mask left to right
SC_SQ_lod_correct	SC→SQ	24	LOD correction per quad (6 bits per quad)
SC_SQ_flat_vertex	SC→SQ	2	Provoking vertex for flat shading
SC_SQ_param_ptr0	SC→SQ	11	P Store pointer for vertex 0
SC_SQ_param_ptr1	SC→SQ	11	P Store pointer for vertex 1
SC_SQ_param_ptr2	SC→SQ	11	P Store pointer for vertex 2
SC_SQ_end_of_vect	SC→SQ	1	End of the vector
SC_SQ_store_dealloc	SC→SQ	1	Deallocation token for the P Store
SC_SQ_state	SC→SQ	3	State/constant pointer ~~(6*3+3)~~
SC_SQ_valid_pixel	SC→SQ	16	Valid bits for all pixels
SC_SQ_null_prim	SC→SQ	1	Null Primitive (for PC deallocation purposes)
SC_SQ_end_of_prim	SC→SQ	1	End Of the primitive
SC_SQ_fbface	SC→SQ	1	Front face = 1, back face = 0
SC_SQ_send_xy	SC→SQ	1	Sending XY information [XY information is going to be sent on the next clock]
SC_SQ_prim_type	SC→SQ	3	Real time command need to load tex cords from alternate buffer. Line AA, Point AA and Sprite reads their parameters from GEN_T and GEN_S ~~registers~~GPRs. 000 : Normal 011 : Real Time 100 : Line AA 101 : Point AA 110 : Sprite
SC_SQ_new_vector	SC→SQ	1	This primitive comes from a new vector of vertices. Make sure that the corresponding vertex shader has finished before starting the group of pixels.
SC_SQ_RTRn	SQ→SC	1	Stalls the PA in n clocks
SC_SQ_RTS	SC→SQ	1	SC ready to send data

~~25.1.3~~25.1.2 *SQ to SP: Interpolator bus*

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
SQ_SPx_interp_prim_type	SQ→SPx	3	Type of the primitive 000 : Normal 011 : Real Time 100 : Line AA 101 : Point AA 110 : Sprite
SQ_SPx_interp_flat_vtx	SQ→SPx	2	Provoking vertex for flat shading
SQ_SPx_interp_flat_gouraud	SQ→SPx	1	Flat or gouraud shading
SQ_SPx_interp_cyl_wrap	SQ→SPx	4	Wich parameter needs to be cylindrical wrapped
SQ_SPx_interp_ijline	SQ→SPx	2	Line in the IJ/XY buffer to use to interpolate
SQ_SPx_interp_buff_swap	SQ→SPx	1	Swap the IJ/XY buffers at the end of the interpolation
SQ_SPx_interp_gen_I0	SQ→SPx	1	Generate I0 or not. This tells the interpolators not to use the parameter cache but rather overwrite the data with interpolated 1 and 0. Overwrite if gen_I0 is high.

~~25.1.4~~25.1.3 *SQ to SP: GPR Input Mux select*

Formatted: Bullets and Numbering

This interface is synchronized with the Interpolator bus. This controls the input mux to the GPRs. The three types of data are: generated index, Interpolated data, vertex index data (coming from the staging ~~registers~~registers).

Name	Direction	Bits	Description
SQ_SPx_data_type	SQ→SPx	2	00: Interpolated data 01: Staging register data 1x: Count
SQ_SPx_index_count	SQ→SPx	12?	Index count, common for all shader pipes
SQ_SPx_stage_addr	SQ→SPx	1	Staging register address 0: First staging register 1: second staging register

~~25.1.5 SQ to SPx: Parameter cache write control~~

Formatted: Bullets and Numbering

~~25.1.6~~25.1.4 SQ to SP: Parameter Cache Read control bus

The four following interfaces (SQ→SP, SQ→SX,SP→SX and SX→Interpolators) are all SYNCHRONIZED together.

Name	Direction	Bits	Description
SQ_SPx_ptr0	SQ→SPx	9	Pointer of PC
SQ_SPx_ptr1	SQ→SPx	9	Pointer of PC
SQ_SPx_ptr2	SQ→SPx	9	Pointer of PC
SQ_SP0_read_ena	SQ→SP0	4	Read enables for the 4 memories in the SP0
SQ_SP1_read_ena	SQ→SP1	4	Read enables for the 4 memories in the SP1
SQ_SP2_read_ena	SQ→SP2	4	Read enables for the 4 memories in the SP2
SQ_SP3_read_ena	SQ→SP3	4	Read enables for the 4 memories in the SP3

~~25.1.7~~25.1.5 SQ to SX: Parameter Cache Mux control Bus

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
SQ_SXx_mux0	SQ→SXx	4	Mux control for PC (4 MSbs of Pointer)
SQ_SXx_mux1	SQ→SXx	4	Mux control for PC (4 MSbs of Pointer)
SQ_SXx_mux2	SQ→SXx	4	Mux control for PC (4 MSbs of Pointer)

~~25.1.8 SP to SX: Parameter data~~

Formatted: Bullets and Numbering

~~25.1.9 SX to Interpolators: Parameter Cache Return bus~~

Formatted: Bullets and Numbering

~~25.1.10~~25.1.6 SQ to SP~~0~~: Staging Register Data

Name	Direction	Bits	Description
SQ_SP0_vgt_vsisr_data	SQ→SP0	96	Pointers of indexes or HOS surface information
SQ_SP0_vgt_vsisr_double	SQ→SP0	1	0: Normal 96 bits per vert 1: double 192 bits per vert
SQ_SP0_data_valid	SQ→SP0	1	Data is valid
SQ_SP1_vgt_vsisr_data	SQ→SP1	96	Pointers of indexes or HOS surface information
SQ_SP1_vgt_vsisr_double	SQ→SP1	1	0: Normal 96 bits per vert 1: double 192 bits per vert
SQ_SP1_data_valid	SQ→SP1	1	Data is valid
SQ_SP2_vgt_vsisr_data	SQ→SP2	96	Pointers of indexes or HOS surface information
SQ_SP2_vgt_vsisr_double	SQ→SP2	1	0: Normal 96 bits per vert 1: double 192 bits per vert
SQ_SP2_data_valid	SQ→SP2	1	Data is valid
SQ_SP3_vgt_vsisr_data	SQ→SP3	96	Pointers of indexes or HOS surface information
SQ_SP3_vgt_vsisr_double	SQ→SP3	1	0: Normal 96 bits per vert 1: double 192 bits per vert
SQ_SP3_data_valid	SQ→SP3	1	Data is valid

~~25.1.11~~25.1.7 PA to SQ : Vertex interface

Formatted: Bullets and Numbering

~~25.1.11.1~~25.1.7.1 Interface Signal Table

The area difference between the two methods is not sufficient to warrant complicating the interface or the state requirements of the VSISRs. **Therefore, the POR for this interface is that the VGT will transmit the data to the**

VSISRs (via the Shader Sequencer) in full, 32-bit floating-point format. The VGT can transmit up to six 32-bit floating-point values to each VSISR where four or more values require two transmission clocks. The data bus is 96 bits wide.

Name	Bits	Description
PA_SQ_vgt_vsisr_data	96	Pointers of indexes or HOS surface information
PA_SQ_vgt_vsisr_double	1	0: Normal 96 bits per vert 1: double 192 bits per vert
PA_SQ_vgt_end_of_vector	1	Indicates the last VSISR data set for the current process vector (for double vector data, "end_of_vector" is set on the second vector)
PA_SQ_vgt_state	3	Render State (6*3+3 for constants). This signal is guaranteed to be correct when “PA_SQ_vgt_end_of_vector” is high.
PA_SQ_vgt_send	1	Data on the VGT_SQ is valid receive (see write-up for standard R400 SEND/RTR interface handshaking)
SQ_PA_vgt_rtr	1	Ready to receive (see write-up for standard R400 SEND/RTR interface handshaking)

~~25.1.12~~25.1.8 *SQ to CP: State report*

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
SQ_CP_vrtx_ state	SEQ→CP	3	Oldest vertex state still in the pipe
SQ_CP_pix_state	SEQ→CP	3	Oldest pixel state still in the pipe

~~25.1.13 *SP to SX : Pixel/Vertex write to SX*~~

Formatted: Bullets and Numbering

~~25.1.14~~25.1.9 *SQ to SX: Control bus*

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
SQ_SXx_exp_Pixel	SQ→SXx	1	1: Pixel 0: Vertex
SQ_SXx_exp_start	SQ→SXx	1	Raised to indicate that the SQ is starting an export
SQ_SXx_exp_Clause	SQ→SXx	3	Clause number, which is needed for vertex clauses
SQ_SXx_exp_State	SQ→SXx	3	State ID, which is needed for vertex clauses

These fields are sent synchronously with SP export data, described in SP0→SX0 interface
{ISSUE: Where are the PC pointers}

~~25.1.15~~25.1.10 *SX to SQ : Output file control*

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
SXx_SQ_Export_count_rdy	SXx→SQ	1	Raised by SX0 to indicate that the following two fields reflect the result of the most recent export
SXx_SQ_Export_Position	SXx→SQ	1	Specifies whether there is room for another position.
SXx_SQ_Export_Buffer	SXx→SQ	7	Specifies the space available in the output buffers. 0: buffers are full 1: 2K-bits available (32-bits for each of the 64 pixels in a clause) ... 64: 128K-bits available (16 128-bit entries for each of 64 pixels) 65-127: RESERVED

~~25.1.16 *Shader Engine to Fetch Unit Bus*~~

Formatted: Bullets and Numbering

~~Four quad's worth of addresses is transferred to Fetch Unit every clock. These are sourced from a different pixel within each of the sub-engines repeating every 4 clocks. The register file index to read must precede the data by 2 clocks. The Read address associated with Quad 0 must be sent 1 clock after the Instruction Start signal is sent, so that data is read 3 clocks after the Instruction Start.~~

~~Four Quad's worth of Fetch Data may be written to the Register file every clock. These are directed to a different pixel of the sub-engines repeating every 4 clocks. The register file index to write must accompany the data. Data and Index associated with the Quad 0 must be sent 3 clocks after the Instruction Start signal is sent.~~

~~25.1.17~~25.1.11 *~~Sequencer to Fetch Unit bus~~SQ to TP: Control bus*

Formatted: Bullets and Numbering

Once every clock, the fetch unit sends to the sequencer on which clause it is now working and if the data in the ~~registers~~GPRs is ready or not. This way the sequencer can update the fetch counters for the reservation station fifos. The sequencer also provides the instruction and constants for the fetch to execute and the address in the register file where to write the fetch return data.

Name	Direction	Bits	Description
TPx_SQ_data_rdy	TPx→ SQ	1	Data ready

TPx_SQ_clause_num	TPx→ SQ	3	Clause number
SQ_TPx_const	SQ→TPx	64	Fetch state sent over 4 clocks
SQ_TPx_instuct	SQ→TPx	24	Fetch instruction sent over 4 clocks
SQ_TPx_end_of_clause	SQ→TPx	1	Last instruction of the clause
SQ_TPx_phase	SQ→TPx	2	Write phase signal

26. Examples of program executions

26.1.1 *Sequencer Control of a Vector of Vertices*

1. PA sends a vector of 64 vertices (actually vertex indices – 32 bits/index for 2048 bit total) to the RE's Vertex FIFO
   - state pointer as well as tag into position cache is sent along with vertices
   - space was allocated in the position cache for transformed position before the vector was sent
   - **also before the vector is sent to the RE, the CP has loaded the global instruction store with the vertex shader program (using the MH?)**
   - The vertex program is assumed to be loaded when we receive the vertex vector.
     - the SEQ then accesses the IS base for this shader using the local state pointer (provided to all sequencers by the RBBM when the CP is done loading the program)
2. SEQ arbitrates between the Pixel FIFO and the Vertex FIFO – basically the Vertex FIFO always has priority
   - at this point the vector is removed from the Vertex FIFO
   - the arbiter is not going to select a vector to be transformed if the parameter cache is full unless the pipe as nothing else to do (ie no pixels are in the pixel fifo).

3. SEQ allocates space in the SP register file for index data plus GPRs used by the program
   - the number of GPRs required by the program is stored in a local state register, which is accessed using the state pointer that came down with the vertices
   - SEQ will not send vertex data until space in the register file has been allocated
4. SEQ sends the vector to the SP register file over the RE_SP interface (which has a bandwidth of 2048 bits/cycle)
   - the 64 vertex indices are sent to the 64 register files over 4 cycles
     - RF0 of SU0, SU1, SU2, and SU3 is written the first cycle
     - RF1 of SU0, SU1, SU2, and SU3 is written the second cycle
     - RF2 of SU0, SU1, SU2, and SU3 is written the third cycle
     - RF3 of SU0, SU1, SU2, and SU3 is written the fourth cycle
   - the index is written to the least significant 32 bits **(floating point format?) (what about compound indices)** of the 128-bit location within the register file (w); the remaining data bits are set to zero (x, y, z)
5. SEQ constructs a control packet for the vector and sends it to the first reservation station (the FIFO in front of fetch state machine 0, or TSM0 FIFO)
   - the control packet contains the state pointer, the tag to the position cache and a register file base pointer.
6. TSM0 accepts the control packet and fetches the instructions for fetch clause 0 from the global instruction store
   - TSM0 was first selected by the TSM arbiter before it could start
7. all instructions of fetch clause 0 are issued by TSM0
8. the control packet is passed to the next reservation station (the FIFO in front of ALU state machine 0, or ASM0 FIFO)
   - TSM0 does not wait for requests made to the Fetch Unit to complete; it passes the register file write index for the fetch data to the TU, which will write the data to the RF as it is received
   - once the TU has written all the data to the register files, it increments a counter that is associated with ASM0 FIFO; a count greater than zero indicates that the ALU state machine can go ahead start to execute the ALU clause
9. ASM0 accepts the control packet (after being selected by the ASM arbiter) and gets the instructions for ALU clause 0 from the global instruction store
10. all instructions of ALU clause 0 are issued by ASM0, then the control packet is passed to the next reservation station (the FIFO in front of fetch state machine 1, or TSM1 FIFO)
11. the control packet continues to travel down the path of reservation stations until all clauses have been executed
    - position can be exported in ALU clause 3 (or 4?); the data (and the tag) is sent over a position bus (which is shared with all four shader pipes) back to the PA's position cache
    - A parameter cache pointer is also sent along with the position data. This tells to the PA where the data is going to be in the parameter cache.
      - there is a position export FIFO in the SP that buffers position data before it gets sent back to the PA
      - the ASM arbiter will prevent a packet from starting an exporting clause if the position export FIFO is full
    - parameter data is exported in clause 7 (as well as position data if it was not exported earlier)
      - parameter data is sent to the Parameter Cache over a dedicated bus
      - the SEQ allocates storage in the Parameter Cache, and the SEQ deallocates that space when there is no longer a need for the parameters (it is told by the PA when using a token).
      - the ASM arbiter will prevent a packet from starting on ASM7 if the parameter cache (or the position buffer if position is being exported) is full
12. after the shader program has completed, the SEQ will free up the GPRs so that they can be used by another shader program

26.1.2 *Sequencer Control of a Vector of Pixels*

1. **As with vertex shader programs, pixel shaders are loaded into the global instruction store by the CP**

   - At this point it is assumed that the pixel program is loaded into the instruction store and thus ready to be read.

2. the RE's Pixel FIFO is loaded with the barycentric coordinates for pixel quads by the detailed walker
   - the state pointer and the LOD correction bits are also placed in the Pixel FIF0
   - the Pixel FIFO is wide enough to source four quad's worth of barycentrics per cycle

3. SEQ arbitrates between Pixel FIFO and Vertex FIFO – when there are no vertices pending OR there is no space left in the register files for vertices, the Pixel FIFO is selected
4. SEQ allocates space in the SP register file for all the GPRs used by the program
   - the number of GPRs required by the program is stored in a local state register, which is accessed using the state pointer
   - SEQ will not allow interpolated data to be sent to the shader until space in the register file has been allocated
5. SEQ controls the transfer of interpolated data to the SP register file over the RE_SP interface (which has a bandwidth of 2048 bits/cycle). See interpolated data bus diagrams for details.
6. SEQ constructs a control packet for the vector and sends it to the first reservation station (the FIFO in front of fetch state machine 0, or TSM0 FIFO)
   - note that there is a separate set of reservation stations/arbiters/state machines for vertices and for pixels
   - the control packet contains the state pointer, the register file base pointer, and the LOD correction bits
   - all other information (such as quad address for example) travels in a separate FIFO
7. TSM0 accepts the control packet and fetches the instructions for fetch clause 0 from the global instruction store
   - TSM0 was first selected by the TSM arbiter before it could start
8. all instructions of fetch clause 0 are issued by TSM0
9. the control packet is passed to the next reservation station (the FIFO in front of ALU state machine 0, or ASM0 FIFO)
   - TSM0 does not wait for fetch requests made to the Fetch Unit to complete; it passes the register file write index for the fetch data to the TU, which will write the data to the RF as it is received
   - once the TU has written all the data for a particular clause to the register files, it increments a counter that is associated with the ASM0 FIFO; a count greater than zero indicates that the ALU state machine can go ahead and pop the FIFO and start to execute the ALU clause
10. ASM0 accepts the control packet (after being selected by the ASM arbiter) and gets the instructions for ALU clause 0 from the global instruction store
11. all instructions of ALU clause 0 are issued by ASM0, then the control packet is passed to the next reservation station (the FIFO in front of fetch state machine 1, or TSM1 FIFO)
12. the control packet continues to travel down the path of reservation stations until all clauses have been executed
    - pixel data is exported in the last ALU clause (clause 7)
      - it is sent to an output FIFO where it will be picked up by the render backend
      - the ASM arbiter will prevent a packet from starting on ASM7 if the output FIFO is full
13. after the shader program has completed, the SEQ will free up the GPRs so that they can be used by another shader program

26.1.3 *Notes*

14. The state machines and arbiters will operate ahead of time so that they will be able to immediately start the real threads or stall.
15. The register file base pointer for a vector needs to travel with the vector through the reservation stations, but the instruction store base pointer does not – this is because the RF pointer is different for all threads, but the IS pointer is only different for each state and thus can be accessed via the state pointer.

~~16. Waterfalling still needs to be specked out.~~

Formatted: Bullets and Numbering

27. Open issues

~~There is currently an issue with constants. If the constants are not the same for the whole vector of vertices, we don't have the bandwidth from the fetch store to feed the ALUs. Two solutions exists for this problem:~~

~~1)Let the compiler handle the case and put those instructions in a fetch clause so we can use the bandwidth there to operate. This requires a significant amount of temporary storage in the register store.~~

Formatted: Bullets and Numbering

~~2)Waterfall down the pipe allowing only at a given time the vertices having the same constants to operate in parallel. This might in the worst case slow us down by a factor of 16.~~

Need to do some testing on the size of the register file as well as on the register file allocation method (dynamic VS static).

Saving power?

Version 1.6~~5~~

Overview: This is an architectural specification for the R400 Sequencer block (SEQ). It provides an overview of the required capabilities and expected uses of the block. It also describes the block interfaces, internal sub-blocks, and provides internal state diagrams.

Revision Changes:

Rev 0.1 (Laurent Lefebvre) Date: May 7, 2001	First draft.
Rev 0.2 (Laurent Lefebvre) Date : July 9, 2001	Changed the interfaces to reflect the changes in the SP. Added some details in the arbitration section.
Rev 0.3 (Laurent Lefebvre) Date : August 6, 2001	Reviewed the Sequencer spec after the meeting on August 3, 2001.
Rev 0.4 (Laurent Lefebvre) Date : August 24, 2001	Added the dynamic allocation method for register file and an example (written in part by Vic) of the flow of pixels/vertices in the sequencer.
Rev 0.5 (Laurent Lefebvre) Date : September 7, 2001	Added timing diagrams (Vic)
Rev 0.6 (Laurent Lefebvre) Date : September 24, 2001	Changed the spec to reflect the new R400 architecture. Added interfaces.
Rev 0.7 (Laurent Lefebvre) Date : October 5, 2001	Added constant store management, instruction store management, control flow management and data dependant predication.
Rev 0.8 (Laurent Lefebvre) Date : October 8, 2001	Changed the control flow method to be more flexible. Also updated the external interfaces.
Rev 0.9 (Laurent Lefebvre) Date : October 17, 2001	Incorporated changes made in the 10/18/01 control flow meeting. Added a NOP instruction, removed the conditional_execute_or_jump. Added debug registers.
Rev 1.0 (Laurent Lefebvre) Date : October 19, 2001	Refined interfaces to RB. Added state registers.
Rev 1.1 (Laurent Lefebvre) Date : October 26, 2001	Added SEQ→SP0 interfaces. Changed delta precision. Changed VGT→SP0 interface. Debug Methods added.
Rev 1.2 (Laurent Lefebvre) Date : November 16, 2001	Interfaces greatly refined. Cleaned up the spec.
Rev 1.3 (Laurent Lefebvre) Date : November 26, 2001	Added the different interpolation modes.
Rev 1.4 (Laurent Lefebvre) Date : December 6, 2001	Added the auto incrementing counters. Changed the VGT→SQ interface. Added content on constant management. Updated GPRs.
Rev 1.5 (Laurent Lefebvre) Date : December 11, 2001	Removed from the spec all interfaces that weren't directly tied to the SQ. Added explanations on constant management. Added PA→SQ synchronization fields and explanation.
Rev 1.6 (Laurent Lefebvre) Date : January 7, 2002	Added more details on the staging register. Added detail about the parameter caches. Changed the call instruction to a Conditionnal call instruction. Added details on constant management and updated the diagram.

1. Overview

The sequencer is based on the R300 design. It chooses two ALU clauses and a fetch clause to execute, and executes all of the instructions in a clause before looking for a new clause of the same type. Two ALU clauses are executed interleaved to hide the ALU latency. Each vector will have eight fetch and eight ALU clauses, but clauses do not need to contain instructions. A vector of pixels or vertices ping-pongs along the sequencer FIFO, bouncing from fetch reservation station to alu reservation station. A FIFO exists between each reservation stage, holding up vectors until the vector currently occupying a reservation station has left. A vector at a reservation station can be chosen to execute. The sequencer looks at all eight alu reservation stations to choose an alu clause to execute and all eight fetch stations to choose a fetch clause to execute. The arbitrator will give priority to clauses/reservation stations closer to the bottom of the pipeline. It will not execute an alu clause until the fetch fetches initiated by the previous fetch clause have completed. There are two separate sets of reservation stations, one for pixel vectors and one for vertices vectors. This way a pixel can pass a vertex and a vertex can pass a pixel.

To support the shader pipe the sequencer also contains the shader instruction cache, constant store, control flow constants and texture state. The four shader pipes also execute the same instruction thus there is only one sequencer for the whole chip.

The sequencer first arbitrates between vectors of 64 vertices that arrive directly from primitive assembly and vectors of 16 quads (64 pixels) that are generated in the scan converter.

The vertex or pixel program specifies how many GPRs it needs to execute. The sequencer will not start the next vector until the needed space is available in the GPRs.

There are two sets of the above figure, one for vertices and one for pixels.

Depending on the arbitration state, the sequencer will either choose a vertex or a pixel packet. The control packet consists of 3 bits of state, 7 bits for the base address of the Shader program and some information on the coverage to determine fetch LOD plus other various small state bits.

On receipt of a packet, the input state machine (not pictured but just before the first FIFO) allocated enough space in the GPRs to store the interpolated values and temporaries. Following this, the barycentric coordinates (and XY screen position if needed) are sent to the interpolator which will use them to interpolate the parameters and place the results into the GPRs. Then, the input state machine stacks the packet in the first FIFO.

On receipt of a command, the level 0 fetch machine issues a fetch request to the TP and corresponding GPR address for the fetch address (ta). A small command (tcmd) is passed to the fetch system identifying the current level number (0) as well as the GPR write address for the fetch return data. One fetch request is sent every 4 clocks causing the texturing of sixteen 2x2s worth of data (or 64 vertices). Once all the requests are sent the packet is put in FIFO 1.

Upon receipt of the return data, the fetch unit writes the data to the register file using the write address that was provided by the level 0 fetch machine and sends the clause number (0) to the level 0 fetch state machine to signify that the write is done and thus the data is ready. Then, the level 0 fetch machine increments the counter of FIFO 1 to signify to the ALU 0 that the data is ready to be processed.

On receipt of a command, the level 0 ALU machine first decrements the input FIFO 1 counter and then issues a complete set of level 0 shader instructions. For each instruction, the ALU state machine generates 3 source addresses, one destination address and an instruction. Once the last instruction has been issued, the packet is put into FIFO 2.

There will always be two active ALU clauses at any given time (and two arbiters). One arbiter will arbitrate over the odd instructions (4 clocks cycles) and the other one will arbitrate over the even instructions (4 clocks cycles). The only constraints between the two arbiters is that they are not allowed to pick the same clause number as the other one is currently working on if the packet is not of the same type (render state).

If the packet is a vertex packet, upon reaching ALU clause 3, it can export the position if the position is ready. So the arbiter must prevent ALU clause 3 to be selected if the positional buffer is full (or can't be accessed). Along with the positional data, if needed the sprite size and/or edge flags can also be sent.

~~{ISSUE: How do we handle parameter cache pointers (computed, semi-computed or not computed)?}~~

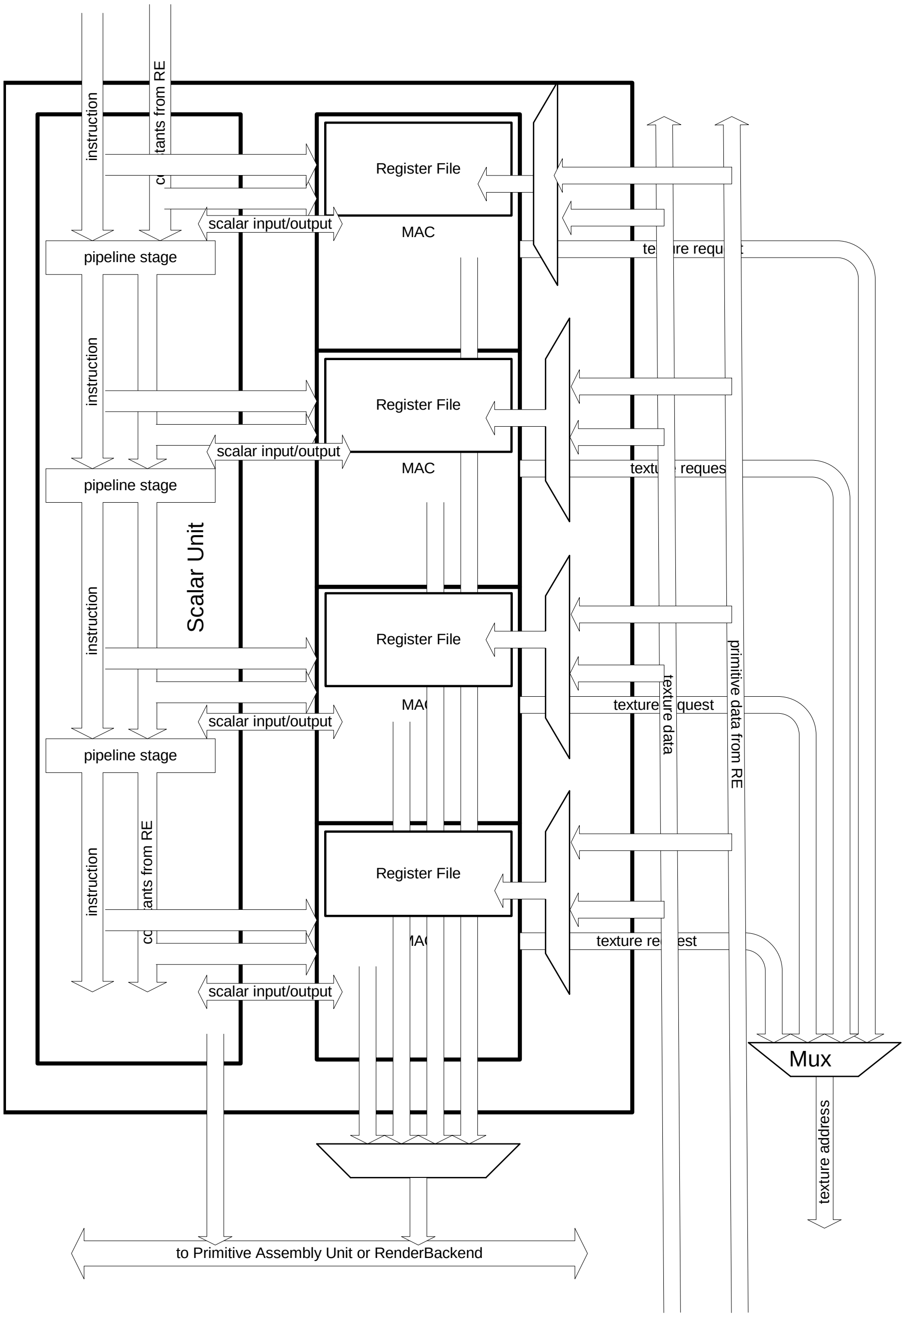
A special case is for multipass vertex shaders, which can export 12 parameters per last 6 clauses to the output buffer. If the output buffer is full or doesn't have enough space the sequencer will prevent such a vertex group to enter an exporting clause.

Multipass pixel shaders can export 12 parameters to memory from the last clause only (7).

All other clauses process in the same way until the packet finally reaches the last ALU machine (7).

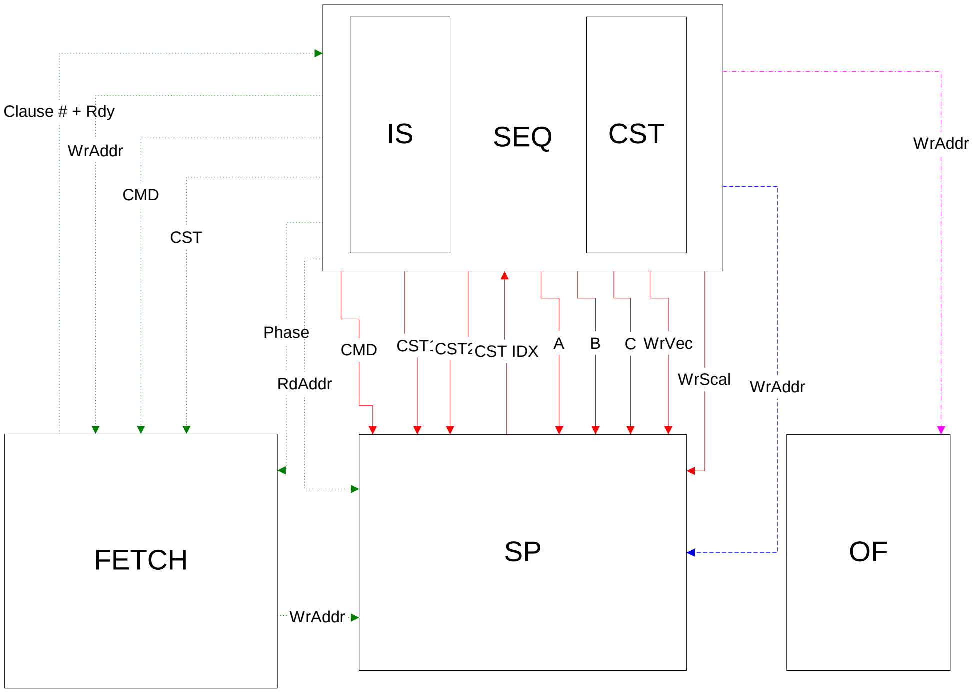
Only one pair of interleaved ALU state machines may have access to the register file address bus or the instruction decode bus at one time. Similarly, only one fetch state machine may have access to the register file address bus at one time. Arbitration is performed by three arbiter blocks (two for the ALU state machines and one for the fetch state machines). The arbiters always favor the higher number state machines, preventing a bunch of half finished jobs from clogging up the register files.

1.2 Data Flow graph (SP)



The gray area represents blocks that are replicated 4 times per shader pipe (16 times on the overall chip).

1.3 Control Graph



In green is represented the Fetch control interface, in red the ALU control interface, in blue the Interpolated/Vector control interface and in purple is the output file control interface.

2. Interpolated data bus

The interpolators contain an IJ buffer to pack the information as much as possible before writing it to the register file.

Above is an example of a tile the sequencer might receive from the SC. The write side is how the data get stacked into the XY and IJ buffers, the read side is how the data is passed to the GPRs. The IJ information is packed in the IJ buffer 4 quads at a time or two clocks. The sequencer allows at any given time as many as four quads to interpolate a parameter. They all have to come from the same primitive. Then the sequencer controls the write mask to the GPRs to write the valid data in.

3. Instruction Store

There is going to be only one instruction store for the whole chip. It will contain 4096 instructions of 96 bits each.

It is likely to be a 1 port memory; we use 1 clock to load the ALU instruction, 1 clocks to load the Fetch instruction, 1 clock to load 2 control flow instructions and 1 clock to write instructions.

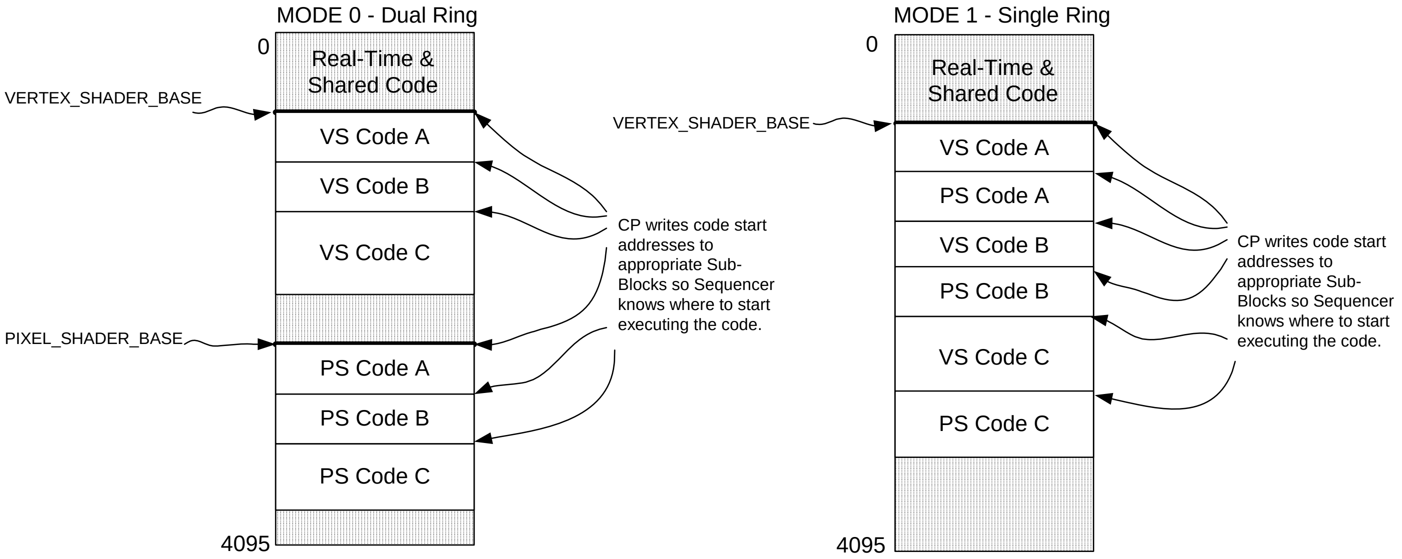
The instruction store is loaded by the CP thru the ~~INST_DATA, INST_INDEX_PORT control register. The INST_INDEX_PORT is auto-incremented on both reads and writes to the INST_DATA register.~~register mapped registers.

The next picture shows the various modes the CP can load the memory. The Sequencer has to keep track of the loading modes in order to wrap around the correct boundaries. ~~The MSB of the INST_INDEX_PORT register contains the packet type for the sequencer to know where it must wrap around.~~ The ~~wrap around points are~~wrap around points are arbitrary and they are specified in the VS_BASE and PIX_BASE registers.

For the Real time commands the story is quite the same but for some small differences. ~~The CP will use the INST_INDEX_PORT_RT and INST_DATA_RT register pair instead of the regular ones and T~~there are no wrap around points for real time so the driver must be careful not to overwrite regular shader data. The shared code (shared subroutines) uses the same path as real time.

R400 CP's Views of Instruction Memory

Updated: 11/14/2001
John A. Carey



4. Sequencer Instructions

All control flow instructions and move instructions are handled by the sequencer only. The ALUs will perform NOPs during this time (MOV PV,PV, PS,PS) if they have nothing else to do.

5. Constant Stores

5.1 Memory organizations

A likely size for the ALU constant store is 1024x128 bits. The read BW from the ALU constant store is 128 bits/clock and the write bandwidth is 32 bits/clock (directed by the CP bus size not by memory ports).

The maximum logical size of the constant store for a given shader is 256 constants. Or 512 for the pixel/vertex shader pair. The size of the re-mapping table is 128 lines (each line addresses 4 constants). The write granularity is 4 constants or 512 bits. It takes 16 clocks to write the four constants.

The texture state is also kept in a similar memory. The size of this memory is 192x128. The memory thus holds 128 texture states (192 bits per state). The logical size exposes 32 different states total, which are going to be shared between the pixel and the vertex shader. The size of the re-mapping table to for the texture state memory is 16 lines (each line addresses 2 texture state lines in the real memory). The write granularity is 2 texture state lines (or 384 bits). The driver sends 512 bits but the CP ignores the top 128 bits. It thus takes 12 clocks to write the two texture states.

The control flow constant memory doesn’t sit behind a renaming table. It is register mapped and thus the driver must reload its content each time there is a state change. Its size is 320*32 because it must hold 8 copies of the 32 dwords of control flow constants and the loop construct constants must be aligned.

~~The CP is loading the constant store using the CONST_DATA and CONST_ADDR registers. It does so by writing to the CONST_ADDR register the logical address for the constant block it wants to update and then writes 16 times to the CONST_DATA register. The CONST_ADDR is auto-incremented on both reads and writes to the CONST_DATA register.~~ The constant re-mapping tables for texture state and ALU constants are logically register mapped for regular mode and physically register mapped for RT operation.

5.2 Management of the re-mapping tables

The sequencer is responsible to manage two re-mapping tables (one for the constant store and one for the texture state). On a state change (by the driver), the sequencer will broadside copy the contents of its re-mapping tables to a new one. We have 8 different re-mapping tables we can use concurrently.

The constant memory update will be incremental, the driver only need to update the constants that actually changed between the two state changes.

For this model to work, the requirement is that the physical memory MUST be at least twice as large as the logical address space. In our case, since the logical address space is 512, the memory must be of sizes 1024 and above.

5.2.1 *Dirty bits*

Two sets of dirty bits will be maintained per logical address. The first one will be set to zero on reset and set when the logical address is addressed. The second one will be set to zero when ever a new context is written and set for each address written while in this context. The reset dirty is not set, then writing to that logical address will not require de-allocation of whatever address stored in the renaming table. If it is set and the context dirty is not set, then the physical address store needs to be de-allocated and a new physical address is necessary to store the incoming data. If they are both set, then the data will be written into the physical address held in the renaming for the current logical address. No de-allocation or allocation takes place. This will happen when the driver does a set constant twice to the same logical address between context changes. NOTE: It is important to detect and prevent this, failure to do it will allow multiple writes to allocate all physical memory and thus hang because a context will not fit for rendering to start and thus free up space.

5.2.2 *Free List Block*

A free list block that would consist of a counter (called the IFC or Initial Free Counter) that would reset to zero and incremented every time a chunk of physical memory is used until they have all been used once. This counter would be checked each time a physical block is needed, and if the original ones have not been used up, us a new one, else check the free list for an available physical block address. The count is the physical address for when getting a chunk from the counter.

Storage of a free list big enough to store all physical block addresses.

Maintain three pointers for the free list that are reset to zero. The first one we will call write_ptr. This pointer will identify the next location to write the physical address of a block to be de-allocated. Note: we can never free more physical memory locations than we have. Once recording address the pointer will be incremented to walk the free list like a ring.

The second pointer will be called stop_ptr. The stop_ptr pointer will be advanced by the number of address chunks de-allocates when a context finishes. The address between the stop_ptr and write_ptr cannot be reused because they are still in use. But as soon as the context using then is dismissed the stop_ptr will be advanced.

The third pointer will be called read_ptr. This pointer will point will point to the next address that can be used for allocation as long as the read_ptr does not equal the stop_ptr and the IFC is at its maximum count.

~~A free list block that would consist of a counter (called the IFC or Initial Free Counter) that would reset to zero and incremented every time a chunk of physical memory is used until they have all been used once. This counter would be checked each time a physical block is needed, and if the original ones have not been used up, us a new one, else check the free list for an available physical block address. The count is the physical address for when getting a chunk from the counter.~~

~~Storage of a free list big enough to store all physical block addresses.~~

~~Maintain three pointers for the free list that are reset to zero. The first one we will call NTF (Next To Free). This pointer will identify the next location to write the physical address of a block to be de-allocated. Note: we can never free more physical memory locations than we have. Once recording address the pointer will be incremented to walk the free list like a ring.~~

~~The second pointer will be called YTF (Yet To Free). The YTF pointer will be advanced by the number of address chunks de-allocates when a context finishes. The address between the YTF and NTF cannot be reused because they are still in use. But as soon as the context using then is dismissed the YTF will be advanced.~~

~~The third pointer will be called NTA (Next To Allocate). This pointer will point will point to the next address that can be used for allocation as long as the NTA does not equal the YTF and the IFC is at its maximum count.~~

5.2.3 *De-allocate Block*

This block will maintain a free physical address block count for each context. While in current context, a count shall be maintained specifying how many blocks were written into the free list at the write_ptr pointer. This count will be reset upon reset or when this context is active on the back and different than the previous context. It is actually a count of blocks in the previous context that will no longer be used. This count will be used to advance the write_ptr pointer to make available the set of physical blocks freed when the previous context was done. This allows the discard or de-allocation of any number of blocks in one clock.

~~This block will maintain a free physical address block count for each context. While in current context, a count shall be maintained specifying how many blocks were written into the free list at the NTF pointer. This count will be reset upon reset or when this context is active on the back and different than the previous context. It is actually a count of blocks in the previous context that will no longer be used. This count will be used to advance the NTF pointer to make available the set of physical blocks freed when the previous context was done. This allows the discard or de-allocation of any number of blocks in one clock.~~

5.2.4 *Operation of Incremental model*

The basic operation of the model would start with the write_ptr, stop_ptr, read_ptr pointers in the free list set to zero and the free list counter is set to zero. Also all the dirty bits and the previous context will be initialized to zero. When the first set constants happen, the reset dirty bit will not be set, so we will allocate a physical location from the free list counter because its not at the max value. The data will be written into physical address zero. Both the additional copy of the renaming table and the context zeros of the big renaming table will be updated for the logical address that was written by set start with physical address of 0. This process will be repeated for any logical address that are not dirty until the context changes. If a logical address is hit that has its dirty bits set while in the same context, both dirty bits would be set, so the new data will be over-written to the last physical address assigned for this logical address. When the first draw command of the context is detected, the previous context stored in the additional renaming table will be copied to the larger renaming table in the current (new) context location. Then the set constant logical address with be loaded with a new physical address during the copy and if the reset dirty was set, the physical address it replaced in the renaming table would be entered at the write_ptr pointer location on the free list and the write_ptr will be incremented. The de-allocation counter for the previous context (eight) will be incremented. This as set states come in for this context one of the following will happen:

1.) No dirty bits are set for the logical address being updated. A line will be allocated of the free-list counter or the free list at read_ptr pointer if read_ptr != to stop_ptr .
2.) Reset dirty set and Context dirty not set. A new physical address is allocated, the physical address in the renaming table is put on the free list at write_ptr and it is incremented along with the de-allocate counter for the last context.
3.) Context dirty is set then the data will be written into the physical address specified by the logical address.

Formatted: Bullets and Numbering

This process will continue as long as set states arrive. This block will provide backpressure to the CP whenever he has not free list entries available (counter at max and stop_ptr == read_ptr). The command stream will keep a count of contexts of constants in use and prevent more than max constants contexts from being sent.

Now preferable when the constant context leaves the last ALU clause it will be sent to this block and compared with the previous context that left. (Init to zero) If they differ than the older context will no longer be referenced and thus can be de-allocated in the physical memory. This is accomplished by adding the number of blocks freed this context to the stop_ptr pointer. This will make all the physical addresses used by this context available to the read_ptr allocate pointer for future allocation.

This device allows representation of multiple contexts of constants data with N copies of the logical address space. It also allows the second context to be represented as the first set plus some new additional data by just storing the delta's. It allows memory to be efficiently used and when the constants updates are small it can store multiple context. However, if the updates are large, less contexts will be stored and potentially performance will be degraded. Although it will still perform as well as a ring could in this case.~~The basic operation of the model would start with the NTF, YTF, NTA pointers in the free list set to zero and the free list counter is set to zero. Also all the dirty bits and the previous context will be initialized to zero. When the first set constants happen, the reset dirty bit will not be set, so we will allocate a physical location from the free list counter because its not at the max value. It allows memory to be efficiently used and when the constants updates are small it can store multiple context. However, if the updates are large, less contexts will be stored and potentially performance will be degraded. Although it will still perform as well as a ring could in this case.~~

5.3 Constant Store Indexing

In order to do constant store indexing, the sequencer must be loaded first with the indexes (that come from the GPRs). There are 144 wires from the exit of the SP to the sequencer (9 bits pointers x 16 vertexes/clock). Since the data must pass thru the Shader pipe for the float to fixed conversion, there is a latency of 4 clocks (1 instruction) between the time the sequencer is loaded and the time one can index into the constant store. The assembly will look like this

```
MOVA  R1.X,R2.X       // Loads the sequencer with the content of R2.X, also copies the content of R2.X into R1.X
NOP                   // latency of the float to fixed conversion
ADD   R3,R4,C0[R2.X]// Uses the state from the sequencer to add R4 to C0[R2.X] into R3
```

Note that we don't really care about what is in the brackets because we use the state from the MOVA instruction. R2.X is just written again for the sake of simplicity and coherency.

The storage needed in the sequencer in order to support this feature is 2*64*9 bits = 1152 bits.

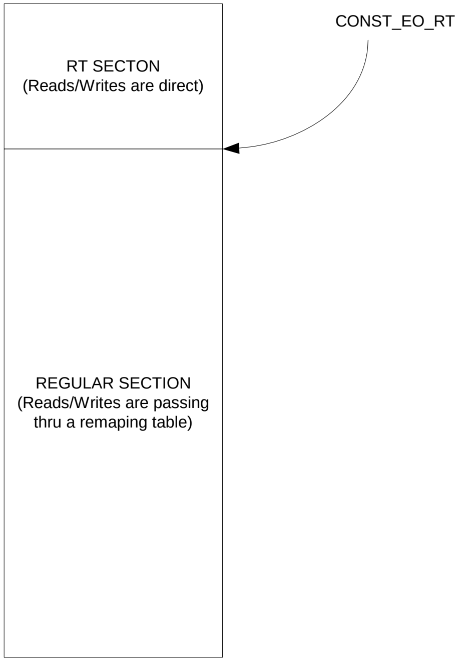
5.4 Real Time Commands

The real time commands constants are written by the CP using the ~~CONST_DATA_RT and CONST_ADDR_RT GPRs~~register mapped registers allocated for RT. It works is the same way than when dealing with regular constant loads BUT in this case the CP is not sending a logical address but rather a physical address and the reads are not passing thru the re-mapping table but are directly read from the memory. The boundary between the two zones is defined by the CONST_EO_RT control register.

5.5 Constant Waterfalling

Formatted: Bullets and Numbering

In order to have a reasonable performance in the case of constant store indexing using the address register, we are going to have the possibility of using the physical memory port for read only. This way we can read 1 constant per clock and thus have a worst-case waterfall mode of 1 vertex per clock. There is a small synchronization issue related with this as we need for the SQ to make sure that the constants where actually written to memory (not only sent to the sequencer) before it can allow the first vector of pixels or vertices of the state to go thru the ALUs. To do so, the sequencer keeps 8 bits (one per render state) and sets the bits whenever the last render state is written to memory and clears the bit whenever a state is freed.



CONST_EO_RT
RT SECTON
(Reads/Writes are direct)
REGULAR SECTION
(Reads/Writes are passing thru a remaping table)

6. Looping and Branches

Loops and branches are planned to be supported and will have to be dealt with at the sequencer level. We plan on supporting constant loops and branches using a control program.

6.1 The controlling state.

The R400 controling state consists of:

Boolean[256:0]
Loop_count[7:0][31:0]
Loop_Start[7:0][31:0]
Loop_Step[7:0][31:0]

That is 256 Booleans and 32 loops.

We have a stack of 4 elements for nested calls of subroutines and 4 loop counters to allow for nested loops.

This state is available on a per shader program basis.

6.2 The Control Flow Program

Examples of control flow programs are located in the R400 programming guide document.

The basic model is as follows:

The render state defined the clause boundaries:
Vertex_shader_fetch[7:0][7:0]   // eight 8 bit pointers to the location where each clauses control program is located
Vertex_shader_alu[7:0][7:0]   // eight 8 bit pointers to the location where each clauses control program is located

Pixel_shader_fetch[7:0][7:0]   // eight 8 bit pointers to the location where each clauses control program is located
Pixel_shader_alu[7:0][7:0]   // eight 8 bit pointers to the location where each clauses control program is located

A pointer value of FF means that the clause doesn’t contain any instructions.

The control program for a given clause is executed to completion before moving to another clause, (with the exception of the pick two nature of the alu execution). The control program is the only program aware of the clause boundaries.

The control program has eleven basic instructions:

Execute
Conditional_execute
Conditional_Execute_Predicates
Conditional_jump
Conditionnal_Call
Return
Loop_start
Loop_end
End_of_clause
Conditional_End_of_clause
NOP

Execute, causes the specified number of instructions in instruction store to be executed.
Conditional_execute checks a condition first, and if true, causes the specified number of instructions in instruction store to be executed.
Loop_start resets the corresponding loop counter to the start value on the first pass after it checks for the end condition and if met jumps over to a specified address.
Loop_end increments (decrements?) the loop counter and jumps back the specified number of instructions.
Conditionnal_Call jumps to an address and pushes the IP counter on the stack if the condition is met. On the return instruction, the IP is popped from the stack.
Conditional_execute_or_Jump executes a block of instructions or jumps to an address is the condition is not met.
Conditional_execute_Predicates executes a block of instructions if all bits in the predicate vectors meet the condition.
End_of_clause marks the end of a clause.
Conditional_End_of_clause marks the end of a clause if the condition is met.
Conditional_jumps jumps to an address if the condition is met.
NOP is a regular NOP

NOTE THAT ALL JUMPS MUST JUMP TO EVEN CFP ADDRESSES since there are two control flow instructions per memory line. Thus the compiler must insert NOPs where needed to align the jumps on even CFP addresses.

Also if the jump is logically bigger than pshader_cntl_size (or vshader_cntl_size) we break the program (clause) and set the debug registers. If an execute or conditional_execute is lower than cntl_size or bigger than size we also break the program (clause) and set the debug registers.

We have to fit instructions into 48 bits in order to be able to put two control flow instruction per line in the instruction store.

Note that whenever a field is marked as RESERVED, it is assumed that all the bits of the field are cleared (0).

Execute				
47	46… 42	41 … 24	23 … 12	11 … 0
Addressing	00001	RESERVED	Instruction count	Exec Address

Execute up to 4k instructions at the specified address in the instruction memory.

NOP		
47	46 … 42	41 … 0

Addressing	00010	RESERVED

This is a regular NOP.

Conditional_Execute							
47	46 … 42	41	40 … 33	32	31 … 24	23 … 12	11 … 0
Addressing	00011	RESERVED	Boolean address	Condition	RESERVED	Instruction count	Exec Address

If the specified Boolean (8 bits can address 256 Booleans) meets the specified condition then execute the specified instructions (up to 4k instructions)

Conditional_Execute_Predicates							
47	46 … 42	41 … 35	34 … 33	32	31 … 24	23 … 12	11 … 0
Addressing	00100	RESERVED	Predicate vector	Condition	RESERVED	Instruction count	Exec Address

Check the AND/OR of all current predicate bits. If AND/OR matches the condition execute the specified number of instructions. We need to AND/OR this with the kill mask in order not to consider the pixels that aren't valid.

Loop_Start				
47	46 … 42	41 … 17	16 … 12	11 … 0
Addressing	00101	RESERVED	loop ID	Jump address

Loop Start. Compares the loop iterator with the end value. If loop condition not met jump to the address. Forward jump only. Also computes the index value. The loop id must match between the start to end, and also indicates which control flow constants should be used with the loop.

Loop_End				
47	46 … 42	41 … 17	16 … 12	11 … 0
Addressing	00111	RESERVED	loop ID	start address

Loop end. Increments the counter by one, compares the loop count with the end value. If loop condition met, continue, else, jump BACK to the start of the loop.

The way this is described does not prevent nested loops, and the inclusion of the loop id make this easy to do.

Conditionnal_Call						
47	46 … 42	41 … 35~~41…12~~	34 … 33	32	31 … 12	11 … 0
Addressing	01000	RESERVED	Predicate vector	Condition	RESERVED	Jump address

If the condition is met, j~~J~~umps to the specified address and pushes the control flow program counter on the stack.

Return		
47	46 … 42	41 … 0
Addressing	01001	RESERVED

Pops the topmost address from the stack and jumps to that address. If nothing is on the stack, the program will just continue to the next instruction.

Conditionnal_Jump							
47	46 … 42	41	40 … 33	32	31	30 … 12	11 … 0

Addressing	01010	RESERVED	Boolean address	Condition	FW only	RESERVED	Jump address

If condition met, jumps to the address. FORWARD jump only allowed if bit 31 set. Bit 31 is only an optimization for the compiler and should NOT be exposed to the API.

Conditional_End_of_Clause					
47	46 … 42	41	40 … 33	32	31 … 0
Addressing	01011	RESERVED	Boolean address	Condition	RESERVED

This is an optimization in the case of very short shaders (where the control flow instruction can't be hidden anymore and thus are not free. In this case, if the condition is met, the clause is ended, else we continue the execution of the clause.

End_of_Clause		
47	46 … 42	41 … 0
Addressing	01011	RESERVED

Marks the end of a clause.

To prevent infinite loops, we will keep 9 bits loop counters instead of 8 (we are only able to loop 256 times). If the counter goes higher than 255 then the loop_end or the loop_start instruction is going to break the loop and set the debug GPRs.

6.3 Data dependant predicate instructions

Data dependant conditionals will be supported in the R400. The only way we plan to support those is by supporting three vector/scalar predicate operations of the form:

PRED_SETE_# - similar to SETE except that the result is 'exported' to the sequencer.
PRED_SETNE_# - similar to SETNE except that the result is 'exported' to the sequencer.
PRED_SETGT_# - similar to SETGT except that the result is 'exported' to the sequencer
PRED_SETGTE_# - similar to SETGTE except that the result is 'exported' to the sequencer

For the scalar operations only we will also support the two following instructions:
PRED_SETE0_# – SETE0
PRED_SETE1_# – SETE1

The export is a single bit - 1 or 0 that is sent using the same data path as the MOVA instruction. The sequencer will maintain 4 sets of 64 bit predicate vectors (in fact 8 sets because we interleave two programs but only 4 will be exposed) and use it to control the write masking. This predicate is not maintained across clause boundaries. The # sign is used to specify which predicate set you want to use 0 thru 3.

Then we have two conditional execute bits. The first bit is a conditional execute "on" bit and the second bit tells us if we execute on 1 or 0. For example, the instruction:

P0_ADD_# R0,R1,R2

Is only going to write the result of the ADD into those GPRs whose predicate bit is 0. Alternatively, P1_ADD_# would only write the results to the GPRs whose predicate bit is set. The use of the P0 or P1 without precharging the sequencer with a PRED instruction is undefined.

{Issue: do we have to have a NOP between PRED and the first instruction that uses a predicate?}

6.4 HW Detection of PV,PS

Because of the control program, the compiler cannot detect statically dependant instructions. In the case of non-masked writes and subsequent reads the sequencer will insert uses of PV,PS as needed. This will be done by comparing the read address and the write address of consecutive instructions. For masked writes, the sequencer will insert NOPs wherever there is a dependant read/write.

The sequencer will also have to insert NOPs between PRED_SET and MOVA instructions and their uses.

6.5 Register file indexing

Because we can have loops in fetch clause, we need to be able to index into the register file in order to retrieve the data created in a fetch clause loop and use it into an ALU clause. The instruction will include the base address for register indexing and the instruction will contain these controls:

Bit7	Bit 6	
0	0	'absolute register'
0	1	'relative register'
1	0	'previous vector'
1	1	'previous scalar'

In the case of an absolute register we just take the address as is. In the case of a relative register read we take the base address and we add to it the loop_index and this becomes our new address that we give to the shader pipe.

The sequencer is going to keep a loop index computed as such:

Index = Loop_iterator*Loop_step + Loop_start.

The index is going to return 0 if it is out of the range. We loop until loop_iterator = loop_count. Loop_step is a signed value [-128…127].

6.6 Predicated Instruction support for Texture clauses

For texture clauses, we support the following optimization: we keep 1 bit (thus 4 bits for the four predicate vectors) per predicate vector in the reservation stations. A value of 1 means that one ore more elements in the vector have a value of one (thus we have to do the texture fetches for the whole vector). A value of 0 means that no elements in the vector have his predicate bit set and we can thus skip over the texture fetch. **We have to make sure the invalid pixels aren't considered with this optimization.**

6.7 Debugging the Shaders

In order to be able to debug the pixel/vertex shaders efficiently, we provide 2 methods.

6.7.1 *Method 1: Debugging registers*

Current plans are to expose 2 debugging, or error notification, registers:
1. address register where the first error occurred
2. count of the number of errors

The sequencer will detect the following groups of errors:
- count overflow
~~- jump error~~
~~-relative jump address > size of the control flow program~~
~~-relative jump address > length of the shader program~~
- ~~-~~constant overflow
-
- register overflow
~~- register overflow~~
~~- call stack~~
~~-call with stack full~~
~~-return with stack empty~~
Compiler recognizable errors:
- jump errors

Formatted: Bullets and Numbering

relative jump address > size of the control flow program
relative jump address > length of the shader program
- call stack
call with stack full
return with stack empty

With two of the errors, a jump error or a register overflow will cause the program to break. In this case, a break means that a clause will halt execution, but allowing further clauses to be executed.

With the other errors, program can continue to run, potentially to worst-case limits.

If indexing outside of the constant range, causing an overflow error, the hardware is specified to return the value with an index of 0. This could be exploited to generate error tokens, by reserving and initializing the 0th register (or constant) for errors.

{ISSUE : Interrupt to the driver or not?}

6.7.2 *Method 2: Exporting the values in the GPRs (12)*

The sequencer will have a count register and an address register for this mode and 3 bits per clause specifying the execution mode for each clause. The modes can be :

1) Normal
2) Debug Kill
3) Debug Addr + Count

Under the normal mode execution follows the normal course. Under the kill mode, all control flow instructions are executed but all normal shader instructions of the clause are replaced by NOPs. Only debug_export instructions of clause 7 will be executed under the debug kill setting. Under the other mode, normal execution is done until we reach an address specified by the address register and instruction count (useful for loops) specified by the count register. After we have hit the instruction n times (n=count) we switch the clause to the kill mode.

Under the debug mode (debug kill OR debug Addr + count), it is assumed that clause 7 is always exporting 12 debug vectors and that all other exports to the SX block (position, color, z, ect) will been turned off (changed into NOPs) by the sequencer (even if they occur before the address stated by the ADDR debug register).

7. Pixel Kill Mask

A vector of 64 bits is kept by the sequencer per group of pixels/vertices. Its purpose is to optimize the texture fetch requests and allow the shader pipe to kill pixels using the following instructions:

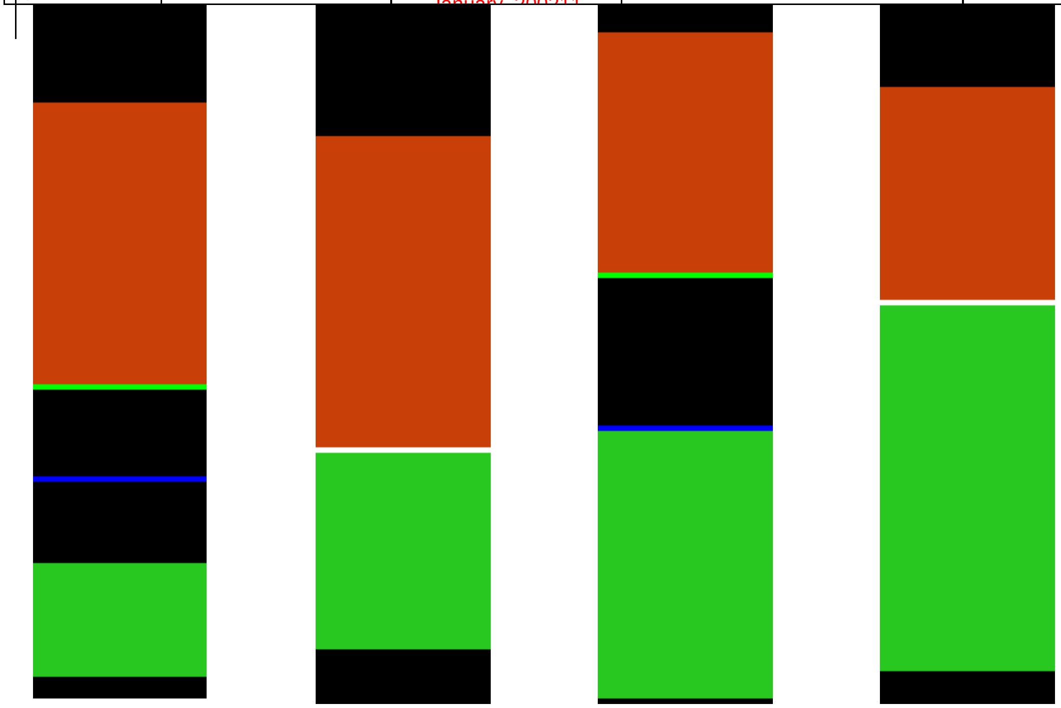
MASK_SETE
MASK_SETNE
MASK_SETGT
MASK_SETGTE

8. Multipass vertex shaders (HOS)

Multipass vertex shaders are able to export from the 6 last clauses but to memory ONLY.

9. Register file allocation

The register file allocation for vertices and pixels can either be static or dynamic. In both cases, the register file in managed using two round robins (one for pixels and one for vertices). In the dynamic case the boundary between pixels and vertices is allowed to move, in the static case it is fixed to VERTEX_REG_SIZE for vertices and 256-VERTEX_REG_SIZE for pixels.



Above is an example of how the algorithm works. Vertices come in from top to bottom; pixels come in from bottom to top. Vertices are in orange and pixels in green. The blue line is the tail of the vertices and the green line is the tail of the pixels. Thus anything between the two lines is shared. When pixels meets vertices the line turns white and the boundary is static until both vertices and pixels share the same “unallocated bubble”. Then the boundary is allowed to move again.

10. Fetch Arbitration

The fetch arbitration logic chooses one of the 8 potentially pending fetch clauses to be executed. The choice is made by looking at the fifos from 7 to 0 and picking the first one ready to execute. Once chosen, the clause state machine will send one 2x2 fetch per clock (or 4 fetches in one clock every 4 clocks) until all the fetch instructions of the clause are sent. This means that there cannot be any dependencies between two fetches of the same clause.

The arbitrator will not wait for the fetches to return prior to selecting another clause for execution. The fetch pipe will be able to handle up to X(?) in flight fetches and thus there can be a fair number of active clauses waiting for their fetch return data.

11. ALU Arbitration

ALU arbitration proceeds in almost the same way than fetch arbitration. The ALU arbitration logic chooses one of the 8 potentially pending ALU clauses to be executed. The choice is made by looking at the fifos from 7 to 0 and picking the first one ready to execute. There are two ALU arbiters, one for the even clocks and one for the odd clocks. For example, here is the sequencing of two interleaved ALU clauses (E and O stands for Even and Odd sets of 4 clocks):

Einst0 Oinst0 Einst1 Oinst1 Einst2 Oinst2 Einst0 Oinst3 Einst1 Oinst4 Einst2 Oinst0…
Proceeding this way hides the latency of 8 clocks of the ALUs. Also note that the interleaving also occurs across clause boundaries.

12. Handling Stalls

When the output file is full, the sequencer prevents the ALU arbitration logic from selecting the last clause (this way nothing can exit the shader pipe until there is place in the output file. If the packet is a vertex packet and the position buffer is full (POS_FULL) then the sequencer also prevents a thread from entering the exporting clause (3?). The sequencer will set the OUT_FILE_FULL signal n clocks before the output file is actually full and thus the ALU arbiter will be able read this signal and act accordingly by not preventing exporting clauses to proceed.

13. Content of the reservation station FIFOs

The reservation FIFOs contain the state of the vector of pixels and vertices. We have two sets of those: one for pixels, and one for vertices. They contain 3 bits of Render State 7 bits for the base address of the GPRs, some bits for LOD correction and coverage mask information in order to fetch fetch for only valid pixels, the quad address.

14. The Output File

The output file is where pixels are put before they go to the RBs. The write BW to this store is 256 bits/clock. Just before this output file are staging registers with write BW 512 bits/clock and read BW 256 bits/clock. The staging registers are 4x128 (and there are 16 of those on the whole chip).

15. IJ Format

The IJ information sent by the PA is of this format on a per quad basis:

We have a vector of IJ's (one IJ per pixel at the centroid of the fragment or at the center of the pixel depending on the mode bit). The interpolation is done at a different precision across the 2x2. The upper left pixel's parameters are always interpolated at full 20x24 mantissa precision. Then the result of the interpolation along with the difference in IJ in reduced precision is used to interpolate the parameter for the other three pixels of the 2x2. Here is how we do it:

Assuming P0 is the interpolated parameter at Pixel 0 having the barycentric coordinates I(0), J(0) and so on for P1,P2 and P3. Also assuming that A is the parameter value at V0 (interpolated with I), B is the parameter value at V1 (interpolated with J) and C is the parameter value at V2 (interpolated with (1-I-J).

$$\Delta 01I = I(1) - I(0)$$
$$\Delta 01J = J(1) - J(0)$$
$$\Delta 02I = I(2) - I(0)$$
$$\Delta 02J = J(2) - J(0)$$
$$\Delta 03I = I(3) - I(0)$$
$$\Delta 03J = J(3) - J(0)$$

P0	P1
P2	P3

$$P0 = C + I(0) * (A - C) + J(0) * (B - C)$$
$$P1 = P0 + \Delta 01I * (A - C) + \Delta 01J * (B - C)$$
$$P2 = P0 + \Delta 02I * (A - C) + \Delta 02J * (B - C)$$
$$P3 = P0 + \Delta 03I * (A - C) + \Delta 03J * (B - C)$$

P0 is computed at 20x24 mantissa precision and P1 to P3 are computed at 8X24 mantissa precision. So far no visual degradation of the image was seen using this scheme.

Subtracts 19x24 (Parameters): 2
Adds: 8

FORMAT OF P0’s IJ : Mantissa 20 Exp 4 for I + Sign
Mantissa 20 Exp 4 for J + Sign

FORMAT of Deltas (x3):Mantissa 8 Exp 4 for I + Sign
Mantissa 8 Exp 4 for J + Sign

Total number of bits : 20*2 + 8*6 + 4*8 + 4*2 = 128

All numbers are kept using the un-normalized floating point convention: if exponent is different than 0 the number is normalized if not, then the number is un-normalized. The maximum range for the IJs (Full precision) is +/- 63 and the range for the Deltas is +/- 127.

15.1 Interpolation of constant attributes

Because of the floating point imprecision, we need to take special provisions if all the interpolated terms are the same or if two of the barycentric coordinates are the same.

We start with the premise that if A = B and B = C and C = A, then P0,1,2,3 = A. Since one or more of the IJ terms may be zero, so we extend this to:

```
if (A=B and B=C and C=A)
  P0,1,2,3 = A;
else if ((I = 0) or (J = 0)) and
        ((J = 0) or (1-I-J = 0)) and
        ((1-J-I = 0) or (I = 0))) {
            if(I != 0) {
               P0 = A;
            } else if(J != 0) {
               P0 = B;
            } else {
               P0 = C;
           }
          //rest of the quad interpolated normally
}
else
{
          normal interpolation
}
```

16. -Staging Registers

Formatted: Bullets and Numbering

In order for the reuse of the vertices to be 14, the sequencer will have to re-order the data sent IN ORDER by the VGT for it to be aligned with the parameter cache memory arrangement. Given the following group of vertices sent by the VGT:

0 1 2 3 4 5 6 7 8 9 10 11 12 13 14 15 || 16 17 18 19 20 21 22 23 24 25 26 27 28 29 30 31 || 32 33 34 35 36 37 38 39 40 41 42 43 44 45 46 47 || 48 49 50 51 52 53 54 55 56 57 58 59 60 61 62 63

The sequencer will re-arrange them in this fashion:

0 1 2 3 16 17 18 19 32 33 34 35 48 49 50 51 || 4 5 6 7 20 21 22 23 36 37 38 39 52 53 54 55 || 8 9 10 11 24 25 26 27 40 41 42 43 56 57 58 59 || 12 13 14 15 28 29 30 31 44 45 46 47 60 61 62 63

The || markers show the SP divisions. In the event a shader pipe is broken, the VGT will send padding to account for the missing pipe. For example, if SP1 is broken, vertices 4 5 6 7 20 21 22 23 36 37 38 39 52 53 54 55 will still be sent by the VGT to the SQ **BUT** will not be processed by the SP and thus should be considered invalid (by the SU and VGT).

Formatted

The most straightforward, *non-compressed* interface method would be to convert, in the VGT, the data to 32-bit floating point prior to transmission to the VSISRs. In this scenario, the data would be transmitted to (and stored in) the VSISRs in full 32-bit floating point. This method requires three 24-bit fixed-to-float converters in the VGT. Unfortunately, it also requires and additional 3,072 bits of storage across the VSISRs. This interface is illustrated in Figure 2. The area of the fixed-to-float converters and the VSISRs for this method is roughly estimated as 0.759sqmm using the R300 process. The gate count estimate is shown in Figure 1.

Basis for 8-deep Latch Memory (from R300)			
8x24-bit	11631 μ^2		60.57813 μ^2 per bit
Area of 96x8-deep Latch Memory	46524 μ^2		
Area of 24-bit Fix-to-float Converter	4712 μ^2 per converter		
Method 1	Block	Quantity	Area
	F2F	3	14136
	8x96 Latch	16	744384
			758520 μ^2

Figure 1:Area Estimate for VGT to Shader Interface

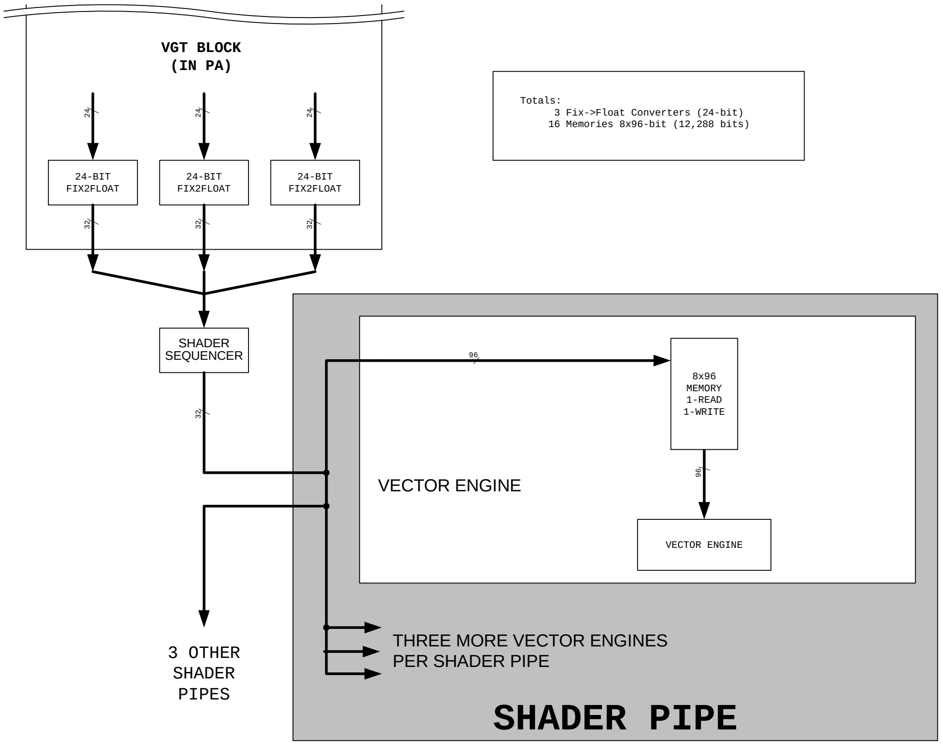

Figure 2:VGT to Shader Interface

~~16.~~17. The parameter cache

Formatted: Bullets and Numbering

The parameter cache is where the vertex shaders export their data. It consists of 16 128x128 memories (1R/1W). The reuse engine will make it so that all vertexes of a given primitive will hit different memories. The allocation method for these memories is a simple round robin. The parameter cache pointers are mapped in the following way: 4MSBs are the memory number and the 7 LSBs are the address within this memory.

MEMORY NUMBER 4 bits	ADDRESS 7 bits

The PA generates the parameter cache addresses as the positions comes from the SQ. All it needs to do is keep a Current_Location pointer (7 bits only) and as the positions comes increment the memory number. When the memory number field wraps around, the PA increments the Current_Location by VS_EXPORT_COUNT_6 (a snooped register from the SQ). As an example, say the memories are all empty to begin with and the vertex shader is exporting 8 parameters per vertex (VS_EXPORT_COUNT_6 = 8). The first position received is going to have the PC address 00000000000 the second one 00010000000, third one 00100000000 and so on up to 11110000000. Then the next position received (the 17th) is going to have the address 00000001000, the 18th 00010001000, the 19th 00100001000 and so on. The Current_location is NEVER reset BUT on chip resets. The only thing to be careful about is that if the SX doesn't send you a full group of positions (<64) then you need to fill the address space so that the next group starts correctly aligned (for example if you receive only 33 positions then you need to add 1*VS_EXPORT_COUNT_6 to Current_Location and reset the memory count to 0 before the next vector begins).

Formatted

Formatted

Formatted

~~17.~~18. Vertex position exporting

Formatted: Bullets and Numbering

On clause 3 the vertex shader can export to the PA both the vertex position and the point sprite. It can also do so at clause 7 if not done at clause 3. The storage needed to perform the position export is at least 64x128 memories for the position and 64x32 memories for the sprite size. It is going to be taken in the pixel output fifo from the SX blocks. The clause where the position export occurs is specified by the EXPORT_LATE register. If turned on, it means that the export is going to occur at ALU clause 7 if unset position export occurs at clause 3.

~~18.~~19. Exporting Arbitration

Formatted: Bullets and Numbering

Any type of exporting clause can be co-issued. The sequencer will have to make sure back to back memory exports (position/straight memory exports) are interleaved with NOPs as we don't have the bandwidth to service them at full speed.

~~Here are the rules for co-issuing exporting ALU clauses.~~

Formatted: Bullets and Numbering

~~1)Position exports and position exports cannot be co-issued.~~
~~2)Position exports and memory exports cannot be co-issued.~~
~~3)Position exports and Z/Color exports cannot be co-issued.~~

~~4)Memory exports and Z/Color exports cannot be co-issued.~~
~~5)Memory exports and memory exports cannot be co-issued.~~
~~6)Z/color exports and Z/color exports cannot be co-issued.~~
~~7)Parameter exports and Z/Color exports CAN be co-issued.~~

~~8)Parameter exports and parameter exports CAN be co-issued.~~
~~9)Parameter exports and memory exports CAN be co-issued.~~

~~19.~~20. Export Types

The export type (or the location where the data should be put) is specified using the destination address field in the ALU instruction. Here is a list of all possible export modes:

~~19.1~~20.1 Vertex Shading

Formatted: Bullets and Numbering

0:15	- 16 parameter cache
16:31	- Empty (Reserved?)
32:43	- 12 vertex exports to the frame buffer and index
44:47	- Empty
48:59	- 12 debug export (interpret as normal vertex export)
60	- export addressing mode
61	- Empty
62	- sprite size export that goes with position export (point_h,point_w,edgeflag,misc)
63	- position

~~19.2~~20.2 Pixel Shading

Formatted: Bullets and Numbering

0	- Color for buffer 0 (primary)
1	- Color for buffer 1
2	- Color for buffer 2
3	- Color for buffer 3
4:7	- Empty
8	- Buffer 0 Color/Fog (primary)
9	- Buffer 1 Color/Fog
10	- Buffer 2 Color/Fog
11	- Buffer 3 Color/Fog
12:15	- Empty
16:31	- Empty (Reserved?)
32:43	- 12 exports for multipass pixel shaders.
44:47	- Empty
48:59	- 12 debug exports (interpret as normal pixel export)
60	- export addressing mode
61:62	- Empty
63	- Z for primary buffer (Z exported to 'alpha' component)

~~20.~~21. Special Interpolation modes

Formatted: Bullets and Numbering

~~20.1~~21.1 Real time commands

We are unable to use the parameter memory since there is no way for a command stream to write into it. Instead we need to add three 16x128 memories (one for each of three vertices x 16 interpolants). These will be mapped onto the register bus and written by type 0 packets, and output to the the parameter busses (the sequencer and/or PA need to be able to address the realtime parameter memory as well as the regular parameter store. For higher performance we should be able able to view them as two banks of 16 and do double buffering allowing one to be loaded, while the other is rasterized with. Most overlay shaders will need 2 or 4 scalar coordinates, one option might be to restrict the memory to 16x64 or 32x64 allowing only two interpolated scalars per cycle, the only problem I see with this is, if we view support for 16 vector-4 interpolants important (true only if we map Microsoft's high priority stream to the realtime stream), then the PA/sequencer need to support a realtime-specific mode where we need to address 32 vectors of parameters instead of 16. This mode is triggered by the primitive type: REAL TIME.

~~20.2~~21.2 Sprites/ XY screen coordinates/ FB information

Formatted: Bullets and Numbering

When working with sprites, one may want to overwrite the parameter 0 with SC generated data. Also, XY screen coordinates may be needed in the shader program. This functionality is controlled by the gen_I0 register (in SQ) in conjunction with the SND_XY register (in SC). Also it is possible to send the faceness information (for OGL front/back special operations) to the shader using the same control register. Here is a list of all the modes and how they interact together:

Gen_st is a bit taken from the interface between the SC and the SQ. This is the MSB of the primitive type. If the bit is set, it means we are dealing with Point AA, Line AA or sprite and in this case the vertex values are going to generated between 0 and 1.

Param_Gen_I0 disable, snd_xy disable, no gen_st – I0 = No modification
Param_Gen_I0 disable, snd_xy disable, gen_st – I0 = No modification
Param_Gen_I0 disable, snd_xy enable, no gen_st – I0 = No modification
Param_Gen_I0 disable, snd_xy enable, gen_st – I0 = No modification
Param_Gen_I0 enable, snd_xy disable, no gen_st – I0 = garbage, garbage, garbage, faceness
Param_Gen_I0 enable, snd_xy disable, gen_st – I0 = garbage, garbage, s, t
Param_Gen_I0 enable, snd_xy enable, no gen_st – I0 = screen x, screen y, garbage, faceness
Param_Gen_I0 enable, snd_xy enable, gen_st – I0 = screen x, screen y, s, t

~~20.3~~21.3 Auto generated counters

Formatted: Bullets and Numbering

In the cases we are dealing with multipass shaders, the sequencer is going to generate a vector count to be able to both use this count to write the 1st pass data to memory and then use the count to retrieve the data on the 2nd pass. The count is always generated in the same way but it is passed to the shader in a slightly different way depending on the shader type (pixel or vertex). This is toggled on and off using the GEN_INDEX register. The sequencer is going to keep two counters, one for pixels and one for vertices. Every time a full vector of vertices or pixels is written to the GPRs the counter is incremented. Every time a state change is detected, the corresponding counter is reset. While there is only one count broadcast to the GPRs, the LSB are hardwired to specific values making the index different for all elements in the vector.

~~20.3.1~~21.3.1 *Vertex shaders*

Formatted: Bullets and Numbering

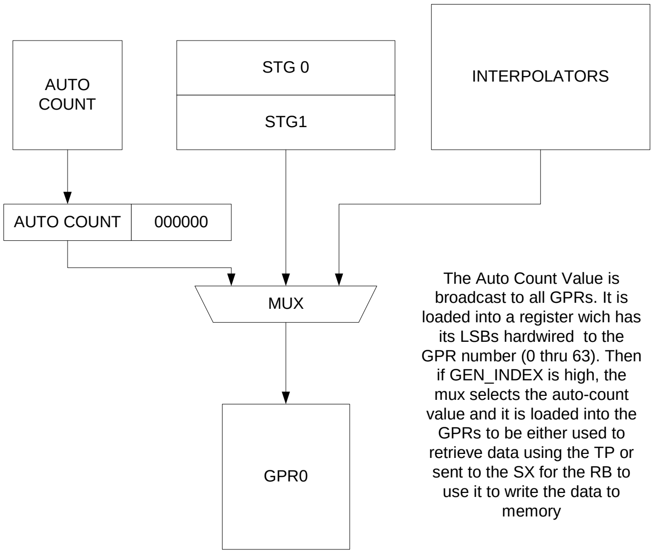
In the case of vertex shaders, if GEN_INDEX is set, the data will be put into the x field of the third register (it means that the compiler must allocate 3 GPRs in all multipass vertex shader modes).

~~20.3.2~~21.3.2 *Pixel shaders*

Formatted: Bullets and Numbering

In the case of pixel shaders, if GEN_INDEX is set and Param_Gen_I0 is enabled, the data will be put in the x field of the 2nd register (R~~l~~1.x), else if GEN_INDEX is set the data will be put into the x field of the 1st register (R0.x).

Formatted



The Auto Count Value is broadcast to all GPRs. It is loaded into a register wich has its LSBs hardwired to the GPR number (0 thru 63). Then if GEN_INDEX is high, the mux selects the auto-count value and it is loaded into the GPRs to be either used to retrieve data using the TP or sent to the SX for the RB to use it to write the data to memory

~~21.~~22. State management

Formatted: Bullets and Numbering

Every clock, the sequencer will report to the CP the oldest states still in the pipe. These are the states of the programs as they enter the last ALU clause.

~~21.1~~22.1 Parameter cache synchronization

Formatted: Bullets and Numbering

In order for the sequencer not to begin a group of pixels before the associated group of vertices has finished, the sequencer will keep a 6 bit count per state (for a total of 8 counters). These counters are initialized to 0 and every time a vertex shader exports its data TO THE PARAMETER CACHE, the corresponding pointer is incremented. When the SC sends a new vector of pixels with the SC_SQ_new_vector bit asserted, the sequencer will first check if the count is greater than 0 before accepting the transmission (it will in fact accept the transmission but then lower its ready to receive). Then the sequencer waits for the count to go to one and decrements it. The sequencer can then issue the group of pixels to the interpolators. Every time the state changes, the new state counter is initialized to 0.

~~22.~~23. XY Address imports

Formatted: Bullets and Numbering

The SC will be able to send the XY addresses to the GPRs. It does so by interleaving the writes of the IJs (to the IJ buffer) with XY writes (to the XY buffer). Then when writing the data to the GPRs, the sequencer is going to interpolate the IJ data or pass the XY data thru a Fix→float converter and expander and write the converted values to the GPRs. The Xys are currently SCREEN SPACE COORDINATES. The values in the XY buffers will wrap. See section 21.2~~21.2~~~~20.2~~ for details on how to control the interpolation in this mode.

~~22.1~~23.1 Vertex indexes imports

Formatted: Bullets and Numbering

In order to import vertex indexes, we have ~~64x2x96~~ 16 8x96 staging registers. These are loaded one line at a time by the VGT block (96 bits). They are loaded in floating point format and can be transferred in 4 or 8 clocks to the GPRs.

~~23.~~24. Registers

Formatted: Bullets and Numbering

~~23.1~~24.1 Control

REG_DYNAMIC	Dynamic allocation (pixel/vertex) of the register file on or off.
REG_SIZE_PIX	Size of the register file's pixel portion (minimal size when dynamic allocation turned on)
REG_SIZE_VTX	Size of the register file's vertex portion (minimal size when dynamic allocation turned on)
ARBITRATION_POLICY	policy of the arbitration between vertexes and pixels
INST_STORE_ALLOC	interleaved, separate
INST_BASE_VTX	start point for the vertex instruction store (RT always ends at vertex_base and Begins at 0)
INST_BASE_PIX	start point for the pixel shader instruction store
ONE_THREAD	debug state register. Only allows one program at a time into the GPRs
ONE_ALU	debug state register. Only allows one ALU program at a time to be executed (instead of 2)
INSTRUCTION_ADDR	This is where the CP puts the base address of the instruction writes and type (auto-incremented on reads/writes)
INSTRUCTION_DATA	This is where the CP puts the actual data going to the instruction memory
~~CONSTANT_DATA~~	~~This is where the CP puts constant data (32 bits)~~
~~CONSTANT_ADDR~~	~~This is where the CP puts the logical constant address (9 bits)~~CONSTANTS 512*4 ALU constants + 32*6 Texture state 32 bits registers (logically mapped)
INSTRUCTION_ADDR_RT	This is where the CP puts the base address of the instruction writes and type for Real Time (auto-incremented on reads/writes)
INSTRUCTION_DATA_RT	This is where the CP puts the actual data going to the instruction memory for Real Time
~~CONSTANT_DATA_RT~~	~~This is where the CP puts constant data for Real Time (32 bits)~~

~~CONSTANT_ADDR_RT~~	~~This is where the CP puts the logical constant address for Real Time (9 bits)~~CONSTANTS_RT 256*4 ALU constants + 32*6 texture states? (physically mapped)
CONSTANT_EO_RT	This is the size of the space reserved for real time in the constant store (from 0 to CONSTANT_EO_RT). The re-mapping table operates on the rest of the memory
EXPORT_LATE	Controls whether or not we are exporting position from clause 3. If set, position exports occur at clause 7.

~~23.2~~24.2 Context

Formatted: Bullets and Numbering

VS_FETCH_{0…7}	eight 8 bit pointers to the location where each clauses control program is located
VS_ALU_{0…7}	eight 8 bit pointers to the location where each clauses control program is located
PS_FETCH_{0…7}	eight 8 bit pointers to the location where each clauses control program is located
PS_ALU_{0…7}	eight 8 bit pointers to the location where each clauses control program is located
PS_BASE	base pointer for the pixel shader in the instruction store
VS_BASE	base pointer for the vertex shader in the instruction store
VS_CF_SIZE	size of the vertex shader (# of instructions in control program/2)
PS_CF_SIZE	size of the pixel shader (# of instructions in control program/2)
PS_SIZE	size of the pixel shader (cntl+instructions)
VS_SIZE	size of the vertex shader (cntl+instructions)
PS_NUM_REG	number of GPRs to allocate for pixel shader programs
VS_NUM_REG	number of GPRs to allocate for vertex shader programs
PARAM_SHADE	One 16 bit register specifying which parameters are to be gouraud shaded (0 = flat, 1 = gouraud)
PARAM_WRAP	64 bits: for which parameters (and channels (xyzw)) do we do the cyl wrapping (0=linear, 1=cylindrical).
PS_EXPORT_MODE	0xxxx : Normal mode 1xxxx : Multipass mode If normal, bbbz where bbb is how many colors (0-4) and z is export z or not If multipass 1-12 exports for color.
VS_EXPORT_MASK	which of the last 6 ALU clauses is exporting (multipass only)
VS_EXPORT_MODE	0: position (1 vector), 1: position (2 vectors), 3:multipass
VS_EXPORT _COUNT_{0…6}	Six 4 bit counters representing the # of interpolated parameters exported in clause 7 (located in VS_EXPORT_COUNT_6) OR # of exported vectors to memory per clause in multipass mode (per clause)
PARAM_GEN_I0	Do we overwrite or not the parameter 0 with XY data and generated T and S values
GEN_INDEX	Auto generates an address from 0 to XX. Puts the results into ~~R1~~ R0-1 for pixel shaders and ~~R3~~ R2 for vertex shaders
CONST_BASE_VTX (9 bits)	Logical Base address for the constants of the Vertex shader
CONST_BASE_PIX (9 bits)	Logical Base address for the constants of the Pixel shader
CONST_SIZE_PIX (8 bits)	Size of the logical constant store for pixel shaders
CONST_SIZE_VTX (8 bits)	Size of the logical constant store for vertex shaders
INST_PRED_OPTIMIZE	Turns on the predicate bit optimization (if of, conditional_execute_predicates is always executed).
CF_BOOLEANS	256 boolean bits
CF_LOOP_COUNT	32x8 bit counters (number of times we traverse the loop)
CF_LOOP_START	32x8 bit counters (init value used in index computation)
CF_LOOP_STEP	32x8 bit counters (step value used in index computation)

~~24.~~25. DEBUG Registers

Formatted: Bullets and Numbering

~~24.1~~25.1 Context

DB_PROB_ADDR	instruction address where the first problem occurred
DB_PROB_COUNT	number of problems encountered during the execution of the program
DB_INST_COUNT	instruction counter for debug method 2
DB_BREAK_ADDR	break address for method number 2

DB_CLAUSE
_MODE_ALU_{0…7}   clause mode for debug method 2 (0: normal, 1: addr, 2: kill)
DB_CLAUSE
_MODE_FETCH_{0…7}   clause mode for debug method 2 (0: normal, 1: addr, 2: kill)

Formatted: Bullets and Numbering

~~25.~~26. Interfaces

~~25.1~~26.1 External Interfaces

Whenever an x is used, it means that the bus is broadcast to all units of the same name. For example, if a bus is named SQ→SPx it means that SQ is going to broadcast the same information to all SP instances.

Formatted: Bullets and Numbering

~~25.1.1~~26.1.1 *SC to SQ : IJ Control bus*

This is the control information sent to the sequencer in order to control the IJ fifos and all other information needed to execute a shader program on the sent pixels. This information is sent over 2 clocks, if SENDXY is asserted the next control packet is going to be ignored and XY information is going to be sent on the IJ bus (for the quads that where just sent). All pixels from the group of quads are from the same primitive, all quads of a vector are from the same render state.

Name	Direction	Bits	Description
SC_SQ_q_wr_mask	SC→SQ	4	Quad Write mask left to right
SC_SQ_lod_correct	SC→SQ	24	LOD correction per quad (6 bits per quad)
SC_SQ_flat_vertex	SC→SQ	2	Provoking vertex for flat shading
SC_SQ_param_ptr0	SC→SQ	11	P Store pointer for vertex 0
SC_SQ_param_ptr1	SC→SQ	11	P Store pointer for vertex 1
SC_SQ_param_ptr2	SC→SQ	11	P Store pointer for vertex 2
SC_SQ_end_of_vect	SC→SQ	1	End of the vector
SC_SQ_store_dealloc	SC→SQ	1	Deallocation token for the P Store
SC_SQ_state	SC→SQ	3	State/constant pointer
SC_SQ_valid_pixel	SC→SQ	16	Valid bits for all pixels
SC_SQ_null_prim	SC→SQ	1	Null Primitive (for PC deallocation purposes)
SC_SQ_end_of_prim	SC→SQ	1	End Of the primitive
SC_SQ_send_xy	SC→SQ	1	Sending XY information [XY information is going to be sent on the next clock]
SC_SQ_prim_type	SC→SQ	3	Real time command need to load tex cords from alternate buffer. Line AA, Point AA and Sprite reads their parameters from GEN_T and GEN_S GPRs. 000 : Normal 011 : Real Time 100 : Line AA 101 : Point AA 110 : Sprite
SC_SQ_new_vector	SC→SQ	1	This primitive comes from a new vector of vertices. Make sure that the corresponding vertex shader has finished before starting the group of pixels.
SC_SQ_RTRn	SQ→SC	1	Stalls the PA in n clocks
SC_SQ_RTS	SC→SQ	1	SC ready to send data

Formatted: Bullets and Numbering

~~25.1.2~~26.1.2 *SQ to SP: Interpolator bus*

Name	Direction	Bits	Description
SQ_SPx_interp_prim_type	SQ→SPx	3	Type of the primitive 000 : Normal 011 : Real Time 100 : Line AA 101 : Point AA 110 : Sprite

SQ_SPx_interp_flat_vtx	SQ→SPx	2	Provoking vertex for flat shading
SQ_SPx_interp_flat_gouraud	SQ→SPx	1	Flat or gouraud shading
SQ_SPx_interp_cyl_wrap	SQ→SPx	4	Wich parameter needs to be cylindrical wrapped
SQ_SPx_interp_ijline	SQ→SPx	2	Line in the IJ/XY buffer to use to interpolate
SQ_SPx_interp_buff_swap	SQ→SPx	1	Swap the IJ/XY buffers at the end of the interpolation
SQ_SPx_interp_gen_I0	SQ→SPx	1	Generate I0 or not. This tells the interpolators not to use the parameter cache but rather overwrite the data with interpolated 1 and 0. Overwrite if gen_I0 is high.

~~25.1.3SQ to SP: GPR Input Mux select~~

Formatted: Bullets and Numbering

~~This interface is synchronized with the Interpolator bus. This controls the input mux to the GPRs. The three types of data are: generated index, Interpolated data, vertex index data (coming from the staging registers).~~

~~25.1.4~~26.1.3 SQ to SP: Parameter Cache Read control bus

Formatted: Bullets and Numbering

The four following interfaces (SQ→SP, SQ→SX,SP→SX and SX→Interpolators) are all SYNCHRONIZED together.

Name	Direction	Bits	Description
SQ_SPx_ptr0	SQ→SPx	9	Pointer of PC
SQ_SPx_ptr1	SQ→SPx	9	Pointer of PC
SQ_SPx_ptr2	SQ→SPx	9	Pointer of PC
SQ_SP0_read_ena	SQ→SP0	4	Read enables for the 4 memories in the SP0
SQ_SP1_read_ena	SQ→SP1	4	Read enables for the 4 memories in the SP1
SQ_SP2_read_ena	SQ→SP2	4	Read enables for the 4 memories in the SP2
SQ_SP3_read_ena	SQ→SP3	4	Read enables for the 4 memories in the SP3

~~25.1.5~~26.1.4 SQ to SX: Parameter Cache Mux control Bus

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
SQ_SXx_mux0	SQ→SXx	4	Mux control for PC (4 MSbs of Pointer)
SQ_SXx_mux1	SQ→SXx	4	Mux control for PC (4 MSbs of Pointer)
SQ_SXx_mux2	SQ→SXx	4	Mux control for PC (4 MSbs of Pointer)

~~25.1.6~~26.1.5 SQ to SP: Staging Register Data

Formatted: Bullets and Numbering

This is a broadcast bus that sends the VSISR information to the staging registers of the shader pipes.

Name	Direction	Bits	Description
SQ_SPx~~0~~_vgt_vsisr_data	SQ→SPx~~0~~	96	Pointers of indexes or HOS surface information
SQ_SP~~0~~x_vgt_vsisr_double	SQ→SPx~~0~~	1	0: Normal 96 bits per vert 1: double 192 bits per vert
SQ_SP0_data_valid	SQ→SP0	1	Data is valid
SQ_SP1_data_valid	SQ→SP1	1	Data is valid
SQ_SP2_data_valid	SQ→SP2	1	Data is valid
SQ_SP3_data_valid	SQ→SP3	1	Data is valid

~~25.1.7~~26.1.6 PA to SQ : Vertex interface

Formatted: Bullets and Numbering

~~25.1.7.1~~26.1.6.1 Interface Signal Table

The area difference between the two methods is not sufficient to warrant complicating the interface or the state requirements of the VSISRs. **Therefore, the POR for this interface is that the VGT will transmit the data to the VSISRs (via the Shader Sequencer) in full, 32-bit floating-point format.** The VGT can transmit up to six 32-bit floating-point values to each VSISR where four or more values require two transmission clocks. The data bus is 96 bits wide.

Name	Bits	Description
PA_SQ_vgt_vsisr_data	96	Pointers of indexes or HOS surface information
PA_SQ_vgt_vsisr_double	1	0: Normal 96 bits per vert 1: double 192 bits per vert
PA_SQ_vgt_end_of_vector	1	Indicates the last VSISR data set for the current process vector (for double vector data, "end_of_vector" is set on the second vector)
PA_SQ_vgt_state	3	Render State (6*3+3 for constants). This signal is guaranteed to be correct when “PA_SQ_vgt_end_of_vector” is high.
PA_SQ_vgt_send	1	Data on the VGT_SQ is valid receive (see write-up for standard R400 SEND/RTR interface handshaking)
SQ_PA_vgt_rtr	1	Ready to receive (see write-up for standard R400 SEND/RTR interface handshaking)

~~25.1.8~~26.1.7 SQ to CP: State report

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
SQ_CP_vrtx_ state	SEQ→CP	3	Oldest vertex state still in the pipe
SQ_CP_pix_state	SEQ→CP	3	Oldest pixel state still in the pipe

~~25.1.9~~26.1.8 SQ to SX: Control bus

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
SQ_SXx_exp_Pixel	SQ→SXx	1	1: Pixel 0: Vertex
SQ_SXx_exp_start	SQ→SXx	1	Raised to indicate that the SQ is starting an export
SQ_SXx_exp_Clause	SQ→SXx	3	Clause number, which is needed for vertex clauses
SQ_SXx_exp_State	SQ→SXx	3	State ID, which is needed for vertex clauses

These fields are sent synchronously with SP export data, described in SP0→SX0 interface
{ISSUE: Where are the PC pointers}

~~25.1.10~~26.1.9 SX to SQ : Output file control

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
SXx_SQ_Export_count_rdy	SXx→SQ	1	Raised by SX0 to indicate that the following two fields reflect the result of the most recent export
SXx_SQ_Export_Position	SXx→SQ	1	Specifies whether there is room for another position.
SXx_SQ_Export_Buffer	SXx→SQ	7	Specifies the space available in the output buffers. 0: buffers are full 1: 2K-bits available (32-bits for each of the 64 pixels in a clause) ... 64: 128K-bits available (16 128-bit entries for each of 64 pixels) 65-127: RESERVED

~~25.1.11~~26.1.10 SQ to TP: Control bus

Formatted: Bullets and Numbering

Once every clock, the fetch unit sends to the sequencer on which clause it is now working and if the data in the GPRs is ready or not. This way the sequencer can update the fetch counters for the reservation station fifos. The sequencer also provides the instruction and constants for the fetch to execute and the address in the register file where to write the fetch return data.

Name	Direction	Bits	Description
TPx_SQ_data_rdy	TPx→ SQ	1	Data ready
TPx_SQ_clause_num	TPx→ SQ	3	Clause number
SQ_TPx_const	SQ→TPx	~~64~~48	Fetch state sent over 4 clocks (192 bits total)
SQ_TPx_instuct	SQ→TPx	24	Fetch instruction sent over 4 clocks
SQ_TPx_end_of_clause	SQ→TPx	1	Last instruction of the clause
SQ_TPx_phase	SQ→TPx	2	Write phase signal
SQ_TP0_lod_correct	SQ→TP0	6	LOD correct 3 bits per comp 2 components per quad
SQ_TP0_pmask	SQ→TP0	4	Pixel mask 1 bit per pixel
SQ_TP1_lod_correct	SQ→TP1	6	LOD correct 3 bits per comp 2 components per quad
SQ_TP1_pmask	SQ→TP1	4	Pixel mask 1 bit per pixel
SQ_TP2_lod_correct	SQ→TP2	6	LOD correct 3 bits per comp 2 components per quad
SQ_TP2_pmask	SQ→TP2	4	Pixel mask 1 bit per pixel
SQ_TP3_lod_correct	SQ→TP3	6	LOD correct 3 bits per comp 2 components per quad
SQ_TP3_pmask	SQ→TP3	4	Pixel mask 1 bit per pixel
SQ_TPx_clause_num	SQ→TPx	3	Clause number
SQ_TPx_write_gpr_index	SQ->TPx	7	Index into Register file for write of returned Fetch Data

~~25.1.12~~26.1.11 TP to SQ: Texture stall

Formatted: Bullets and Numbering

The TP sends this signal to the SQ when its input buffer is full. The SQ is going to send it to the SP X clocks after reception (maximum of 3 clocks of pipeline delay).

Name	Direction	Bits	Description
TP_SQ_fetch_stall	TP→ SQ	1	Do not send more texture request if asserted

~~25.1.13~~26.1.12 SQ to SP: Texture stall

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
SQ_SPx_fetch_stall	SQ→SPx	1	Do not send more texture request if asserted

~~25.1.14~~26.1.13 SQ to SP: GPR, ~~and~~ Parameter cache control and auto counter

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
SQ_SPx_wr_addr	SQ→SPx	7	Write address
SQ_SPx_gpr_rd_addr	SQ→SPx	7	Read address
SQ_SPx_gpr_re_addr	SQ→SPx	1	Read Enable
SQ_SPx_gpr_we_addr	SQ→SPx	1	Write Enable for the GPRs
SQ_SPx_gpr_phase_mux	SQ→SPx	2	The phase mux (arbitrates between inputs, ALU SRC reads and writes)
SQ_SPx_channel_mask	SQ→SPx	4	The channel mask
SQ_SP0_pixel_mask	SQ→SP0	4	The pixel mask
SQ_SP1_pixel_mask	SQ→SP1	4	The pixel mask
SQ_SP2_pixel_mask	SQ→SP2	4	The pixel mask
SQ_SP3_pixel_mask	SQ→SP3	4	The pixel mask
SQ_SPx_pc_we_addr	SQ→SPx	1	Write Enable for the parameter caches
SQ_SPx_gpr_input_mux	SQ→SPx	2	When the phase mux selects the inputs this tells from which source to read from: Interpolated data, VTX0, VTX1, autogen counter.
SQ_SPx_index_count	SQ→SPx	12?	Index count, common for all shader pipes

~~25.1.15~~26.1.14 SQ to SPx: Instructions

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
SQ_SPx_instruct_start	SQ→SPx	1	Instruction start
SQ_SP_instruct	SQ→SPx	20	Instruction sent over 4 clocks
SQ_SPx_stall	SQ→SPx	1	Stall signal
SQ_SPx_export_count	SQ→SPx	3	Each set of four pixels or vectors is exported over eight clocks. This field specifies where the SP is in that sequence.
SQ_SPx_export_last	SQ→SPx	1	Asserted on the first shader count of the last export of the clause
SQ_SP0_export_pvalid	SQ→SP0	4	Result of pixel kill in the shader pipe, which must be output for all pixel exports (depth and all color buffers). 4x4 because 16 pixels are computed per clock
SQ_SP0_export_wvalid	SQ→SP0	2	Specifies whether to write low and/or high 32-bit word of the 64-bit export data from each of the 16 pixels or vectors
SQ_SP1_ export_pvalid	SQ→SP1	4	Result of pixel kill in the shader pipe, which must be output for all pixel exports (depth and all color buffers). 4x4 because 16 pixels are computed per clock
SQ_SP1_ export_wvalid	SQ→SP1	2	Specifies whether to write low and/or high 32-bit word of the 64-bit export data from each of the 16 pixels or vectors
SQ_SP2_ export_pvalid	SQ→SP2	4	Result of pixel kill in the shader pipe, which must be output for all pixel exports (depth and all color buffers). 4x4 because 16 pixels are computed per clock
SQ_SP2_ export_wvalid	SQ→SP2	2	Specifies whether to write low and/or high 32-bit word of the 64-bit export data from each of the 16 pixels or vectors
SQ_SP3_ export_pvalid	SQ→SP3	4	Result of pixel kill in the shader pipe, which must be output for all pixel exports (depth and all color buffers). 4x4 because 16 pixels are computed per clock
SQ_SP3_ export_wvalid	SQ→SP3	2	Specifies whether to write low and/or high 32-bit word of the 64-bit export data from each of the 16 pixels or vectors

~~25.1.16~~26.1.15 SP to SQ: Constant address load

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
SP0_SQ_const_addr	SP0→SQ	36	Constant address load to the sequencer
SP0_SQ_valid	SP0→SQ	1	Data valid
SP1_SQ_const_addr	SP1→SQ	36	Constant address load to the sequencer
SP1_SQ_valid	SP1→SQ	1	Data valid
SP2_SQ_const_addr	SP2→SQ	36	Constant address load to the sequencer
SP2_SQ_valid	SP2→SQ	1	Data valid
SP3_SQ_const_addr	SP3→SQ	36	Constant address load to the sequencer
SP3_SQ_valid	SP3→SQ	1	Data valid

~~25.1.17~~26.1.16 SQ to SPx: constant broadcast

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
SQ_SPx_constant	SQ→SPx	128	Constant broadcast

~~25.1.18~~26.1.17 SP0 to SQ: Kill vector load

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
SP0_SQ_kill_vect	SP0→SQ	4	Kill vector load
SP1_SQ_kill_vect	SP1→SQ	4	Kill vector load
SP2_SQ_kill_vect	SP2→SQ	4	Kill vector load
SP3_SQ_kill_vect	SP3→SQ	4	Kill vector load

~~25.1.19~~26.1.18 SQ to CP: RBBM bus

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
SQ_RBB_rs	SQ→CP	1	Read Strobe
SQ_RBB_rd	SQ→CP	32	Read Data
SQ_RBBM_nrtrtr	SQ→CP	1	Optional
SQ_RBBM_rtr	SQ→CP	1	Real-Time (Optional)

~~25.1.20~~26.1.19 CP to SQ: RBBM bus

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
rbbm_we	CP→SQ	1	Write Enable
rbbm_a	CP→SQ	18	Address -- Upper Extent is TBD
rbbm_wd	CP→SQ	32	Data
rbbm_be	CP→SQ	4	Byte Enables
rbbm_re	CP→SQ	1	Read Enable
rbb_rs0	CP→SQ	1	Read Return Strobe 0
rbb_rs1	CP→SQ	1	Read Return Strobe 1
rbb_rd0	CP→SQ	32	Read Data 0
rbb_rd1	CP→SQ	32	Read Data 0
RBBM_SQ_soft_reset	CP→SQ	1	Soft Reset

~~26.~~27. Examples of program executions

Formatted: Bullets and Numbering

~~26.1.1~~27.1.1 Sequencer Control of a Vector of Vertices

1. PA sends a vector of 64 vertices (actually vertex indices – 32 bits/index for 2048 bit total) to the RE's Vertex FIFO
   - state pointer as well as tag into position cache is sent along with vertices
   - space was allocated in the position cache for transformed position before the vector was sent
   - **also before the vector is sent to the RE, the CP has loaded the global instruction store with the vertex shader program (using the MH?)**
   - The vertex program is assumed to be loaded when we receive the vertex vector.
     - the SEQ then accesses the IS base for this shader using the local state pointer (provided to all sequencers by the RBBM when the CP is done loading the program)

2. SEQ arbitrates between the Pixel FIFO and the Vertex FIFO – basically the Vertex FIFO always has priority
   - at this point the vector is removed from the Vertex FIFO
   - the arbiter is not going to select a vector to be transformed if the parameter cache is full unless the pipe as nothing else to do (ie no pixels are in the pixel fifo).

3. SEQ allocates space in the SP register file for index data plus GPRs used by the program
   - the number of GPRs required by the program is stored in a local state register, which is accessed using the state pointer that came down with the vertices
   - SEQ will not send vertex data until space in the register file has been allocated

4. SEQ sends the vector to the SP register file over the RE_SP interface (which has a bandwidth of 2048 bits/cycle)
   - the 64 vertex indices are sent to the 64 register files over 4 cycles
     - RF0 of SU0, SU1, SU2, and SU3 is written the first cycle
     - RF1 of SU0, SU1, SU2, and SU3 is written the second cycle
     - RF2 of SU0, SU1, SU2, and SU3 is written the third cycle
     - RF3 of SU0, SU1, SU2, and SU3 is written the fourth cycle

- the index is written to the least significant 32 bits **(floating point format?) (what about compound indices)** of the 128-bit location within the register file (w); the remaining data bits are set to zero (x, y, z)

5. SEQ constructs a control packet for the vector and sends it to the first reservation station (the FIFO in front of fetch state machine 0, or TSM0 FIFO)
    - the control packet contains the state pointer, the tag to the position cache and a register file base pointer.
6. TSM0 accepts the control packet and fetches the instructions for fetch clause 0 from the global instruction store
    - TSM0 was first selected by the TSM arbiter before it could start
7. all instructions of fetch clause 0 are issued by TSM0
8. the control packet is passed to the next reservation station (the FIFO in front of ALU state machine 0, or ASM0 FIFO)
    - TSM0 does not wait for requests made to the Fetch Unit to complete; it passes the register file write index for the fetch data to the TU, which will write the data to the RF as it is received
    - once the TU has written all the data to the register files, it increments a counter that is associated with ASM0 FIFO; a count greater than zero indicates that the ALU state machine can go ahead start to execute the ALU clause
9. ASM0 accepts the control packet (after being selected by the ASM arbiter) and gets the instructions for ALU clause 0 from the global instruction store
10. all instructions of ALU clause 0 are issued by ASM0, then the control packet is passed to the next reservation station (the FIFO in front of fetch state machine 1, or TSM1 FIFO)
11. the control packet continues to travel down the path of reservation stations until all clauses have been executed
    - position can be exported in ALU clause 3 (or 4?); the data (and the tag) is sent over a position bus (which is shared with all four shader pipes) back to the PA's position cache
    - A parameter cache pointer is also sent along with the position data. This tells to the PA where the data is going to be in the parameter cache.
        - there is a position export FIFO in the SP that buffers position data before it gets sent back to the PA
        - the ASM arbiter will prevent a packet from starting an exporting clause if the position export FIFO is full
    - parameter data is exported in clause 7 (as well as position data if it was not exported earlier)
        - parameter data is sent to the Parameter Cache over a dedicated bus
        - the SEQ allocates storage in the Parameter Cache, and the SEQ deallocates that space when there is no longer a need for the parameters (it is told by the PA when using a token).
        - the ASM arbiter will prevent a packet from starting on ASM7 if the parameter cache (or the position buffer if position is being exported) is full
12. after the shader program has completed, the SEQ will free up the GPRs so that they can be used by another shader program

~~26.1.2~~27.1.2 *Sequencer Control of a Vector of Pixels*

Formatted: Bullets and Numbering

1. **As with vertex shader programs, pixel shaders are loaded into the global instruction store by the CP**
    - At this point it is assumed that the pixel program is loaded into the instruction store and thus ready to be read.
2. the RE's Pixel FIFO is loaded with the barycentric coordinates for pixel quads by the detailed walker
    - the state pointer and the LOD correction bits are also placed in the Pixel FIF0
    - the Pixel FIFO is wide enough to source four quad's worth of barycentrics per cycle
3. SEQ arbitrates between Pixel FIFO and Vertex FIFO – when there are no vertices pending OR there is no space left in the register files for vertices, the Pixel FIFO is selected
4. SEQ allocates space in the SP register file for all the GPRs used by the program
    - the number of GPRs required by the program is stored in a local state register, which is accessed using the state pointer
    - SEQ will not allow interpolated data to be sent to the shader until space in the register file has been allocated
5. SEQ controls the transfer of interpolated data to the SP register file over the RE_SP interface (which has a bandwidth of 2048 bits/cycle). See interpolated data bus diagrams for details.

6. SEQ constructs a control packet for the vector and sends it to the first reservation station (the FIFO in front of fetch state machine 0, or TSM0 FIFO)
    - note that there is a separate set of reservation stations/arbiters/state machines for vertices and for pixels
    - the control packet contains the state pointer, the register file base pointer, and the LOD correction bits
    - all other information (such as quad address for example) travels in a separate FIFO
7. TSM0 accepts the control packet and fetches the instructions for fetch clause 0 from the global instruction store
    - TSM0 was first selected by the TSM arbiter before it could start
8. all instructions of fetch clause 0 are issued by TSM0
9. the control packet is passed to the next reservation station (the FIFO in front of ALU state machine 0, or ASM0 FIFO)
    - TSM0 does not wait for fetch requests made to the Fetch Unit to complete; it passes the register file write index for the fetch data to the TU, which will write the data to the RF as it is received
    - once the TU has written all the data for a particular clause to the register files, it increments a counter that is associated with the ASM0 FIFO; a count greater than zero indicates that the ALU state machine can go ahead and pop the FIFO and start to execute the ALU clause
10. ASM0 accepts the control packet (after being selected by the ASM arbiter) and gets the instructions for ALU clause 0 from the global instruction store
11. all instructions of ALU clause 0 are issued by ASM0, then the control packet is passed to the next reservation station (the FIFO in front of fetch state machine 1, or TSM1 FIFO)
12. the control packet continues to travel down the path of reservation stations until all clauses have been executed
    - pixel data is exported in the last ALU clause (clause 7)
        - it is sent to an output FIFO where it will be picked up by the render backend
        - the ASM arbiter will prevent a packet from starting on ASM7 if the output FIFO is full
13. after the shader program has completed, the SEQ will free up the GPRs so that they can be used by another shader program

~~26.1.3~~27.1.3 *Notes*

Formatted: Bullets and Numbering

14. The state machines and arbiters will operate ahead of time so that they will be able to immediately start the real threads or stall.
15. The register file base pointer for a vector needs to travel with the vector through the reservation stations, but the instruction store base pointer does not – this is because the RF pointer is different for all threads, but the IS pointer is only different for each state and thus can be accessed via the state pointer.

~~27.~~28. Open issues

Formatted: Bullets and Numbering

Need to do some testing on the size of the register file as well as on the register file allocation method (dynamic VS static).

Saving power?

R400 Sequencer Specification

SQ

Version 1.7~~6~~

Overview: This is an architectural specification for the R400 Sequencer block (SEQ). It provides an overview of the required capabilities and expected uses of the block. It also describes the block interfaces, internal sub-blocks, and provides internal state diagrams.

AUTOMATICALLY UPDATED FIELDS:

Revision Changes:

Rev 0.1 (Laurent Lefebvre) Date: May 7, 2001	First draft.
Rev 0.2 (Laurent Lefebvre) Date : July 9, 2001	Changed the interfaces to reflect the changes in the SP. Added some details in the arbitration section.
Rev 0.3 (Laurent Lefebvre) Date : August 6, 2001	Reviewed the Sequencer spec after the meeting on August 3, 2001.
Rev 0.4 (Laurent Lefebvre) Date : August 24, 2001	Added the dynamic allocation method for register file and an example (written in part by Vic) of the flow of pixels/vertices in the sequencer.
Rev 0.5 (Laurent Lefebvre) Date : September 7, 2001	Added timing diagrams (Vic)
Rev 0.6 (Laurent Lefebvre) Date : September 24, 2001	Changed the spec to reflect the new R400 architecture. Added interfaces.
Rev 0.7 (Laurent Lefebvre) Date : October 5, 2001	Added constant store management, instruction store management, control flow management and data dependant predication.
Rev 0.8 (Laurent Lefebvre) Date : October 8, 2001	Changed the control flow method to be more flexible. Also updated the external interfaces.
Rev 0.9 (Laurent Lefebvre) Date : October 17, 2001	Incorporated changes made in the 10/18/01 control flow meeting. Added a NOP instruction, removed the conditional_execute_or_jump. Added debug registers.
Rev 1.0 (Laurent Lefebvre) Date : October 19, 2001	Refined interfaces to RB. Added state registers.
Rev 1.1 (Laurent Lefebvre) Date : October 26, 2001	Added SEQ→SP0 interfaces. Changed delta precision. Changed VGT→SP0 interface. Debug Methods added.
Rev 1.2 (Laurent Lefebvre) Date : November 16, 2001	Interfaces greatly refined. Cleaned up the spec.
Rev 1.3 (Laurent Lefebvre) Date : November 26, 2001	Added the different interpolation modes.
Rev 1.4 (Laurent Lefebvre) Date : December 6, 2001	Added the auto incrementing counters. Changed the VGT→SQ interface. Added content on constant management. Updated GPRs.
Rev 1.5 (Laurent Lefebvre) Date : December 11, 2001	Removed from the spec all interfaces that weren't directly tied to the SQ. Added explanations on constant management. Added PA→SQ synchronization fields and explanation.
Rev 1.6 (Laurent Lefebvre) Date : January 7, 2002	Added more details on the staging register. Added detail about the parameter caches. Changed the call instruction to a Conditionnal_call instruction. Added details on constant management and updated the diagram.
Rev 1.7 (Laurent Lefebvre) Date : February 4, 2002	Added Real Time parameter control in the SX interface. Updated the control flow section.

1. Overview

The sequencer is based on the R300 design. It chooses two ALU clauses and a fetch clause to execute, and executes all of the instructions in a clause before looking for a new clause of the same type. Two ALU clauses are executed interleaved to hide the ALU latency. Each vector will have eight fetch and eight ALU clauses, but clauses do not need to contain instructions. A vector of pixels or vertices ping-pongs along the sequencer FIFO, bouncing from fetch reservation station to alu reservation station. A FIFO exists between each reservation stage, holding up vectors until the vector currently occupying a reservation station has left. A vector at a reservation station can be chosen to execute. The sequencer looks at all eight alu reservation stations to choose an alu clause to execute and all eight fetch stations to choose a fetch clause to execute. The arbitrator will give priority to clauses/reservation stations closer to the bottom of the pipeline. It will not execute an alu clause until the fetch fetches initiated by the previous fetch clause have completed. There are two separate sets of reservation stations, one for pixel vectors and one for vertices vectors. This way a pixel can pass a vertex and a vertex can pass a pixel.

To support the shader pipe the sequencer also contains the shader instruction cache, constant store, control flow constants and texture state. The four shader pipes also execute the same instruction thus there is only one sequencer for the whole chip.

The sequencer first arbitrates between vectors of 64 vertices that arrive directly from primitive assembly and vectors of 16 quads (64 pixels) that are generated in the scan converter.

The vertex or pixel program specifies how many GPRs it needs to execute. The sequencer will not start the next vector until the needed space is available in the GPRs.

Figure 2: Reservation stations and arbiters

There are two sets of the above figure, one for vertices and one for pixels.

Depending on the arbitration state, the sequencer will either choose a vertex or a pixel packet. The control packet consists of 3 bits of state, 7 bits for the base address of the Shader program and some information on the coverage to determine fetch LOD plus other various small state bits.

On receipt of a packet, the input state machine (not pictured but just before the first FIFO) allocated enough space in the GPRs to store the interpolated values and temporaries. Following this, the barycentric coordinates (and XY screen position if needed) are sent to the ~~interpolator which~~interpolator, which will use them to interpolate the parameters and place the results into the GPRs. Then, the input state machine stacks the packet in the first FIFO.

On receipt of a command, the level 0 fetch machine issues a fetch request to the TP and corresponding GPR address for the fetch address (ta). A small command (tcmd) is passed to the fetch system identifying the current level number (0) as well as the GPR write address for the fetch return data. One fetch request is sent every 4 clocks causing the texturing of sixteen 2x2s worth of data (or 64 vertices). Once all the requests are sent the packet is put in FIFO 1.

Upon receipt of the return data, the fetch unit writes the data to the register file using the write address that was provided by the level 0 fetch machine and sends the clause number (0) to the level 0 fetch state machine to signify that the write is done and thus the data is ready. Then, the level 0 fetch machine increments the counter of FIFO 1 to signify to the ALU 0 that the data is ready to be processed.

On receipt of a command, the level 0 ALU machine first decrements the input FIFO 1 counter and then issues a complete set of level 0 shader instructions. For each instruction, the ALU state machine generates 3 source addresses, one destination address and an instruction. Once the last instruction has been issued, the packet is put into FIFO 2.

There will always be two active ALU clauses at any given time (and two arbiters). One arbiter will arbitrate over the odd instructions (4 clocks cycles) and the other one will arbitrate over the even instructions (4 clocks cycles). The only constraints between the two arbiters is that they are not allowed to pick the same clause number as the other one is currently working on if the packet is not of the same type (render state).

If the packet is a vertex packet, upon reaching ALU clause 3, it can export the position if the position is ready. So the arbiter must prevent ALU clause 3 to be selected if the positional buffer is full (or can't be accessed). Along with the positional data, if needed the sprite size and/or edge flags can also be sent.

A special case is for multipass vertex shaders, which can export 12 parameters per last 6 clauses to the output buffer. If the output buffer is full or doesn't have enough space the sequencer will prevent such a vertex group to enter an exporting clause.

Multipass pixel shaders can export 12 parameters to memory from the last clause only (7).

All other clauses process in the same way until the packet finally reaches the last ALU machine (7).

Only one pair of interleaved ALU state machines may have access to the register file address bus or the instruction decode bus at one time. Similarly, only one fetch state machine may have access to the register file address bus at one time. Arbitration is performed by three arbiter blocks (two for the ALU state machines and one for the fetch state machines). The arbiters always favor the higher number state machines, preventing a bunch of half finished jobs from clogging up the register files.

1.2 Data Flow graph (SP)

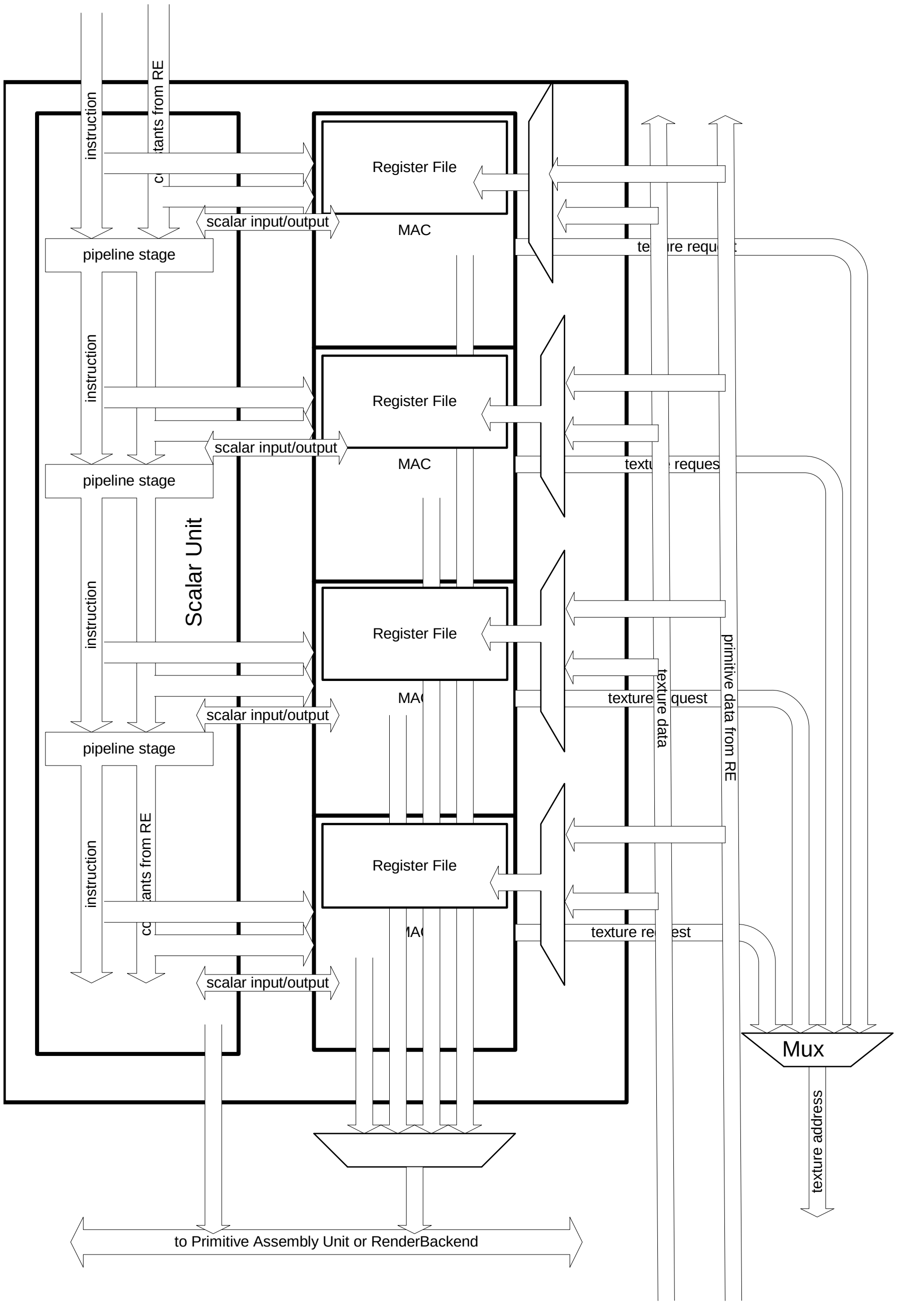

Figure 3: The shader Pipe

The gray area represents blocks that are replicated 4 times per shader pipe (16 times on the overall chip).

1.3 Control Graph

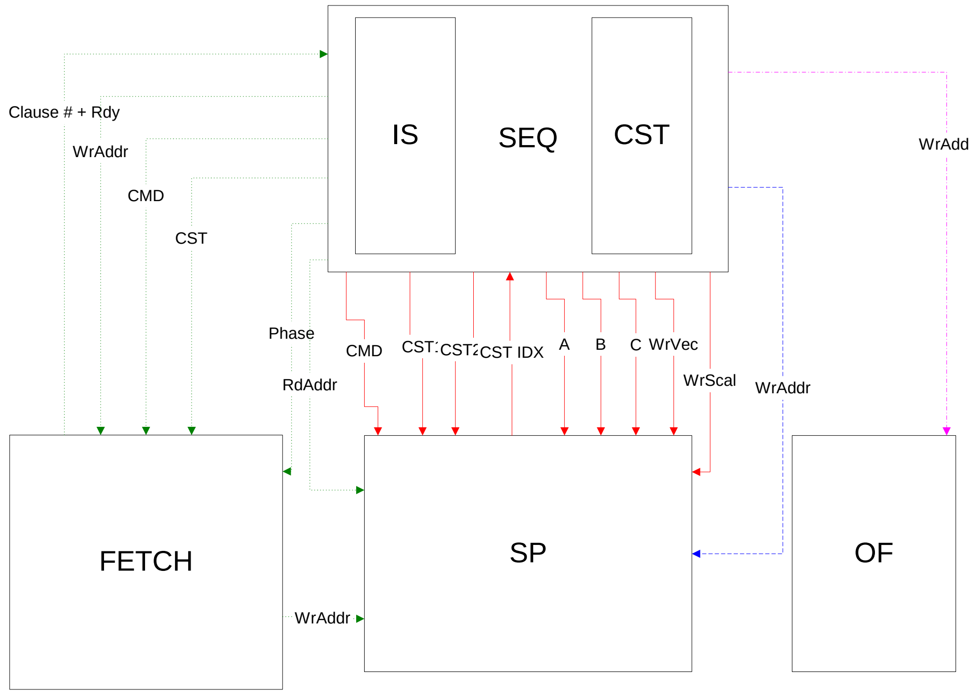

Figure 4: Sequencer Control interfaces

In green is represented the Fetch control interface, in red the ALU control interface, in blue the Interpolated/Vector control interface and in purple is the output file control interface.

2. Interpolated data bus

The interpolators contain an IJ buffer to pack the information as much as possible before writing it to the register file.

Figure 6: Interpolation timing diagram

Above is an example of a tile the sequencer might receive from the SC. The write side is how the data get stacked into the XY and IJ buffers, the read side is how the data is passed to the GPRs. The IJ information is packed in the IJ buffer 4 quads at a time or two clocks. The sequencer allows at any given time as many as four quads to interpolate a parameter. They all have to come from the same primitive. Then the sequencer controls the write mask to the GPRs to write the valid data in.

{ISSUE : Do we do the center + centroid approach using both IJ buffers?}

3. Instruction Store

There is going to be only one instruction store for the whole chip. It will contain 4096 instructions of 96 bits each.

It is likely to be a 1 ~~-~~port memory; we use ~~-~~1 clock to load the ALU instruction, 1 clocks to load the Fetch instruction, 1 clock to load 2 control flow instructions and 1 clock to write instructions.

The instruction store is loaded by the CP thru the register mapped registers.

The next picture shows the various modes the CP can load the memory. The Sequencer has to keep track of the loading modes in order to wrap around the correct boundaries. The wrap-~~-~~around points are arbitrary and they are specified in the VS_BASE and PIX_BASE control registers. The VS_BASE and PS_BASE context registers are used to specify for each context where its shader is in the instruction memory.

For the Real time commands the story is quite the same but for some small differences. There are no wrap-~~-~~around points for real time so the driver must be careful not to overwrite regular shader data. The shared code (shared subroutines) uses the same path as real time.

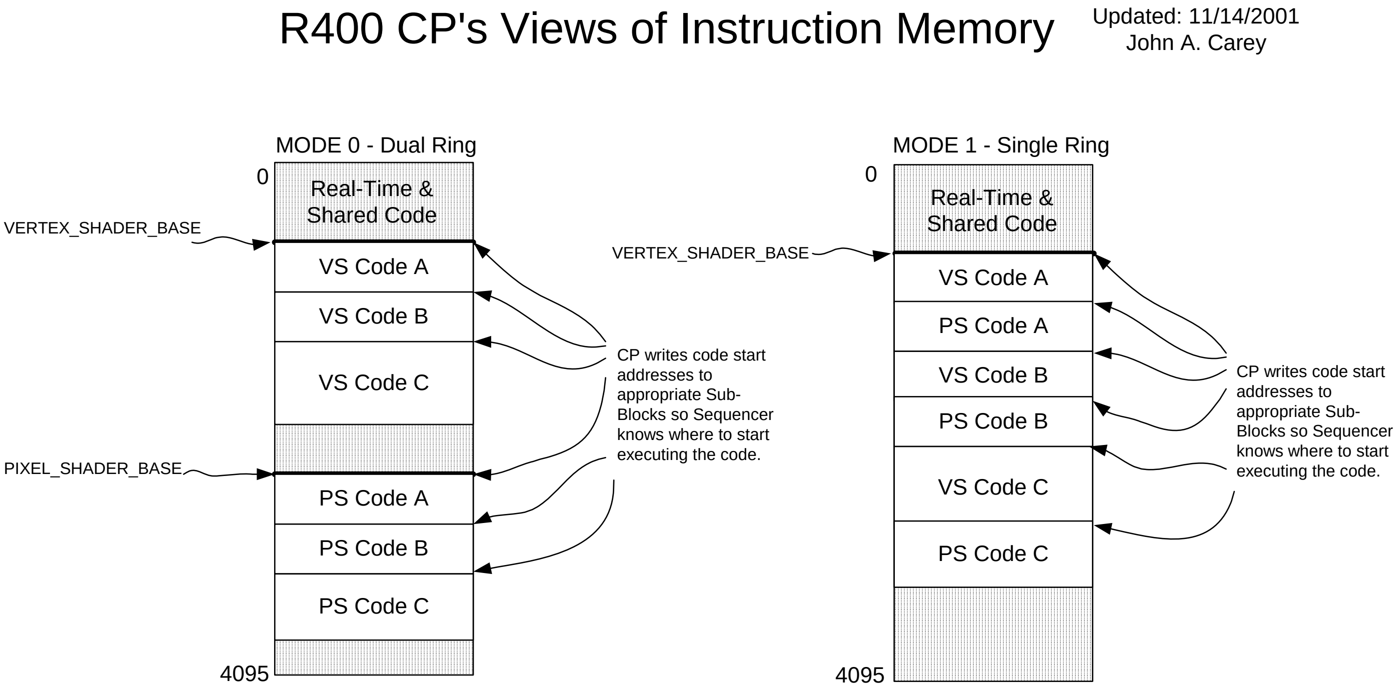

Figure 7: The CP's view of the instruction memory

4. Sequencer Instructions

All control flow instructions and move instructions are handled by the sequencer only. The ALUs will perform NOPs during this time (MOV PV,PV, PS,PS) if they have nothing else to do.

5. Constant Stores

5.1 Memory organizations

A likely size for the ALU constant store is 1024x128 bits. The read BW from the ALU constant store is 128 bits/clock and the write bandwidth is 32 bits/clock (directed by the CP bus size not by memory ports).

The maximum logical size of the constant store for a given shader is 256 constants. Or 512 for the pixel/vertex shader pair. The size of the re-mapping table is 128 lines (each line addresses 4 constants). The write granularity is 4 constants or 512 bits. It takes 16 clocks to write the four constants. Real time requires 256 lines in the physical memory (this is physically register mapped).

The texture state is also kept in a similar memory. The size of this memory is ~~192x128~~128x192 bits. The memory thus holds 128 texture states (192 bits per state). The logical size exposes 32 different states total, which are going to be shared between the pixel and the vertex shader. The size of the re-mapping table to for the texture state memory is ~~16~~ 32 lines (each line addresses ~~2~~ 1 texture state lines in the real memory). The CP write granularity is ~~2~~ 1 textur~~e~~e state lines (or ~~384~~ 192 bits). The driver sends 512 bits but the CP ignores the top ~~128~~ 320 bits. It thus takes ~~12~~ 6 clocks to write the ~~two~~ texture state~~s~~. Real time requires 32 lines in the physical memory (this is physically register mapped).

The control flow constant memory doesn’t sit behind a renaming table. It is register mapped and thus the driver must reload its content each time there is a state change. Its size is 320*32 because it must hold 8 copies of the 32 dwords of control flow constants and the loop construct constants must be aligned.

The constant re-mapping tables for texture state and ALU constants are logically register mapped for regular mode and physically register mapped for RT operation.

5.2 Management of the re-mapping tables

5.2.1 *R400 Constant management*

Formatted: Bullets and Numbering

The sequencer is responsible to manage two re-mapping tables (one for the constant store and one for the texture state). On a state change (by the driver), the sequencer will broadside copy the contents of its re-mapping tables to a new one. We have 8 different re-mapping tables we can use concurrently.

The constant memory update will be incremental, the driver only need to update the constants that actually changed between the two state changes.

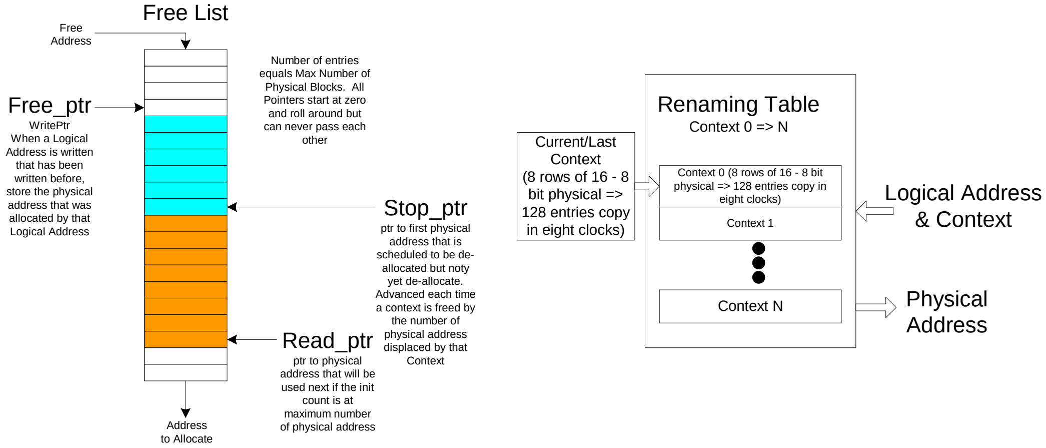
For this model to work in its simplest form, the requirement is that the physical memory MUST be at least twice as large as the logical address space + the space allocated for Real Time. In our case, since the logical address space is 512 and the reserved RT space can be up to 256 entries, the memory must be of sizes ~~1024~~ 1280 and above. Similarly the size of the texture store must be of 32*2+32 = 96 entries and above.

~~5.2.1~~5.2.2 *Proposal for R400LE constant management*

Formatted: Bullets and Numbering

To make this scheme work with only 512+256 = 768 entries, upon reception of a CONTROL packet of state + 1, the sequencer would check for SQ_IDLE and PA_IDLE and if both are idle will erase the content of state to replace it with the new state (this is depicted in Figure 9: De-allocation mechanism~~Figure 9: De-allocation mechanism~~~~Figure 2: De-allocation mechanism~~ ~~Figure 1: Dealocation mechanism~~). Note that in the case a state is cleared a value of 0 is written to the corresponding de-allocation counter location so that when the SQ is going to report a state change, nothing will be de-allocated upon the first report.

The second path sets all context dirty bits that were used in the current state to 1 (thus allowing the new state to reuse these physical addresses if needed). ~~Be careful to set only those bits that the CURENT STATE IS USING (if for example the current state uses only 64 constants we set only lines 0 thru 15 to 1). This is ok to do so because the blocks are idle and thus the context has finished drawing.~~



Free List
Free Address
Free_ptr
WritePtr When a Logical Address is written that has been written before, store the physical address that was allocated by that Logical Address
Number of entries equals Max Number of Physical Blocks. All Pointers start at zero and roll around but can never pass each other
Stop_ptr
ptr to first physical address that is scheduled to be de-allocated but noty yet de-allocate. Advanced each time a context is freed by the number of physical address displaced by that Context
Read_ptr
ptr to physical address that will be used next if the init count is at maximum number of physical address
Address to Allocate
Current/Last Context (8 rows of 16 - 8 bit physical => 128 entries copy in eight clocks)

Copy Last held above to Current Context on receipt of Set Constant for a new context (Hide loading behind Set State load - 16 clocks) all other Set States just write one entry to current state.

Figure 8: Constant management

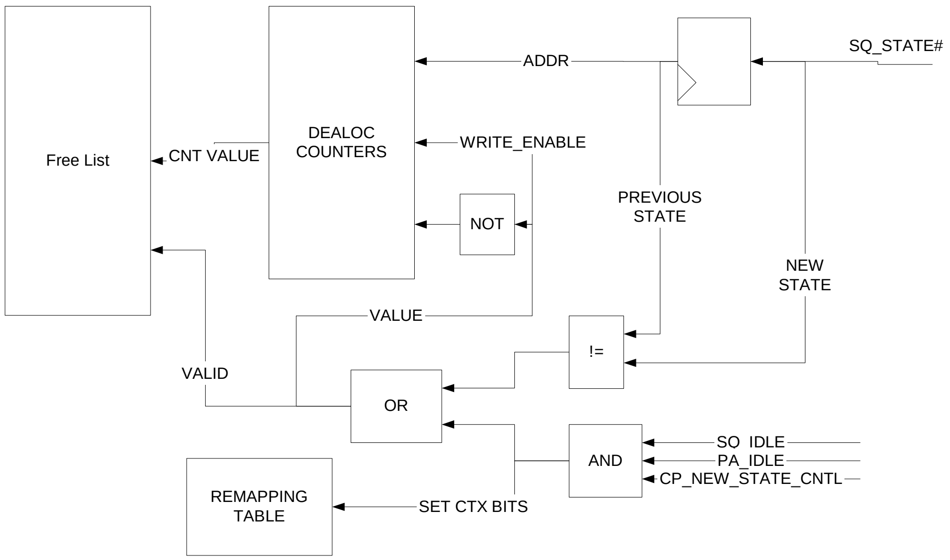

Figure 9: De-allocation mechanism for R400LE

~~5.2.1~~5.2.3 *Dirty bits*

Two sets of dirty bits will be maintained per logical address. The first one will be set to zero on reset and set when the logical address is addressed. The second one will be set to zero when-ever a new context is written and set for each address written while in this context. The reset dirty is not set, then writing to that logical address will not require de-allocation of whatever address stored in the renaming table. If it is set and the context dirty is not set, then the physical address store needs to be de-allocated and a new physical address is necessary to store the incoming data. If they are both set, then the data will be written into the physical address held in the renaming for the current logical address. No de-allocation or allocation takes place. This will happen when the driver does a set constant twice to the same logical address between context changes. NOTE: It is important to detect and prevent this, failure to do it will allow multiple writes to allocate all physical memory and thus hang because a context will not fit for rendering to start and thus free up space.

Formatted: Bullets and Numbering

~~5.2.2~~5.2.4 *Free List Block*

Formatted: Bullets and Numbering

A free list block that would consist of a counter (called the IFC or Initial Free Counter) that would reset to zero and incremented every time a chunk of physical memory is used until they have all been used once. This counter would be checked each time a physical block is needed, and if the original ones have not been used up, us a new one, else check the free list for an available physical block address. The count is the physical address for when getting a chunk from the counter.

Storage of a free list big enough to store all physical block addresses.

Maintain three pointers for the free list that are reset to zero. The first one we will call write_ptr. This pointer will identify the next location to write the physical address of a block to be de-allocated. Note: we can never free more physical memory locations than we have. Once recording address the pointer will be incremented to walk the free list like a ring.

The second pointer will be called stop_ptr. The stop_ptr pointer will be advanced by the number of address chunks de-allocates when a context finishes. The address between the stop_ptr and write_ptr cannot be reused because they are still in use. But as soon as the context using then is dismissed the stop_ptr will be advanced.

The third pointer will be called read_ptr. This pointer will point will point to the next address that can be used for allocation as long as the read_ptr does not equal the stop_ptr and the IFC is at its maximum count.

~~5.2.3~~5.2.5 *De-allocate Block*

Formatted: Bullets and Numbering

This block will maintain a free physical address block count for each context. While in current context, a count shall be maintained specifying how many blocks were written into the free list at the write_ptr pointer. This count will be reset upon reset or when this context is active on the back and different than the previous context. It is actually a count of blocks in the previous context that will no longer be used. This count will be used to advance the write_ptr pointer to make available the set of physical blocks freed when the previous context was done. This allows the discard or de-allocation of any number of blocks in one clock.

~~5.2.4~~5.2.6 *Operation of Incremental model*

Formatted: Bullets and Numbering

The basic operation of the model would start with the write_ptr, stop_ptr, read_ptr pointers in the free list set to zero and the free list counter is set to zero. Also all the dirty bits and the previous context will be initialized to zero. When the first set constants happen, the reset dirty bit will not be set, so we will allocate a physical location from the free list counter because its not at the max value. The data will be written into physical address zero. Both the additional copy of the renaming table and the context zeros of the big renaming table will be updated for the logical address that was written by set start with physical address of 0. This process will be repeated for any logical address that are not dirty until the context changes. If a logical address is hit that has its dirty bits set while in the same context, both dirty bits would be set, so the new data will be over-written to the last physical address assigned for this logical address. When the first draw command of the context is detected, the previous context stored in the additional renaming table will be copied to the larger renaming table in the current (new) context location. Then the set constant logical address with be loaded with a new physical address during the copy and if the reset dirty was set, the physical address it replaced in the renaming table would be entered at the write_ptr pointer location on the free list and the write_ptr will be incremented. The de-allocation counter for the previous context (eight) will be incremented. This as set states come in for this context one of the following will happen:

1.) No dirty bits are set for the logical address being updated. A line will be allocated of the free-list counter or the free list at read_ptr pointer if read_ptr != to stop_ptr .
2.) Reset dirty set and Context dirty not set. A new physical address is allocated, the physical address in the renaming table is put on the free list at write_ptr and it is incremented along with the de-allocate counter for the last context.
3.) Context dirty is set then the data will be written into the physical address specified by the logical address.

This process will continue as long as set states arrive. This block will provide backpressure to the CP whenever he has not free list entries available (counter at max and stop_ptr == read_ptr). The command stream will keep a count of contexts of constants in use and prevent more than max constants contexts from being sent.

Whenever a draw packet arrives, the content of the re-mapping table is written to the correct re-mapping table for the context number. Also if the next context uses less constants than the current one all exceeding lines are moved to the free list to be de-allocated later. This happens in parallel with the writing of the re-mapping table to the correct memory.

Now preferable when the constant context leaves the last ALU clause it will be sent to this block and compared with the previous context that left. (Init to zero) If they differ than the older context will no longer be referenced and thus can be de-allocated in the physical memory. This is accomplished by adding the number of blocks freed this context to the stop_ptr pointer. This will make all the physical addresses used by this context available to the read_ptr allocate pointer for future allocation.

This device allows representation of multiple contexts of constants data with N copies of the logical address space. It also allows the second context to be represented as the first set plus some new additional data by just storing the delta's. It allows memory to be efficiently used and when the constants updates are small it can store multiple context. However, if the updates are large, less contexts will be stored and potentially performance will be degraded. Although it will still perform as well as a ring could in this case.

5.3 Constant Store Indexing

In order to do constant store indexing, the sequencer must be loaded first with the indexes (that come from the GPRs). There are 144 wires from the exit of the SP to the sequencer (9 bits pointers x 16 vertexes/clock). Since the data must pass thru the Shader pipe for the float to fixed conversion, there is a latency of 4 clocks (1 instruction)

between the time the sequencer is loaded and the time one can index into the constant store. The assembly will look like this

```
MOVA  R1.X,R2.X       // Loads the sequencer with the content of R2.X, also copies the content of R2.X into R1.X
NOP                   // latency of the float to fixed conversion
ADD   R3,R4,C0[R2.X]// Uses the state from the sequencer to add R4 to C0[R2.X] into R3
```

Note that we don't really care about what is in the brackets because we use the state from the MOVA instruction. R2.X is just written again for the sake of simplicity and coherency.

The storage needed in the sequencer in order to support this feature is 2*64*9 bits = 1152 bits.

5.4 Real Time Commands

The real time commands constants are written by the CP using the register mapped registers allocated for RT. It works is the same way than when dealing with regular constant loads BUT in this case the CP is not sending a logical address but rather a physical address and the reads are not passing thru the re-mapping table but are directly read from the memory. The boundary between the two zones is defined by the CONST_EO_RT control register. Similarly, for the fetch state, the boundary between the two zones is defined by the TSTATE_EO_RT control register.

5.5 Constant Waterfalling

In order to have a reasonable performance in the case of constant store indexing using the address register, we are going to have the possibility of using the physical memory port for read only. This way we can read 1 constant per clock and thus have a worst-case waterfall mode of 1 vertex per clock. There is a small synchronization issue related with this as we need for the SQ to make sure that the constants where actually written to memory (not only sent to the sequencer) before it can allow the first vector of pixels or vertices of the state to go thru the ALUs. To do so, the sequencer keeps 8 bits (one per render state) and sets the bits whenever the last render state is written to memory and clears the bit whenever a state is freed.

6. Looping and Branches

Loops and branches are planned to be supported and will have to be dealt with at the sequencer level. We plan on supporting constant loops and branches using a control program.

6.1 The controlling state.

The R400 controling state consists of:

Boolean[256:0]
Loop_count[7:0][31:0]
Loop_Start[7:0][31:0]
Loop_Step[7:0][31:0]

That is 256 Booleans and 32 loops.

We have a stack of 4 elements for nested calls of subroutines and 4 loop counters to allow for nested loops.

This state is available on a per shader program basis.

6.2 The Control Flow Program

Examples of control flow programs are located in the R400 programming guide document.

The basic model is as follows:

The render state defined the clause boundaries:

Vertex_shader_fetch[7:0][7:0]	// eight 8 bit pointers to the location where each clauses control program is located
Vertex_shader_alu[7:0][7:0]	// eight 8 bit pointers to the location where each clauses control program is located
Pixel_shader_fetch[7:0][7:0]	// eight 8 bit pointers to the location where each clauses control program is located
Pixel_shader_alu[7:0][7:0]	// eight 8 bit pointers to the location where each clauses control program is located

A pointer value of FF means that the clause doesn't contain any instructions.

The control program for a given clause is executed to completion before moving to another clause, (with the exception of the pick two nature of the alu execution). The control program is the only program aware of the clause boundaries.

The control program has eleven basic instructions:

Execute
Conditional_execute
Conditional_Execute_Predicates
Conditional_jump
Conditionnal_Call
Return
Loop_start
Loop_end
End_of_clause
Conditional_End_of_clause
NOP

Execute, causes the specified number of instructions in instruction store to be executed.
Conditional_execute checks a condition first, and if true, causes the specified number of instructions in instruction store to be executed.
Loop_start resets the corresponding loop counter to the start value on the first pass after it checks for the end condition and if met jumps over to a specified address.
Loop_end increments (decrements?) the loop counter and jumps back the specified number of instructions.

Conditionnal_Call jumps to an address and pushes the IP counter on the stack if the condition is met. On the return instruction, the IP is popped from the stack.
~~Conditional_execute_or_Jump executes a block of instructions or jumps to an address is the condition is not met.~~
Conditional_execute_Predicates executes a block of instructions if all bits in the predicate vectors meet the condition.
End_of_clause marks the end of a clause.
Conditional_End_of_clause marks the end of a clause if the condition is met.
Conditional_jumps jumps to an address if the condition is met.
NOP is a regular NOP

NOTE THAT ALL JUMPS MUST JUMP TO EVEN CFP ADDRESSES since there are two control flow instructions per memory line. Thus the compiler must insert NOPs where needed to align the jumps on even CFP addresses.

Also if the jump is logically bigger than pshader_cntl_size (or vshader_cntl_size) we break the program (clause) and set the debug registers. If an execute or conditional_execute is lower than cntl_size or bigger than size we also break the program (clause) and set the debug registers.

We have to fit instructions into 48 bits in order to be able to put two control flow instruction per line in the instruction store.

Note that whenever a field is marked as RESERVED, it is assumed that all the bits of the field are cleared (0).

Execute				
47	46… 42	41 … 24	23 … 12	11 … 0
Addressing	00001	RESERVED	Instruction count	Exec Address

Execute up to 4k instructions at the specified address in the instruction memory.

NOP		
47	46 … 42	41 … 0
Addressing	00010	RESERVED

This is a regular NOP.

Conditional_Execute							
47	46 … 42	41	40 … 33	32	31 … 24	23 … 12	11 … 0
Addressing	00011	RESERVED	Boolean address	Condition	RESERVED	Instruction count	Exec Address

If the specified Boolean (8 bits can address 256 Booleans) meets the specified condition then execute the specified instructions (up to 4k instructions)

Conditional_Execute_Predicates							
47	46 … 42	41 … 35	34 … 33	32	31 … 24	23 … 12	11 … 0
Addressing	00100	RESERVED	Predicate vector	Condition	RESERVED	Instruction count	Exec Address

Check the AND/OR of all current predicate bits. If AND/OR matches the condition execute the specified number of instructions. We need to AND/OR this with the kill mask in order not to consider the pixels that aren't valid.

Loop_Start				
47	46 … 42	41 … 17	16 … 12	11 … 0
Addressing	00101	RESERVED	loop ID	Jump address

Loop Start. Compares the loop iterator with the end value. If loop condition not met jump to the address. Forward jump only. Also computes the index value. The loop id must match between the start to end, and also indicates which control flow constants should be used with the loop.

Loop_End				
47	46 … 42	41 … 17	16 … 12	11 … 0
Addressing	00110~~1~~	RESERVED	loop ID	start address

Loop end. Increments the counter by one, compares the loop count with the end value. If loop condition met, continue, else, jump BACK to the start of the loop.

The way this is described does not prevent nested loops, and the inclusion of the loop id make this easy to do.

Conditionnal_Call						
47	46 … 42	41 … 35	34 … 33	32	31 … 12	11 … 0
Addressing	0~~1~~0111~~0~~ ~~00~~	RESERVED	Predicate vector	Condition	RESERVED	Jump address

If the condition is met, jumps to the specified address and pushes the control flow program counter on the stack.

Return		
47	46 … 42	41 … 0
Addressing	01000~~00~~ ~~1~~	RESERVED

Pops the topmost address from the stack and jumps to that address. If nothing is on the stack, the program will just continue to the next instruction.

Conditionnal_Jump							
47	46 … 42	41	40 … 33	32	31	30 … 12	11 … 0
Addressing	01001~~10~~	RESERVED	Boolean address	Condition	FW only	RESERVED	Jump address

If condition met, jumps to the address. FORWARD jump only allowed if bit 31 set. Bit 31 is only an optimization for the compiler and should NOT be exposed to the API.

Conditional_End_of_Clause					
47	46 … 42	41	40 … 33	32	31 … 0
Addressing	01010~~1~~	RESERVED	Boolean address	Condition	RESERVED

This is an optimization in the case of very short shaders (where the control flow instruction can't be hidden anymore and thus are not free. In this case, if the condition is met, the clause is ended, else we continue the execution of the clause.

End_of_Clause		
47	46 … 42	41 … 0
Addressing	01011~~0~~ ~~11~~	RESERVED

Marks the end of a clause.

To prevent infinite loops, we will keep ~~9 ~~9 bits loop ~~counters ~~iterators instead of 8 (we are only able to loop 256 times). If the counter goes higher than 255 then the loop_end or the loop_start instruction is going to break the loop and set the debug GPRs.

6.3 Data dependant predicate instructions

Data dependant conditionals will be supported in the R400. The only way we plan to support those is by supporting three vector/scalar predicate operations of the form:

PRED_SETE_# - similar to SETE except that the result is 'exported' to the sequencer.

PRED_SETNE_# - similar to SETNE except that the result is 'exported' to the sequencer.
PRED_SETGT_# - similar to SETGT except that the result is 'exported' to the sequencer
PRED_SETGTE_# - similar to SETGTE except that the result is 'exported' to the sequencer

For the scalar operations only we will also support the two following instructions:
PRED_SETE0_# – SETE0
PRED_SETE1_# – SETE1

The export is a single bit - 1 or 0 that is sent using the same data path as the MOVA instruction. The sequencer will maintain 4 sets of 64 bit predicate vectors (in fact 8 sets because we interleave two programs but only 4 will be exposed) and use it to control the write masking. This predicate is not maintained across clause boundaries. The # sign is used to specify which predicate set you want to use 0 thru 3.

Then we have two conditional execute bits. The first bit is a conditional execute “on” bit and the second bit tells us if we execute on 1 or 0. For example, the instruction:

P0_ADD_# R0,R1,R2

Is only going to write the result of the ADD into those GPRs whose predicate bit is 0. Alternatively, P1_ADD_# would only write the results to the GPRs whose predicate bit is set. The use of the P0 or P1 without precharging the sequencer with a PRED instruction is undefined.

{Issue: do we have to have a NOP between PRED and the first instruction that uses a predicate?}

6.4 HW Detection of PV,PS

Because of the control program, the compiler cannot detect statically dependant instructions. In the case of non-masked writes and subsequent reads the sequencer will insert uses of PV,PS as needed. This will be done by comparing the read address and the write address of consecutive instructions. For masked writes, the sequencer will insert NOPs wherever there is a dependant read/write.

The sequencer will also have to insert NOPs between PRED_SET and MOVA instructions and their uses.

6.5 Register file indexing

Because we can have loops in fetch clause, we need to be able to index into the register file in order to retrieve the data created in a fetch clause loop and use it into an ALU clause. The instruction will include the base address for register indexing and the instruction will contain these controls:

Bit7	Bit 6	
0	0	'absolute register'
0	1	'relative register'
1	0	'previous vector'
1	1	'previous scalar'

In the case of an absolute register we just take the address as is. In the case of a relative register read we take the base address and we add to it the loop_index and this becomes our new address that we give to the shader pipe.

The sequencer is going to keep a loop index computed as such:

Index = Loop_iterator*Loop_step + Loop_start.

~~The index is going to return 0 if it is out of the range.~~
We loop until loop_iterator = loop_count. Loop_step is a signed value [-128…127]. The computed index value is a 10 bit counter that is also signed. Its real range is [-256,256]. The tenth bit is only there so that we can provide an out of range value to the “indexing logic” so that it knows when the provided index is out of range and thus can make the necessary arrangements.

6.6 Predicated Instruction support for Texture clauses

For texture clauses, we support the following optimization: we keep 1 bit (thus 4 bits for the four predicate vectors) per predicate vector in the reservation stations. A value of 1 means that one ore more elements in the vector have a value of one (thus we have to do the texture fetches for the whole vector). A value of 0 means that no elements in the vector have his predicate bit set and we can thus skip over the texture fetch. **We have to make sure the invalid pixels aren't considered with this optimization.**

6.7 Debugging the Shaders

In order to be able to debug the pixel/vertex shaders efficiently, we provide 2 methods.

6.7.1 *Method 1: Debugging registers*

Current plans are to expose 2 debugging, or error notification, registers:
1. address register where the first error occurred
2. count of the number of errors

The sequencer will detect the following groups of errors:
- count overflow
~~-~~- constant indexing overflow
- register indexing overflow

Formatted: Bullets and Numbering

Compiler recognizable errors:
- jump errors
    relative jump address > size of the control flow program
    ~~relative jump address > length of the shader program~~
~~–~~- call stack
    call with stack full
    return with stack empty

~~With two of the errors, a~~A jump error ~~or a register overflow~~ will always cause the program to break. In this case, a break means that a clause will halt execution, but allowing further clauses to be executed.

With all the other errors, program can continue to run, potentially to worst-case limits. The program will only break if the DB_PROB_BREAK register is set.

If indexing outside of the ~~constant~~ constant or the register range, causing an overflow error, the hardware is specified to return the value with an index of 0. This could be exploited to generate error tokens, by reserving and initializing the 0th register (or constant) for errors.

{ISSUE : Interrupt to the driver or not?}

6.7.2 *Method 2: Exporting the values in the GPRs (12)*

The sequencer will have a count register and an address register for this mode and 3 bits per clause specifying the execution mode for each clause. The modes can be :
1) Normal
2) Debug Kill
3) Debug Addr + Count

Under the normal mode execution follows the normal course. Under the kill mode, all control flow instructions are executed but all normal shader instructions of the clause are replaced by NOPs. Only debug_export instructions of clause 7 will be executed under the debug kill setting. Under the other mode, normal execution is done until we reach an address specified by the address register and instruction count (useful for loops) specified by the count register. After we have hit the instruction n times (n=count) we switch the clause to the kill mode.

Under the debug mode (debug kill OR debug Addr + count), it is assumed that clause 7 is always exporting 12 debug vectors and that all other exports to the SX block (position, color, z, ect) will been turned off (changed into NOPs) by the sequencer (even if they occur before the address stated by the ADDR debug register).

7. Pixel Kill Mask

A vector of 64 bits is kept by the sequencer per group of pixels/vertices. Its purpose is to optimize the texture fetch requests and allow the shader pipe to kill pixels using the following instructions:

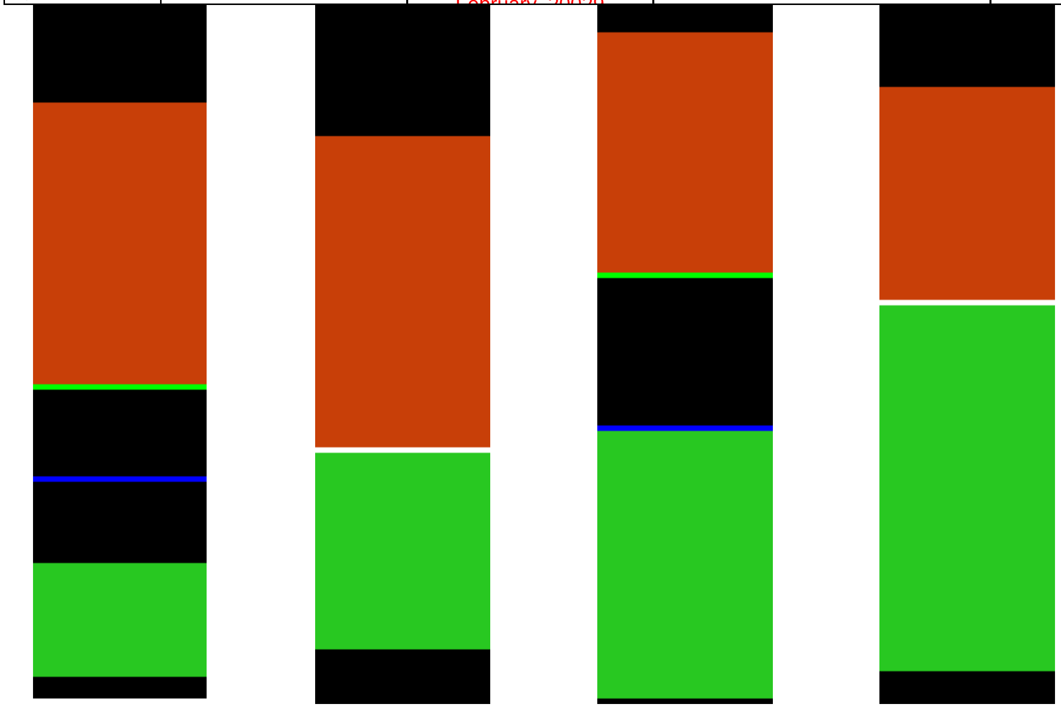
MASK_SETE
MASK_SETNE
MASK_SETGT
MASK_SETGTE

8. Multipass vertex shaders (HOS)

Multipass vertex shaders are able to export from the 6 last clauses but to memory ONLY.

9. Register file allocation

The register file allocation for vertices and pixels can either be static or dynamic. In both cases, the register file in managed using two round robins (one for pixels and one for vertices). In the dynamic case the boundary between pixels and vertices is allowed to move, in the static case it is fixed to 128-VERTEX_REG_SIZE for vertices and ~~256-~~ ~~VERTEX~~PIXEL_REG_SIZE for pixels.



Above is an example of how the algorithm works. Vertices come in from top to bottom; pixels come in from bottom to top. Vertices are in orange and pixels in green. The blue line is the tail of the vertices and the green line is the tail of the pixels. Thus anything between the two lines is shared. When pixels meets vertices the line turns white and the boundary is static until both vertices and pixels share the same “unallocated bubble”. Then the boundary is allowed to move again. The numbering of the GPRs starts from the bottom of the picture at index 0 and goes up to the top at index 127.

10. Fetch Arbitration

The fetch arbitration logic chooses one of the 8 potentially pending fetch clauses to be executed. The choice is made by looking at the fifos from 7 to 0 and picking the first one ready to execute. Once chosen, the clause state machine will send one 2x2 fetch per clock (or 4 fetches in one clock every 4 clocks) until all the fetch instructions of the clause are sent. This means that there cannot be any dependencies between two fetches of the same clause.

The arbitrator will not wait for the fetches to return prior to selecting another clause for execution. The fetch pipe will be able to handle up to X(?) in flight fetches and thus there can be a fair number of active clauses waiting for their fetch return data.

11. ALU Arbitration

ALU arbitration proceeds in almost the same way than fetch arbitration. The ALU arbitration logic chooses one of the 8 potentially pending ALU clauses to be executed. The choice is made by looking at the fifos from 7 to 0 and picking the first one ready to execute. There are two ALU arbiters, one for the even clocks and one for the odd clocks. For example, here is the sequencing of two interleaved ALU clauses (E and O stands for Even and Odd sets of 4 clocks):

Einst0 Oinst0 Einst1 Oinst1 Einst2 Oinst2 Einst0 Oinst3 Einst1 Oinst4 Einst2 Oinst0…
Proceeding this way hides the latency of 8 clocks of the ALUs. Also note that the interleaving also occurs across clause boundaries.

12. Handling Stalls

When the output file is full, the sequencer prevents the ALU arbitration logic from selecting the last clause (this way nothing can exit the shader pipe until there is place in the output file. If the packet is a vertex packet and the position buffer is full (POS_FULL) then the sequencer also prevents a thread from entering the exporting clause (3?). The sequencer will set the OUT_FILE_FULL signal n clocks before the output file is actually full and thus the ALU arbiter will be able read this signal and act accordingly by not preventing exporting clauses to proceed.

13. Content of the reservation station FIFOs

The reservation FIFOs contain the state of the vector of pixels and vertices. We have two sets of those: one for pixels, and one for vertices. They contain 3 bits of Render State 7 bits for the base address of the GPRs, some bits for LOD correction and coverage mask information in order to fetch fetch for only valid pixels, the quad address.

14. The Output File

The output file is where pixels are put before they go to the RBs. The write BW to this store is 256 bits/clock. Just before this output file are staging registers with write BW 512 bits/clock and read BW 256 bits/clock. The staging registers are 4x128 (and there are 16 of those on the whole chip).

15. IJ Format

The IJ information sent by the PA is of this format on a per quad basis:

We have a vector of IJ's (one IJ per pixel at the centroid of the fragment or at the center of the pixel depending on the mode bit). The interpolation is done at a different precision across the 2x2. The upper left pixel's parameters are always interpolated at full 20x24 mantissa precision. Then the result of the interpolation along with the difference in IJ in reduced precision is used to interpolate the parameter for the other three pixels of the 2x2. Here is how we do it:

Assuming P0 is the interpolated parameter at Pixel 0 having the barycentric coordinates I(0), J(0) and so on for P1,P2 and P3. Also assuming that A is the parameter value at V0 (interpolated with I), B is the parameter value at V1 (interpolated with J) and C is the parameter value at V2 (interpolated with (1-I-J).

$$\Delta 01I = I(1) - I(0)$$
$$\Delta 01J = J(1) - J(0)$$
$$\Delta 02I = I(2) - I(0)$$
$$\Delta 02J = J(2) - J(0)$$
$$\Delta 03I = I(3) - I(0)$$
$$\Delta 03J = J(3) - J(0)$$

P0	P1
P2	P3

$$P0 = C + I(0)*(A-C) + J(0)*(B-C)$$
$$P1 = P0 + \Delta 01I*(A-C) + \Delta 01J*(B-C)$$
$$P2 = P0 + \Delta 02I*(A-C) + \Delta 02J*(B-C)$$
$$P3 = P0 + \Delta 03I*(A-C) + \Delta 03J*(B-C)$$

P0 is computed at 20x24 mantissa precision and P1 to P3 are computed at 8X24 mantissa precision. So far no visual degradation of the image was seen using this scheme.

Multiplies (Full Precision): 2
Multiplies (Reduced precision): 6
Subtracts 19x24 (Parameters): 2

Adds: 8

FORMAT OF P0's IJ : Mantissa 20 Exp 4 for I + Sign
Mantissa 20 Exp 4 for J + Sign

FORMAT of Deltas (x3): Mantissa 8 Exp 4 for I + Sign
Mantissa 8 Exp 4 for J + Sign

Total number of bits : 20*2 + 8*6 + 4*8 + 4*2 = 128

All numbers are kept using the un-normalized floating point convention: if exponent is different than 0 the number is normalized if not, then the number is un-normalized. The maximum range for the IJs (Full precision) is +/- 63 and the range for the Deltas is +/- 127.

15.1 Interpolation of constant attributes

Because of the floating point imprecision, we need to take special provisions if all the interpolated terms are the same or if two of the barycentric coordinates are the same.

We start with the premise that if A = B and B = C and C = A, then P0,1,2,3 = A. Since one or more of the IJ terms may be zero, so we extend this to:

```
if (A=B and B=C and C=A)
   P0,1,2,3 = A;
else if ((I = 0) or (J = 0)) and
          ((J = 0) or (1-I-J = 0)) and
          ((1-J-I = 0) or (I = 0))) {
                if(I != 0) {
                    P0 = A;
                } else if(J != 0) {
                    P0 = B;
                } else {
                    P0 = C;
               }
            //rest of the quad interpolated normally
}
else
{
            normal interpolation
}
```

16. Staging Registers

In order for the reuse of the vertices to be 14, the sequencer will have to re-order the data sent IN ORDER by the VGT for it to be aligned with the parameter cache memory arrangement. Given the following group of vertices sent by the VGT:

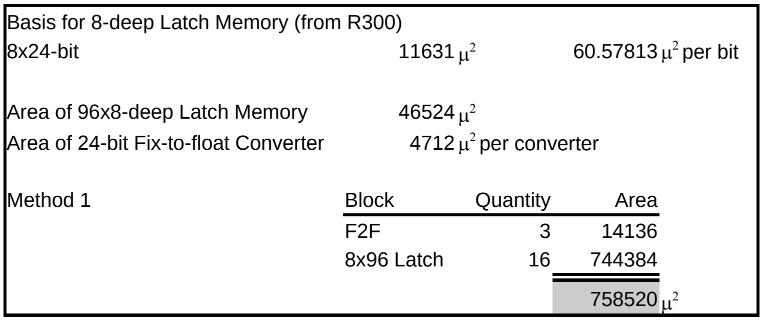
0 1 2 3 4 5 6 7 8 9 10 11 12 13 14 15 || 16 17 18 19 20 21 22 23 24 25 26 27 28 29 30 31 || 32 33 34 35 36 37 38 39 40 41 42 43 44 45 46 47 || 48 49 50 51 52 53 54 55 56 57 58 59 60 61 62 63

The sequencer will re-arrange them in this fashion:

0 1 2 3 16 17 18 19 32 33 34 35 48 49 50 51 || 4 5 6 7 20 21 22 23 36 37 38 39 52 53 54 55 || 8 9 10 11 24 25 26 27 40 41 42 43 56 57 58 59 || 12 13 14 15 28 29 30 31 44 45 46 47 60 61 62 63

The || markers show the SP divisions. In the event a shader pipe is broken, the VGT will send padding to account for the missing pipe. For example, if SP1 is broken, vertices 4 5 6 7 20 21 22 23 36 37 38 39 52 53 54 55 will still be sent by the VGT to the SQ **BUT** will not be processed by the SP and thus should be considered invalid (by the SU and VGT).

The most straightforward, *non-compressed* interface method would be to convert, in the VGT, the data to 32-bit floating point prior to transmission to the VSISRs. In this scenario, the data would be transmitted to (and stored in) the VSISRs in full 32-bit floating point. This method requires three 24-bit fixed-to-float converters in the VGT. Unfortunately, it also requires and additional 3,072 bits of storage across the VSISRs. This interface is illustrated in Figure 12~~Figure 12Figure 2~~. The area of the fixed-to-float converters and the VSISRs for this method is roughly estimated as 0.759sqmm using the R300 process. The gate count estimate is shown in Figure 11~~Figure 11Figure 1~~.



Basis for 8-deep Latch Memory (from R300)			
8x24-bit	11631 μ^2		60.57813 μ^2 per bit
Area of 96x8-deep Latch Memory	46524 μ^2		
Area of 24-bit Fix-to-float Converter	4712 μ^2 per converter		
Method 1	Block	Quantity	Area
	F2F	3	14136
	8x96 Latch	16	744384
			758520 μ^2

Figure 11~~111~~:Area Estimate for VGT to Shader Interface

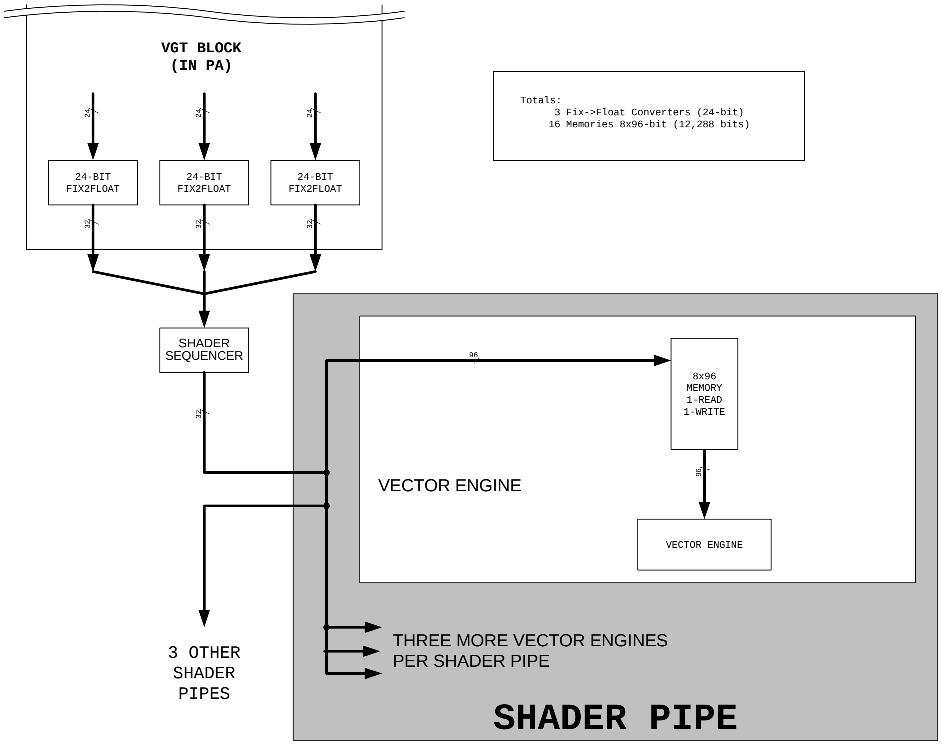


Figure 12~~122~~:VGT to Shader Interface

17. The parameter cache

The parameter cache is where the vertex shaders export their data. It consists of 16 128x128 memories (1R/1W). The reuse engine will make it so that all vertexes of a given primitive will hit different memories. The allocation method for these memories is a simple round robin. The parameter cache pointers are mapped in the following way: 4MSBs are the memory number and the 7 LSBs are the address within this memory.

MEMORY NUMBER 4 bits	ADDRESS 7 bits

The PA generates the parameter cache addresses as the positions come~~s~~ from the SQ. All it needs to do is keep a Current_Location pointer (7 bits only) and as the positions comes increment the memory number. When the memory number field wraps around, the PA increments the Current_Location by VS_EXPORT_COUNT_~~6~~7 (a snooped register from the SQ). As an example, say the memories are all empty to begin with and the vertex shader is exporting 8 parameters per vertex (VS_EXPORT_COUNT_~~6~~ 7 = 8). The first position received is going to have the PC address 00000000000 the second one 00010000000, third one 00100000000 and so on up to 11110000000. Then the next position received (the 17th) is going to have the address 00000001000, the 18th 00010001000, the 19th 00100001000 and so on. The Current_location is NEVER reset BUT on chip resets. The only thing to be careful about is that if the SX doesn't send you a full group of positions (<64) then you need to fill the address space so that the next group starts correctly aligned (for example if you receive only 33 positions then you need to add ~~1~~2*VS_EXPORT_COUNT_~~6~~ 7to Current_Location and reset the memory count to 0 before the next vector begins).

18. Vertex position exporting

On clause 3 the vertex shader can export to the PA both the vertex position and the point sprite. It can also do so at clause 7 if not done at clause 3. The storage needed to perform the position export is at least 64x128 memories for the position and 64x32 memories for the sprite size. It is going to be taken in the pixel output fifo from the SX blocks. The clause where the position export occurs is specified by the EXPORT_LATE register. If turned on, it means that the export is going to occur at ALU clause 7 if unset position export occurs at clause 3.

19. Exporting Arbitration

Here are the rules for co-issuing exporting ALU clauses.

1) Position exports and position exports cannot be co-issued.

Formatted: Bullets and Numbering

All other types of exports can be co-issued as long as there is place in the receiving buffer.

{ISSUE: Do we move the parameter caches to the SX?}
~~Any type of exporting clause can be co-issued. The sequencer will have to make sure back to back memory exports (position/straight memory exports) are interleaved with NOPs as we don't have the bandwidth to service them at full speed.~~

20. Export Types

The export type (or the location where the data should be put) is specified using the destination address field in the ALU instruction. Here is a list of all possible export modes:

20.1 Vertex Shading

0:15	- 16 parameter cache
16:31	- Empty (Reserved?)
32:43	- 12 vertex exports to the frame buffer and index
44:47	- Empty
48:59	- 12 debug export (interpret as normal vertex export)
60	- export addressing mode
61	- Empty
62	- position ~~sprite size export that goes with position export (point_h,point_w,edgeflag,misc)~~
63	- ~~position~~sprite size export that goes with position export (point_h,point_w,edgeflag,misc)

20.2 Pixel Shading

0	- Color for buffer 0 (primary)
1	- Color for buffer 1
2	- Color for buffer 2
3	- Color for buffer 3
4:7	- Empty
8	- Buffer 0 Color/Fog (primary)
9	- Buffer 1 Color/Fog
10	- Buffer 2 Color/Fog
11	- Buffer 3 Color/Fog
12:15	- Empty
16:31	- Empty (Reserved?)
32:43	- 12 exports for multipass pixel shaders.
44:47	- Empty
48:59	- 12 debug exports (interpret as normal pixel export)
60	- export addressing mode
61:62	- Empty
63	- Z for primary buffer (Z exported to 'alpha' component)

21. Special Interpolation modes

21.1 Real time commands

We are unable to use the parameter memory since there is no way for a command stream to write into it. Instead we need to add three 16x128 memories (one for each of three vertices x 16 interpolants). These will be mapped onto the register bus and written by type 0 packets, and output to the the parameter busses (the sequencer and/or PA need to be able to address the reatime parameter memory as well as the regular parameter store. For higher performance we should be able able to view them as two banks of 16 and do double buffering allowing one to be loaded, while the other is rasterized with. Most overlay shaders will need 2 or 4 scalar coordinates, one option might be to restrict the memory to 16x64 or 32x64 allowing only two interpolated scalars per cycle, the only problem I see with this is, if we view support for 16 vector-4 interpolants important (true only if we map Microsoft's high priority stream to the realtime stream), then the PA/sequencer need to support a realtime-specific mode where we need to address 32 vectors of parameters instead of 16. This mode is triggered by the primitive type: REAL TIME. The actual memories are in the in the SX blocks. The parameter data memories are hooked on the RBBM bus and are loaded by the CP using register mapped memory.

21.2 Sprites/ XY screen coordinates/ FB information

When working with sprites, one may want to overwrite the parameter 0 with SC generated data. Also, XY screen coordinates may be needed in the shader program. This functionality is controlled by the gen_I0 register (in SQ) in conjunction with the SND_XY register (in SC). Also it is possible to send the faceness information (for OGL front/back special operations) to the shader using the same control register. Here is a list of all the modes and how they interact together:

Gen_st is a bit taken from the interface between the SC and the SQ. This is the MSB of the primitive type. If the bit is set, it means we are dealing with Point AA, Line AA or sprite and in this case the vertex values are going to generated between 0 and 1.

Param_Gen_I0 disable, snd_xy disable, no gen_st – I0 = No modification
Param_Gen_I0 disable, snd_xy disable, gen_st – I0 = No modification
Param_Gen_I0 disable, snd_xy enable, no gen_st – I0 = No modification
Param_Gen_I0 disable, snd_xy enable, gen_st – I0 = No modification
Param_Gen_I0 enable, snd_xy disable, no gen_st – I0 = garbage, garbage, garbage, faceness
Param_Gen_I0 enable, snd_xy disable, gen_st – I0 = garbage, garbage, s, t
Param_Gen_I0 enable, snd_xy enable, no gen_st – I0 = screen x, screen y, garbage, faceness
Param_Gen_I0 enable, snd_xy enable, gen_st – I0 = screen x, screen y, s, t

21.3 Auto generated counters

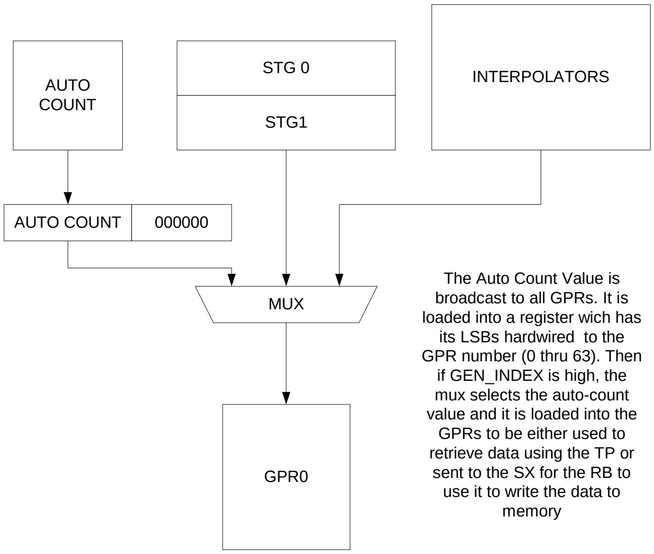
In the cases we are dealing with multipass shaders, the sequencer is going to generate a vector count to be able to both use this count to write the 1^{st} pass data to memory and then use the count to retrieve the data on the 2^{nd} pass. The count is always generated in the same way but it is passed to the shader in a slightly different way depending on the shader type (pixel or vertex). This is toggled on and off using the GEN_INDEX register. The sequencer is going to keep two counters, one for pixels and one for vertices. Every time a full vector of vertices or pixels is written to the GPRs the counter is incremented. Every time a state change is detected, the corresponding counter is reset. While there is only one count broadcast to the GPRs, the LSB are hardwired to specific values making the index different for all elements in the vector.

21.3.1 *Vertex shaders*

In the case of vertex shaders, if GEN_INDEX is set, the data will be put into the x field of the third register (it means that the compiler must allocate 3 GPRs in all multipass vertex shader modes).

21.3.2 *Pixel shaders*

In the case of pixel shaders, if GEN_INDEX is set and Param_Gen_I0 is enabled, the data will be put in the x field of the 2^{nd} register (R1.x), else if GEN_INDEX is set the data will be put into the x field of the 1^{st} register (R0.x).



The Auto Count Value is broadcast to all GPRs. It is loaded into a register wich has its LSBs hardwired to the GPR number (0 thru 63). Then if GEN_INDEX is high, the mux selects the auto-count value and it is loaded into the GPRs to be either used to retrieve data using the TP or sent to the SX for the RB to use it to write the data to memory

Figure 13: GPR input mux Control

22. State management

Every clock, the sequencer will report to the CP the oldest states still in the pipe. These are the states of the programs as they enter the last ALU clause.

22.1 Parameter cache synchronization

In order for the sequencer not to begin a group of pixels before the associated group of vertices has finished, the sequencer will keep a 6 bit count per state (for a total of 8 counters). These counters are initialized to 0 and every time a vertex shader exports its data TO THE PARAMETER CACHE, the corresponding pointer is incremented. When the SC sends a new vector of pixels with the SC_SQ_new_vector bit asserted, the sequencer will first check if the count is greater than 0 before accepting the transmission (it will in fact accept the transmission but then lower its ready to receive). Then the sequencer waits for the count to go to one and decrements it. The sequencer can then issue the group of pixels to the interpolators. Every time the state changes, the new state counter is initialized to 0.

23. XY Address imports

The SC will be able to send the XY addresses to the GPRs. It does so by interleaving the writes of the IJs (to the IJ buffer) with XY writes (to the XY buffer). Then when writing the data to the GPRs, the sequencer is going to interpolate the IJ data or pass the XY data thru a Fix→float converter and expander and write the converted values to the GPRs. The Xys are currently SCREEN SPACE COORDINATES. The values in the XY buffers will wrap. See section 21.2 for details on how to control the interpolation in this mode.

23.1 Vertex indexes imports

In order to import vertex indexes, we have 16 8x96 staging registers. These are loaded one line at a time by the VGT block (96 bits). They are loaded in floating point format and can be transferred in 4 or 8 clocks to the GPRs.

24. Registers

24.1 Control

REG_DYNAMIC	Dynamic allocation (pixel/vertex) of the register file on or off.
REG_SIZE_PIX	Size of the register file's pixel portion (minimal size when dynamic allocation turned on)
REG_SIZE_VTX	Size of the register file's vertex portion (minimal size when dynamic allocation turned on)
ARBITRATION_POLICY	policy of the arbitration between vertexes and pixels
INST_STORE_ALLOC	interleaved, separate
INST_BASE_VTX	start point for the vertex instruction store (RT always ends at vertex_base and Begins at 0)
INST_BASE_PIX	start point for the pixel shader instruction store
ONE_THREAD	debug state register. Only allows one program at a time into the GPRs
ONE_ALU	debug state register. Only allows one ALU program at a time to be executed (instead of 2)
INSTRUCTION~~_ADDR~~	This is where the CP puts the base address of the instruction writes and type (auto-incremented on reads/writes) Register mapped
~~INSTRUCTION_DATA~~	~~This is where the CP puts the actual data going to the instruction memory~~
CONSTANTS	512*4 ALU constants + 32*6 Texture state 32 bits registers (logically mapped)
~~INSTRUCTION_ADDR_RT~~	~~This is where the CP puts the base address of the instruction writes and type for Real Time (auto-incremented on reads/writes)~~
~~INSTRUCTION_DATA_RT~~	~~This is where the CP puts the actual data going to the instruction memory for Real Time~~
CONSTANTS_RT	256*4 ALU constants + 32*6 texture states? (physically mapped)
CONSTANT_EO_RT	This is the size of the space reserved for real time in the constant store (from 0 to CONSTANT_EO_RT). The re-mapping table operates on the rest of the memory
TSTATE_EO_RT	This is the size of the space reserved for real time in the fetch state store (from 0 to TSTATE_EO_RT). The re-mapping table operates on the rest of the memory
EXPORT_LATE	Controls whether or not we are exporting position from clause 3. If set, position exports occur at clause 7.

24.2 Context

VS_FETCH_{0…7}	eight 8 bit pointers to the location where each clauses control program is located
VS_ALU_{0…7}	eight 8 bit pointers to the location where each clauses control program is located
PS_FETCH_{0…7}	eight 8 bit pointers to the location where each clauses control program is located
PS_ALU_{0…7}	eight 8 bit pointers to the location where each clauses control program is located
PS_BASE	base pointer for the pixel shader in the instruction store
VS_BASE	base pointer for the vertex shader in the instruction store
VS_CF_SIZE	size of the vertex shader (# of instructions in control program/2)
PS_CF_SIZE	size of the pixel shader (# of instructions in control program/2)
PS_SIZE	size of the pixel shader (cntl+instructions)
VS_SIZE	size of the vertex shader (cntl+instructions)
PS_NUM_REG	number of GPRs to allocate for pixel shader programs
VS_NUM_REG	number of GPRs to allocate for vertex shader programs
PARAM_SHADE	One 16 bit register specifying which parameters are to be gouraud shaded (0 = flat, 1 = gouraud)
PARAM_WRAP	64 bits: for which parameters (and channels (xyzw)) do we do the cyl wrapping (0=linear, 1=cylindrical).
PS_EXPORT_MODE	0xxxx : Normal mode 1xxxx : Multipass mode If normal, bbbz where bbb is how many colors (0-4) and z is export z or not If multipass 1-12 exports for color.
VS_EXPORT_MASK	which of the last 6 ALU clauses is exporting (multipass only)
VS_EXPORT_MODE	0: position (1 vector), 1: position (2 vectors), 3:multipass
VS_EXPORT	

_COUNT_{0…6}	Six 4 bit counters representing the # of interpolated parameters exported in clause 7 (located in VS_EXPORT_COUNT_6) OR # of exported vectors to memory per clause in multipass mode (per clause)
PARAM_GEN_I0	Do we overwrite or not the parameter 0 with XY data and generated T and S values
GEN_INDEX	Auto generates an address from 0 to XX. Puts the results into R0-1 for pixel shaders and R2 for vertex shaders
CONST_BASE_VTX (9 bits)	Logical Base address for the constants of the Vertex shader
CONST_BASE_PIX (9 bits)	Logical Base address for the constants of the Pixel shader
CONST_SIZE_PIX (8 bits)	Size of the logical constant store for pixel shaders
CONST_SIZE_VTX (8 bits)	Size of the logical constant store for vertex shaders
INST_PRED_OPTIMIZE	Turns on the predicate bit optimization (if of, conditional_execute_predicates is always executed).
CF_BOOLEANS	256 boolean bits
CF_LOOP_COUNT	32x8 bit counters (number of times we traverse the loop)
CF_LOOP_START	32x8 bit counters (init value used in index computation)
CF_LOOP_STEP	32x8 bit counters (step value used in index computation)

25. DEBUG Registers

25.1 Context

DB_PROB_ADDR	instruction address where the first problem occurred
DB_PROB_COUNT	number of problems encountered during the execution of the program
DB_PROB_BREAK	break the clause if an error is found.
DB_INST_COUNT	instruction counter for debug method 2
DB_BREAK_ADDR	break address for method number 2
DB_CLAUSE _MODE_ALU_{0…7}	clause mode for debug method 2 (0: normal, 1: addr, 2: kill)
DB_CLAUSE _MODE_FETCH_{0…7}	clause mode for debug method 2 (0: normal, 1: addr, 2: kill)

25.2 Control

Formatted: Bullets and Numbering

DB_ALUCST_MEMSIZE	Size of the physical ALU constant memory
DB_TSTATE_MEMSIZE	Size of the physical texture state memory

26. Interfaces

26.1 External Interfaces

Whenever an x is used, it means that the bus is broadcast to all units of the same name. For example, if a bus is named SQ→SPx it means that SQ is going to broadcast the same information to all SP instances.

26.1.1 *SC to SQ : IJ Control bus*

This is the control information sent to the sequencer in order to control the IJ fifos and all other information needed to execute a shader program on the sent pixels. This information is sent over 2 clocks, if SENDXY is asserted the next control packet is going to be ignored and XY information is going to be sent on the IJ bus (for the quads that where just sent). All pixels from the group of quads are from the same primitive, all quads of a vector are from the same render state.

Name	Direction	Bits	Description
SC_SQ_q_wr_mask	SC→SQ	4	Quad Write mask left to right
SC_SQ_lod_correct	SC→SQ	24	LOD correction per quad (6 bits per quad)
SC_SQ_flat_vertex	SC→SQ	2	Provoking vertex for flat shading
SC_SQ_param_ptr0	SC→SQ	11	P Store pointer for vertex 0
SC_SQ_param_ptr1	SC→SQ	11	P Store pointer for vertex 1
SC_SQ_param_ptr2	SC→SQ	11	P Store pointer for vertex 2
SC_SQ_end_of_vect	SC→SQ	1	End of the vector
SC_SQ_store_dealloc	SC→SQ	1	Deallocation token for the P Store
SC_SQ_state	SC→SQ	3	State/constant pointer
SC_SQ_valid_pixel	SC→SQ	16	Valid bits for all pixels
SC_SQ_null_prim	SC→SQ	1	Null Primitive (for PC deallocation purposes)
SC_SQ_end_of_prim	SC→SQ	1	End Of the primitive
SC_SQ_send_xy	SC→SQ	1	Sending XY information [XY information is going to be sent on the next clock]
SC_SQ_prim_type	SC→SQ	3	Real time command need to load tex cords from alternate buffer. Line AA, Point AA and Sprite reads their parameters from GEN_T and GEN_S GPRs. 000 : Normal 011 : Real Time 100 : Line AA 101 : Point AA 110 : Sprite
SC_SQ_new_vector	SC→SQ	1	This primitive comes from a new vector of vertices. Make sure that the corresponding vertex shader has finished before starting the group of pixels.
SC_SQ_RTRn	SQ→SC	1	Stalls the PA in n clocks
SC_SQ_RTS	SC→SQ	1	SC ready to send data

26.1.2 *SQ to SP: Interpolator bus*

Name	Direction	Bits	Description
SQ_SPx_interp_prim_type	SQ→SPx	3	Type of the primitive 000 : Normal 011 : Real Time 100 : Line AA 101 : Point AA 110 : Sprite
SQ_SPx_interp_ijline	SQ→SPx	2	Line in the IJ/XY buffer to use to interpolate
SQ_SPx_interp_buff_swap	SQ→SPx	1	Swap the IJ/XY buffers at the end of the interpolation
SQ_SPx_interp_gen_I0	SQ→SPx	1	Generate I0 or not. This tells the interpolators not to use the parameter cache but rather overwrite the data with interpolated 1 and 0. Overwrite if gen_I0 is high.

26.1.3 *SQ to SX: Interpolator bus*

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
SQ_SPx_interp_flat_vtx	SQ→SPx	2	Provoking vertex for flat shading
SQ_SPx_interp_flat_gouraud	SQ→SPx	1	Flat or gouraud shading
SQ_SPx_interp_cyl_wrap	SQ→SPx	4	Wich channel needs to be cylindrical wrapped

~~26.1.3~~26.1.4 *SQ to SP: Parameter Cache Read control bus*

Formatted: Bullets and Numbering

The four following interfaces (SQ→SP, SQ→SX,SP→SX and SX→Interpolators) are all SYNCHRONIZED together.

Name	Direction	Bits	Description
SQ_SPx_ptr0~~SQ_SPx_ptr0~~	SQ→SPx~~SQ→SPx~~	7~~9~~	Parameter Pointer into PC ~~Pointer of PC~~
SQ_SPx_ptr1~~SQ_SPx_ptr1~~	SQ→SPx~~SQ→SPx~~	7~~9~~	Parameter Pointer into PC ~~Pointer of PC~~

SQ_SPx_ptr2~~SQ_SPx_ptr2~~	SQ→SPx~~SQ→SPx~~	7~~9~~	Parameter Pointer into Parameter Cache~~Pointer of PC~~
SQ_SPx_pc0_addr_sel~~SQ_SP0_read_ena~~	SQ→SPx~~SQ→SP0~~	2~~4~~	Selection one of the pointers for parameter cache 0~~Read enables for the 4 memories in the SP0~~
SQ_SPx_pc1_addr_sel~~SQ_SP1_read_ena~~	SQ→SPx~~SQ→SP1~~	2~~4~~	Selection one of the pointers for parameter cache 1~~Read enables for the 4 memories in the SP1~~
SQ_SPx_pc2_addr_sel~~SQ_SP2_read_ena~~	SQ→SPx~~SQ→SP2~~	2~~4~~	Selection one of the pointers for parameter cache 2~~Read enables for the 4 memories in the SP2~~
SQ_SPx_pc3_addr_sel~~SQ_SP3_read_ena~~	SQ→SPx~~SQ→SP3~~	2~~4~~	Selection one of the pointers for parameter cache 3~~Read enables for the 4 memories in the SP3~~
SQ_SP0_read_ena	SQ→SP0	4	Read enables for the 4 memories in the SP0
SQ_SP1_read_ena	SQ→SP1	4	Read enables for the 4 memories in the SP1
SQ_SP2_read_ena	SQ→SP2	4	Read enables for the 4 memories in the SP2
SQ_SP3_read_ena	SQ→SP3	4	Read enables for the 4 memories in the SP3

~~26.1.4~~26.1.5 *SQ to SX: Parameter Cache Mux control Bus*

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
SQ_SXx_mux0	SQ→SXx	4	Mux control for PC or RT (4 MSbs of Pointer in the PC case)
SQ_SXx_mux1	SQ→SXx	4	Mux control for PC or RT (4 MSbs of Pointer in the PC case)
SQ_SXx_mux2	SQ→SXx	4	Mux control for PC or RT (4 MSbs of Pointer in the PC case)
SQ_SXx_RT_switch	SQ→SXx	1	Selects between RT and Normal data

~~26.1.5~~26.1.6 *SQ to SP: Staging Register Data*

Formatted: Bullets and Numbering

This is a broadcast bus that sends the VSISR information to the staging registers of the shader pipes.

Name	Direction	Bits	Description
SQ_SPx_vgt_vsisr_data	SQ→SPx	96	Pointers of indexes or HOS surface information
SQ_SPx_vgt_vsisr_double	SQ→SPx	1	0: Normal 96 bits per vert 1: double 192 bits per vert
SQ_SP0_data_valid	SQ→SP0	1	Data is valid
SQ_SP1_data_valid	SQ→SP1	1	Data is valid
SQ_SP2_data_valid	SQ→SP2	1	Data is valid
SQ_SP3_data_valid	SQ→SP3	1	Data is valid

~~26.1.6~~26.1.7 *PA to SQ : Vertex interface*

Formatted: Bullets and Numbering

~~26.1.6.1~~26.1.7.1 Interface Signal Table

The area difference between the two methods is not sufficient to warrant complicating the interface or the state requirements of the VSISRs. **Therefore, the POR for this interface is that the VGT will transmit the data to the VSISRs (via the Shader Sequencer) in full, 32-bit floating-point format.** The VGT can transmit up to six 32-bit floating-point values to each VSISR where four or more values require two transmission clocks. The data bus is 96 bits wide.

Name	Bits	Description
PA_SQ_vgt_vsisr_data	~~9~~96~~6~~	Pointers of indexes or HOS surface information
PA_SQ_vgt_vsisr_double	1	0: Normal ~~96~~ 96 bits per vert 1: double ~~192~~ 192 bits per vert
PA_SQ_vgt_end_of_vector	1	Indicates the last VSISR data set for the current process vector (for double vector data, "end_of_vector" is set on the second vector)
PA_SQ_vgt_vsisr_valid	1	Vsisr data is valid
PA_SQ_vgt_state	3	Render State (6*3+3 for constants). This signal is guaranteed to be correct when “PA_SQ_vgt_end_of_vector” is high.
PA_SQ_vgt_send	1	Data on the VGT_SQ is valid receive (see write-up for standard R400 SEND/RTR interface handshaking)
SQ_PA_vgt_rtr	1	Ready to receive (see write-up for standard R400 SEND/RTR interface handshaking)

~~26.1.7~~26.1.8 SQ to CP: State report

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
SQ_CP_vrtx_state	SEQ→CP	3	Oldest vertex state still in the pipe
SQ_CP_pix_state	SEQ→CP	3	Oldest pixel state still in the pipe

~~26.1.8~~26.1.9 SQ to SX: Control bus

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
SQ_SXx_exp_Pixel	SQ→SXx	1	1: Pixel 0: Vertex
SQ_SXx_exp_start	SQ→SXx	1	Raised to indicate that the SQ is starting an export
SQ_SXx_exp_Clause	SQ→SXx	3	Clause number, which is needed for vertex clauses
SQ_SXx_exp_State	SQ→SXx	3	State ID, which is needed for vertex clauses

These fields are sent synchronously with SP export data, described in SP0→SX0 interface
{ISSUE: Where are the PC pointers}

~~26.1.9~~26.1.10 SX to SQ : Output file control

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
SXx_SQ_Export_count_rdy	SXx→SQ	1	Raised by SX0 to indicate that the following two fields reflect the result of the most recent export
SXx_SQ_Export_Position	SXx→SQ	1	Specifies whether there is room for another position.
SXx_SQ_Export_Buffer	SXx→SQ	7	Specifies the space available in the output buffers. 0: buffers are full 1: 2K-bits available (32-bits for each of the 64 pixels in a clause) ... 64: 128K-bits available (16 128-bit entries for each of 64 pixels) 65-127: RESERVED

~~26.1.10~~26.1.11 SQ to TP: Control bus

Formatted: Bullets and Numbering

Once every clock, the fetch unit sends to the sequencer on which clause it is now working and if the data in the GPRs is ready or not. This way the sequencer can update the fetch counters for the reservation station fifos. The sequencer also provides the instruction and constants for the fetch to execute and the address in the register file where to write the fetch return data.

Name	Direction	Bits	Description
TPx_SQ_data_rdy	TPx→ SQ	1	Data ready
TPx_SQ_clause_num	TPx→ SQ	3	Clause number
TPx_SQ_Type~~TPx_SQ_clause_num~~	TPx→ SQ~~TPx→ SQ~~	1~~3~~	Type of data sent (0:PIXEL, 1:VERTEX)~~Clause number~~
SQ_TPx_const	SQ→TPx	48	Fetch state sent over 4 clocks (192 bits total)
SQ_TPx_instuct	SQ→TPx	24	Fetch instruction sent over 4 clocks
SQ_TPx_end_of_clause	SQ→TPx	1	Last instruction of the clause
SQ_TPx_Type	SQ→TPx	1	Type of data sent (0:PIXEL, 1:VERTEX)
SQ_TPx_phase	SQ→TPx	2	Write phase signal
SQ_TP0_lod_correct	SQ→TP0	6	LOD correct 3 bits per comp 2 components per quad
SQ_TP0_pmask	SQ→TP0	4	Pixel mask 1 bit per pixel
SQ_TP1_lod_correct	SQ→TP1	6	LOD correct 3 bits per comp 2 components per quad
SQ_TP1_pmask	SQ→TP1	4	Pixel mask 1 bit per pixel
SQ_TP2_lod_correct	SQ→TP2	6	LOD correct 3 bits per comp 2 components per quad

SQ_TP2_pmask	SQ→TP2	4	Pixel mask 1 bit per pixel
SQ_TP3_lod_correct	SQ→TP3	6	LOD correct 3 bits per comp 2 components per quad
SQ_TP3_pmask	SQ→TP3	4	Pixel mask 1 bit per pixel
SQ_TPx_clause_num	SQ→TPx	3	Clause number
SQ_TPx_write_gpr_index	SQ->TPx	7	Index into Register file for write of returned Fetch Data

~~26.1.11~~26.1.12 *TP to SQ: Texture stall*

Formatted: Bullets and Numbering

The TP sends this signal to the SQ when its input buffer is full. The SQ is going to send it to the SP X clocks after reception (maximum of 3 clocks of pipeline delay).

Name	Direction	Bits	Description
TP_SQ_fetch_stall	TP→ SQ	1	Do not send more texture request if asserted

~~26.1.12~~26.1.13 *SQ to SP: Texture stall*

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
SQ_SPx_fetch_stall	SQ→SPx	1	Do not send more texture request if asserted

~~26.1.13~~26.1.14 *SQ to SP: GPR, Parameter cache control and auto counter*

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
SQ_SPx_wr_addr	SQ→SPx	7	Write address
SQ_SPx_gpr_rd_addr	SQ→SPx	7	Read address
SQ_SPx_gpr_re_addr	SQ→SPx	1	Read Enable
SQ_SPx_gpr_we_addr	SQ→SPx	1	Write Enable for the GPRs
SQ_SPx_gpr_phase_mux	SQ→SPx	2	The phase mux (arbitrates between inputs, ALU SRC reads and writes)
SQ_SPx_channel_mask	SQ→SPx	4	The channel mask
SQ_SP0_pixel_mask	SQ→SP0	4	The pixel mask
SQ_SP1_pixel_mask	SQ→SP1	4	The pixel mask
SQ_SP2_pixel_mask	SQ→SP2	4	The pixel mask
SQ_SP3_pixel_mask	SQ→SP3	4	The pixel mask
SQ_SPx_pc_we_addr	SQ→SPx	1	Write Enable for the parameter caches
SQ_SPx_gpr_input_mux	SQ→SPx	2	When the phase mux selects the inputs this tells from which source to read from: Interpolated data, VTX0, VTX1, autogen counter.
SQ_SPx_index_count	SQ→SPx	12?	Index count, common for all shader pipes

~~26.1.14~~26.1.15 SQ to SPx: Instructions

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
SQ_SPx_instruct_start	SQ→SPx	1	Instruction start
SQ_SP_instruct	SQ→SPx	21~~20~~	Transferred over 4 cycles 0: SRC A Select 2:0 SRC A Argument Modifier 3:3 SRC A swizzle 11:4 Unused 20:12 -- - 1: SRC B Select 2:0 SRC B Argument Modifier 3:3 SRC B swizzle 11:4 Unused 20:12 -- - 2: SRC C Select 2:0 SRC C Argument Modifier 3:3 SRC C swizzle 11:4 Unused 20:12 -- - 3: Vector Opcode 4:0 Scalar Opcode 10:5 Vector Clamp 11:11 Scalar Clamp 12:12 Vector Write Mask 16:13 Scalar Write Mask 20:17~~Instruction sent over 4 clocks~~
SQ_SPx_stall	SQ→SPx	1	Stall signal
SQ_SPx_export_count	SQ→SPx	3	Each set of four pixels or vectors is exported over eight clocks. This field specifies where the SP is in that sequence.
SQ_SPx_export_last	SQ→SPx	1	Asserted on the first shader count of the last export of the clause
SQ_SP0_export_pvalid	SQ→SP0	4	Result of pixel kill in the shader pipe, which must be output for all pixel exports (depth and all color buffers). 4x4 because 16 pixels are computed per clock
SQ_SP0_export_wvalid	SQ→SP0	2	Specifies whether to write low and/or high 32-bit word of the 64-bit export data from each of the 16 pixels or vectors
SQ_SP1_ export_pvalid	SQ→SP1	4	Result of pixel kill in the shader pipe, which must be output for all pixel exports (depth and all color buffers). 4x4 because 16 pixels are computed per clock
SQ_SP1_ export_wvalid	SQ→SP1	2	Specifies whether to write low and/or high 32-bit word of the 64-bit export data from each of the 16 pixels or vectors
SQ_SP2_ export_pvalid	SQ→SP2	4	Result of pixel kill in the shader pipe, which must be output for all pixel exports (depth and all color buffers). 4x4 because 16 pixels are computed per clock
SQ_SP2_ export_wvalid	SQ→SP2	2	Specifies whether to write low and/or high 32-bit word of the 64-bit export data from each of the 16 pixels or vectors
SQ_SP3_ export_pvalid	SQ→SP3	4	Result of pixel kill in the shader pipe, which must be output for all pixel exports (depth and all color buffers). 4x4 because 16 pixels are computed per

			clock
SQ_SP3_ export_wvalid	SQ→SP3	2	Specifies whether to write low and/or high 32-bit word of the 64-bit export data from each of the 16 pixels or vectors

~~26.1.15~~26.1.16 *SP to SQ: Constant address load/ Predicate Set*

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
SP0_SQ_const_addr	SP0→SQ	36	Constant address load / predicate vector load (4 bits only) to the sequencer
SP0_SQ_valid	SP0→SQ	1	Data valid
SP1_SQ_const_addr	SP1→SQ	36	Constant address load / predicate vector load (4 bits only) to the sequencer
SP1_SQ_valid	SP1→SQ	1	Data valid
SP2_SQ_const_addr	SP2→SQ	36	Constant address load / predicate vector load (4 bits only) to the sequencer
SP2_SQ_valid	SP2→SQ	1	Data valid
SP3_SQ_const_addr	SP3→SQ	36	Constant address load / predicate vector load (4 bits only) to the sequencer
SP3_SQ_valid	SP3→SQ	1	Data valid

~~26.1.16~~26.1.17 *SQ to SPx: constant broadcast*

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
SQ_SPx_constant	SQ→SPx	128	Constant broadcast

~~26.1.17~~26.1.18 *SP0 to SQ: Kill vector load*

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
SP0_SQ_kill_vect	SP0→SQ	4	Kill vector load
SP1_SQ_kill_vect	SP1→SQ	4	Kill vector load
SP2_SQ_kill_vect	SP2→SQ	4	Kill vector load
SP3_SQ_kill_vect	SP3→SQ	4	Kill vector load

~~26.1.18~~26.1.19 *SQ to CP: RBBM bus*

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
SQ_RBB_rs	SQ→CP	1	Read Strobe
SQ_RBB_rd	SQ→CP	32	Read Data
SQ_RBBM_nrtrtr	SQ→CP	1	Optional
SQ_RBBM_rtr	SQ→CP	1	Real-Time (Optional)

~~26.1.19~~26.1.20 *CP to SQ: RBBM bus*

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
rbbm_we	CP→SQ	1	Write Enable
rbbm_a	CP→SQ	~~18~~15	Address -- Upper Extent is TBD (16:2)
rbbm_wd	CP→SQ	32	Data
rbbm_be	CP→SQ	4	Byte Enables
rbbm_re	CP→SQ	1	Read Enable
rbb_rs0	CP→SQ	1	Read Return Strobe 0
rbb_rs1	CP→SQ	1	Read Return Strobe 1
rbb_rd0	CP→SQ	32	Read Data 0
rbb_rd1	CP→SQ	32	Read Data 0
RBBM_SQ_soft_reset	CP→SQ	1	Soft Reset

27. Examples of program executions

27.1.1 *Sequencer Control of a Vector of Vertices*

1. PA sends a vector of 64 vertices (actually vertex indices – 32 bits/index for 2048 bit total) to the RE's Vertex FIFO
    - state pointer as well as tag into position cache is sent along with vertices
    - space was allocated in the position cache for transformed position before the vector was sent
    - **also before the vector is sent to the RE, the CP has loaded the global instruction store with the vertex shader program (using the MH?)**
    - The vertex program is assumed to be loaded when we receive the vertex vector.
        - the SEQ then accesses the IS base for this shader using the local state pointer (provided to all sequencers by the RBBM when the CP is done loading the program)
2. SEQ arbitrates between the Pixel FIFO and the Vertex FIFO – basically the Vertex FIFO always has priority
    - at this point the vector is removed from the Vertex FIFO
    - the arbiter is not going to select a vector to be transformed if the parameter cache is full unless the pipe as nothing else to do (ie no pixels are in the pixel fifo).
3. SEQ allocates space in the SP register file for index data plus GPRs used by the program
    - the number of GPRs required by the program is stored in a local state register, which is accessed using the state pointer that came down with the vertices
    - SEQ will not send vertex data until space in the register file has been allocated
4. SEQ sends the vector to the SP register file over the RE_SP interface (which has a bandwidth of 2048 bits/cycle)
    - the 64 vertex indices are sent to the 64 register files over 4 cycles
        - RF0 of SU0, SU1, SU2, and SU3 is written the first cycle
        - RF1 of SU0, SU1, SU2, and SU3 is written the second cycle
        - RF2 of SU0, SU1, SU2, and SU3 is written the third cycle
        - RF3 of SU0, SU1, SU2, and SU3 is written the fourth cycle
    - the index is written to the least significant 32 bits **(floating point format?) (what about compound indices)** of the 128-bit location within the register file (w); the remaining data bits are set to zero (x, y, z)
5. SEQ constructs a control packet for the vector and sends it to the first reservation station (the FIFO in front of fetch state machine 0, or TSM0 FIFO)
    - the control packet contains the state pointer, the tag to the position cache and a register file base pointer.
6. TSM0 accepts the control packet and fetches the instructions for fetch clause 0 from the global instruction store
    - TSM0 was first selected by the TSM arbiter before it could start
7. all instructions of fetch clause 0 are issued by TSM0
8. the control packet is passed to the next reservation station (the FIFO in front of ALU state machine 0, or ASM0 FIFO)
    - TSM0 does not wait for requests made to the Fetch Unit to complete; it passes the register file write index for the fetch data to the TU, which will write the data to the RF as it is received
    - once the TU has written all the data to the register files, it increments a counter that is associated with ASM0 FIFO; a count greater than zero indicates that the ALU state machine can go ahead start to execute the ALU clause
9. ASM0 accepts the control packet (after being selected by the ASM arbiter) and gets the instructions for ALU clause 0 from the global instruction store
10. all instructions of ALU clause 0 are issued by ASM0, then the control packet is passed to the next reservation station (the FIFO in front of fetch state machine 1, or TSM1 FIFO)
11. the control packet continues to travel down the path of reservation stations until all clauses have been executed
    - position can be exported in ALU clause 3 (or 4?); the data (and the tag) is sent over a position bus (which is shared with all four shader pipes) back to the PA's position cache
    - A parameter cache pointer is also sent along with the position data. This tells to the PA where the data is going to be in the parameter cache.
        - there is a position export FIFO in the SP that buffers position data before it gets sent back to the PA

    - the ASM arbiter will prevent a packet from starting an exporting clause if the position export FIFO is full
- parameter data is exported in clause 7 (as well as position data if it was not exported earlier)
    - parameter data is sent to the Parameter Cache over a dedicated bus
    - the SEQ allocates storage in the Parameter Cache, and the SEQ deallocates that space when there is no longer a need for the parameters (it is told by the PA when using a token).
    - the ASM arbiter will prevent a packet from starting on ASM7 if the parameter cache (or the position buffer if position is being exported) is full

12. after the shader program has completed, the SEQ will free up the GPRs so that they can be used by another shader program

27.1.2 *Sequencer Control of a Vector of Pixels*

1. **As with vertex shader programs, pixel shaders are loaded into the global instruction store by the CP**
    - At this point it is assumed that the pixel program is loaded into the instruction store and thus ready to be read.
2. the RE's Pixel FIFO is loaded with the barycentric coordinates for pixel quads by the detailed walker
    - the state pointer and the LOD correction bits are also placed in the Pixel FIF0
    - the Pixel FIFO is wide enough to source four quad's worth of barycentrics per cycle
3. SEQ arbitrates between Pixel FIFO and Vertex FIFO – when there are no vertices pending OR there is no space left in the register files for vertices, the Pixel FIFO is selected
4. SEQ allocates space in the SP register file for all the GPRs used by the program
    - the number of GPRs required by the program is stored in a local state register, which is accessed using the state pointer
    - SEQ will not allow interpolated data to be sent to the shader until space in the register file has been allocated
5. SEQ controls the transfer of interpolated data to the SP register file over the RE_SP interface (which has a bandwidth of 2048 bits/cycle). See interpolated data bus diagrams for details.
6. SEQ constructs a control packet for the vector and sends it to the first reservation station (the FIFO in front of fetch state machine 0, or TSM0 FIFO)
    - note that there is a separate set of reservation stations/arbiters/state machines for vertices and for pixels
    - the control packet contains the state pointer, the register file base pointer, and the LOD correction bits
    - all other information (such as quad address for example) travels in a separate FIFO
7. TSM0 accepts the control packet and fetches the instructions for fetch clause 0 from the global instruction store
    - TSM0 was first selected by the TSM arbiter before it could start
8. all instructions of fetch clause 0 are issued by TSM0
9. the control packet is passed to the next reservation station (the FIFO in front of ALU state machine 0, or ASM0 FIFO)
    - TSM0 does not wait for fetch requests made to the Fetch Unit to complete; it passes the register file write index for the fetch data to the TU, which will write the data to the RF as it is received
    - once the TU has written all the data for a particular clause to the register files, it increments a counter that is associated with the ASM0 FIFO; a count greater than zero indicates that the ALU state machine can go ahead and pop the FIFO and start to execute the ALU clause
10. ASM0 accepts the control packet (after being selected by the ASM arbiter) and gets the instructions for ALU clause 0 from the global instruction store
11. all instructions of ALU clause 0 are issued by ASM0, then the control packet is passed to the next reservation station (the FIFO in front of fetch state machine 1, or TSM1 FIFO)
12. the control packet continues to travel down the path of reservation stations until all clauses have been executed
    - pixel data is exported in the last ALU clause (clause 7)
        - it is sent to an output FIFO where it will be picked up by the render backend
        - the ASM arbiter will prevent a packet from starting on ASM7 if the output FIFO is full
13. after the shader program has completed, the SEQ will free up the GPRs so that they can be used by another shader program

27.1.3 *Notes*

14. The state machines and arbiters will operate ahead of time so that they will be able to immediately start the real threads or stall.
15. The register file base pointer for a vector needs to travel with the vector through the reservation stations, but the instruction store base pointer does not – this is because the RF pointer is different for all threads, but the IS pointer is only different for each state and thus can be accessed via the state pointer.

28. Open issues

Need to do some testing on the size of the register file as well as on the register file allocation method (dynamic VS static).

Saving power?

Parameter caches in SX?

Using both IJ buffers for center + centroid interpolation?

R400 Sequencer Specification

SQ

Version 1.8~~7~~

Overview: This is an architectural specification for the R400 Sequencer block (SEQ). It provides an overview of the required capabilities and expected uses of the block. It also describes the block interfaces, internal sub-blocks, and provides internal state diagrams.

AUTOMATICALLY UPDATED FIELDS:

Revision Changes:

Rev 0.1 (Laurent Lefebvre) Date: May 7, 2001	First draft.
Rev 0.2 (Laurent Lefebvre) Date : July 9, 2001	Changed the interfaces to reflect the changes in the SP. Added some details in the arbitration section.
Rev 0.3 (Laurent Lefebvre) Date : August 6, 2001	Reviewed the Sequencer spec after the meeting on August 3, 2001.
Rev 0.4 (Laurent Lefebvre) Date : August 24, 2001	Added the dynamic allocation method for register file and an example (written in part by Vic) of the flow of pixels/vertices in the sequencer.
Rev 0.5 (Laurent Lefebvre) Date : September 7, 2001	Added timing diagrams (Vic)
Rev 0.6 (Laurent Lefebvre) Date : September 24, 2001	Changed the spec to reflect the new R400 architecture. Added interfaces.
Rev 0.7 (Laurent Lefebvre) Date : October 5, 2001	Added constant store management, instruction store management, control flow management and data dependant predication.
Rev 0.8 (Laurent Lefebvre) Date : October 8, 2001	Changed the control flow method to be more flexible. Also updated the external interfaces.
Rev 0.9 (Laurent Lefebvre) Date : October 17, 2001	Incorporated changes made in the 10/18/01 control flow meeting. Added a NOP instruction, removed the conditional_execute_or_jump. Added debug registers.
Rev 1.0 (Laurent Lefebvre) Date : October 19, 2001	Refined interfaces to RB. Added state registers.
Rev 1.1 (Laurent Lefebvre) Date : October 26, 2001	Added SEQ→SP0 interfaces. Changed delta precision. Changed VGT→SP0 interface. Debug Methods added.
Rev 1.2 (Laurent Lefebvre) Date : November 16, 2001	Interfaces greatly refined. Cleaned up the spec.
Rev 1.3 (Laurent Lefebvre) Date : November 26, 2001	Added the different interpolation modes.
Rev 1.4 (Laurent Lefebvre) Date : December 6, 2001	Added the auto incrementing counters. Changed the VGT→SQ interface. Added content on constant management. Updated GPRs.
Rev 1.5 (Laurent Lefebvre) Date : December 11, 2001	Removed from the spec all interfaces that weren't directly tied to the SQ. Added explanations on constant management. Added PA→SQ synchronization fields and explanation.
Rev 1.6 (Laurent Lefebvre) Date : January 7, 2002	Added more details on the staging register. Added detail about the parameter caches. Changed the call instruction to a Conditionnal_call instruction. Added details on constant management and updated the diagram.
Rev 1.7 (Laurent Lefebvre) Date : February 4, 2002	Added Real Time parameter control in the SX interface. Updated the control flow section.
Rev 1.8 (Laurent Lefebvre) Date : March 4, 2002	New interfaces to the SX block. Added the end of clause modifier, removed the end of clause instructions.

1. Overview

The sequencer is based on the R300 design. It chooses two ALU clauses and a fetch clause to execute, and executes all of the instructions in a clause before looking for a new clause of the same type. Two ALU clauses are executed interleaved to hide the ALU latency. Each vector will have eight fetch and eight ALU clauses, but clauses do not need to contain instructions. A vector of pixels or vertices ping-pongs along the sequencer FIFO, bouncing from fetch reservation station to alu reservation station. A FIFO exists between each reservation stage, holding up vectors until the vector currently occupying a reservation station has left. A vector at a reservation station can be chosen to execute. The sequencer looks at all eight alu reservation stations to choose an alu clause to execute and all eight fetch stations to choose a fetch clause to execute. The arbitrator will give priority to clauses/reservation stations closer to the bottom of the pipeline. It will not execute an alu clause until the fetch fetches initiated by the previous fetch clause have completed. There are two separate sets of reservation stations, one for pixel vectors and one for vertices vectors. This way a pixel can pass a vertex and a vertex can pass a pixel.

To support the shader pipe the sequencer also contains the shader instruction cache, constant store, control flow constants and texture state. The four shader pipes also execute the same instruction thus there is only one sequencer for the whole chip.

The sequencer first arbitrates between vectors of 64 vertices that arrive directly from primitive assembly and vectors of 16 quads (64 pixels) that are generated in the scan converter.

The vertex or pixel program specifies how many GPRs it needs to execute. The sequencer will not start the next vector until the needed space is available in the GPRs.

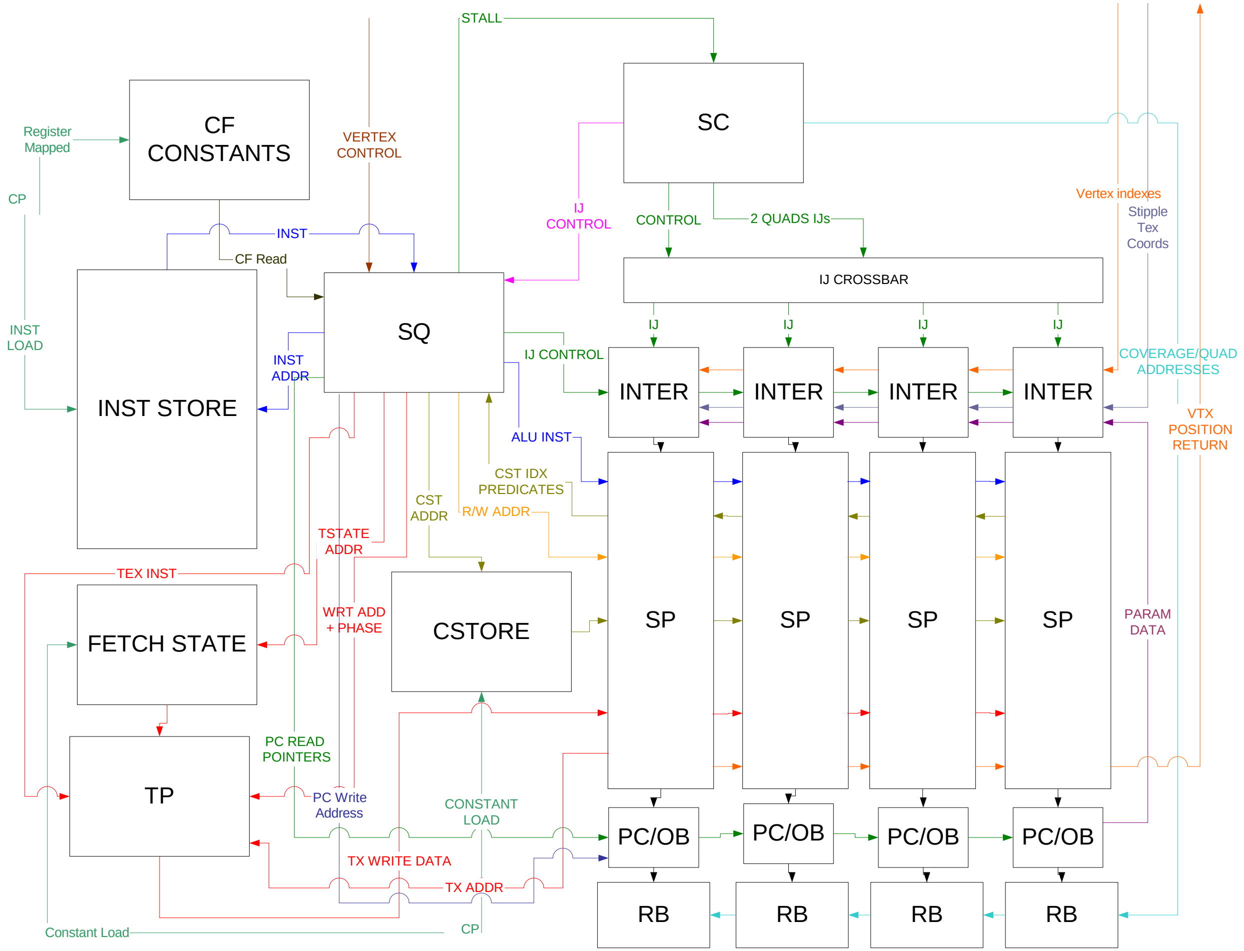

Figure 1: General Sequencer overview

Figure 2: Reservation stations and arbiters

There are two sets of the above figure, one for vertices and one for pixels.

Depending on the arbitration state, the sequencer will either choose a vertex or a pixel packet. The control packet consists of 3 bits of state, 7 bits for the base address of the Shader program and some information on the coverage to determine fetch LOD plus other various small state bits.

On receipt of a packet, the input state machine (not pictured but just before the first FIFO) allocated enough space in the GPRs to store the interpolated values and temporaries. Following this, the barycentric coordinates (and XY screen position if needed) are sent to the interpolator, which will use them to interpolate the parameters and place the results into the GPRs. Then, the input state machine stacks the packet in the first FIFO.

On receipt of a command, the level 0 fetch machine issues a fetch request to the TP and corresponding GPR address for the fetch address (ta). A small command (tcmd) is passed to the fetch system identifying the current level number (0) as well as the GPR write address for the fetch return data. One fetch request is sent every 4 clocks causing the texturing of sixteen 2x2s worth of data (or 64 vertices). Once all the requests are sent the packet is put in FIFO 1.

Upon receipt of the return data, the fetch unit writes the data to the register file using the write address that was provided by the level 0 fetch machine and sends the clause number (0) to the level 0 fetch state machine to signify that the write is done and thus the data is ready. Then, the level 0 fetch machine increments the counter of FIFO 1 to signify to the ALU 0 that the data is ready to be processed.

On receipt of a command, the level 0 ALU machine first decrements the input FIFO 1 counter and then issues a complete set of level 0 shader instructions. For each instruction, the ALU state machine generates 3 source addresses, one destination address and an instruction. Once the last instruction has been issued, the packet is put into FIFO 2.

There will always be two active ALU clauses at any given time (and two arbiters). One arbiter will arbitrate over the odd instructions (4 clocks cycles) and the other one will arbitrate over the even instructions (4 clocks cycles). The only constraints between the two arbiters is that they are not allowed to pick the same clause number as the other one is currently working on if the packet is not of the same type (render state).

If the packet is a vertex packet, upon reaching ALU clause 3, it can export the position if the position is ready. So the arbiter must prevent ALU clause 3 to be selected if the positional buffer is full (or can't be accessed). Along with the positional data, if needed the sprite size and/or edge flags can also be sent.

A special case is for multipass vertex shaders, which can export 12 parameters per last 6 clauses to the output buffer. If the output buffer is full or doesn't have enough space the sequencer will prevent such a vertex group to enter an exporting clause.

Multipass pixel shaders can export 12 parameters to memory from the last clause only (7).

All other clauses process in the same way until the packet finally reaches the last ALU machine (7).

Only one pair of interleaved ALU state machines may have access to the register file address bus or the instruction decode bus at one time. Similarly, only one fetch state machine may have access to the register file address bus at one time. Arbitration is performed by three arbiter blocks (two for the ALU state machines and one for the fetch state machines). The arbiters always favor the higher number state machines, preventing a bunch of half finished jobs from clogging up the register files.

1.2 Data Flow graph (SP)

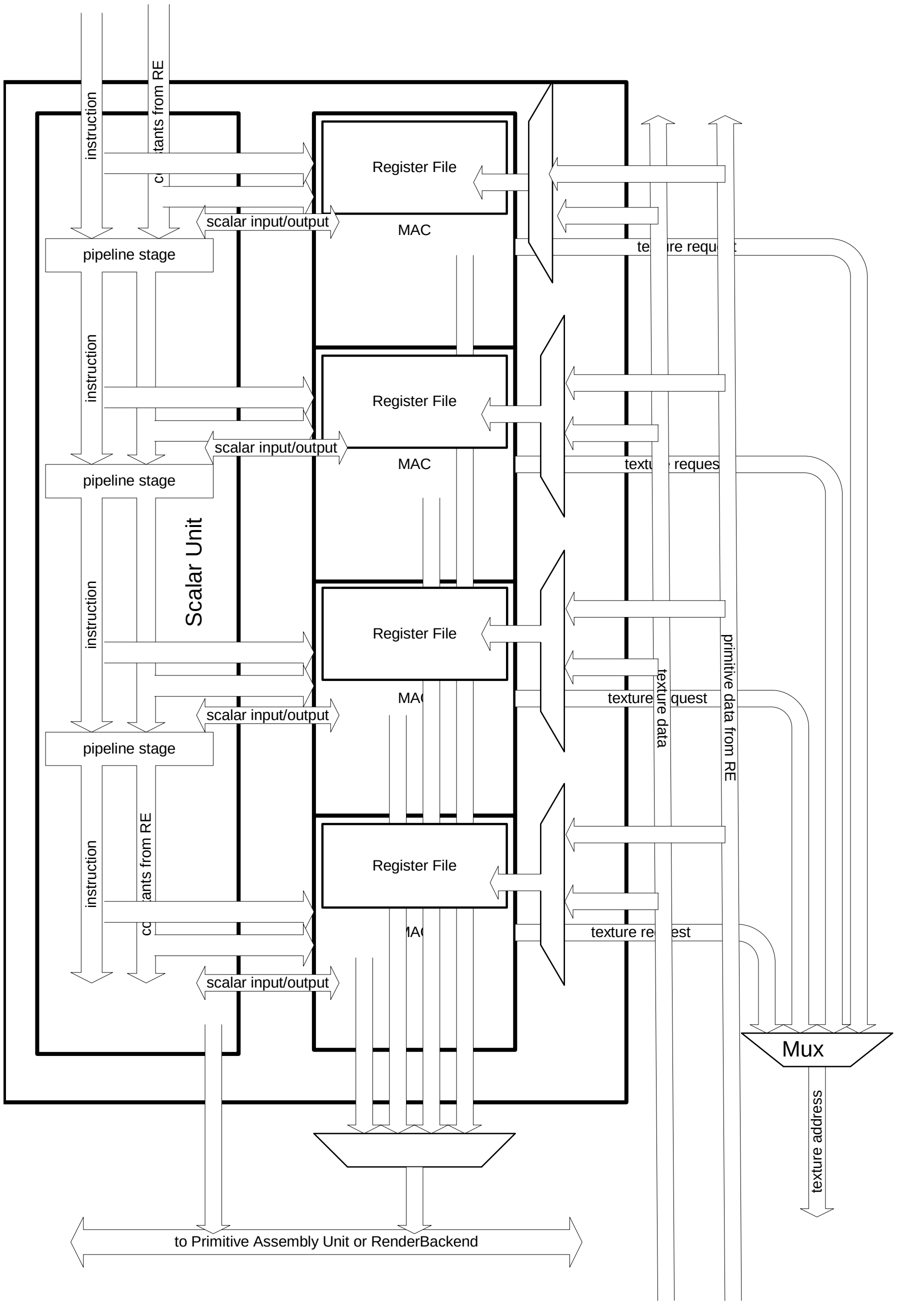

Figure 3: The shader Pipe

The gray area represents blocks that are replicated 4 times per shader pipe (16 times on the overall chip).

1.3 Control Graph

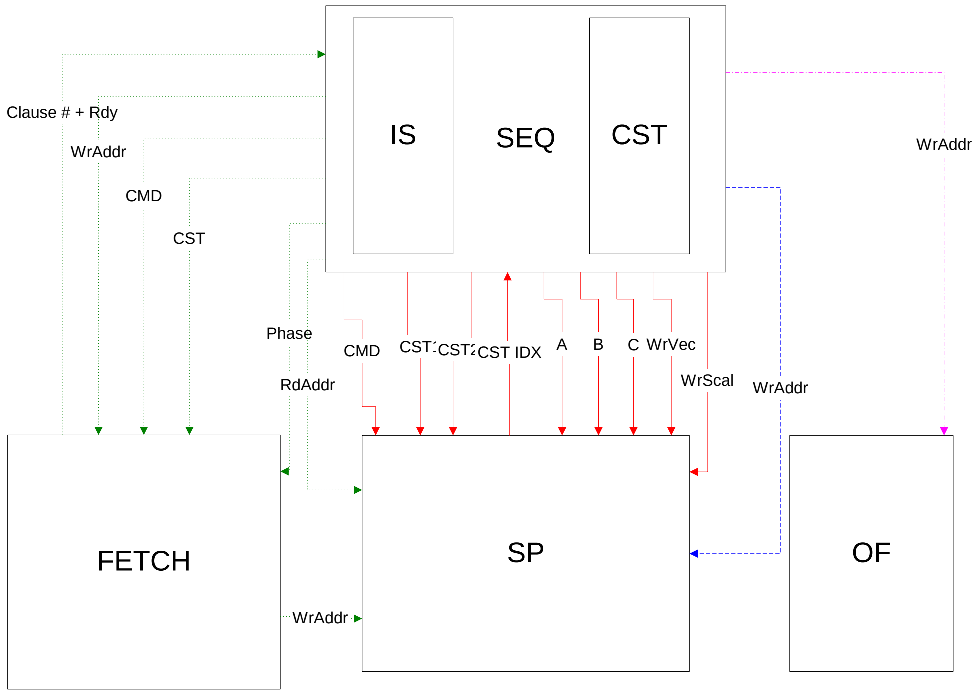

Figure 4: Sequencer Control interfaces

In green is represented the Fetch control interface, in red the ALU control interface, in blue the Interpolated/Vector control interface and in purple is the output file control interface.

2. Interpolated data bus

The interpolators contain an IJ buffer to pack the information as much as possible before writing it to the register file.

Figure 6: Interpolation timing diagram

Above is an example of a tile the sequencer might receive from the SC. The write side is how the data get stacked into the XY and IJ buffers, the read side is how the data is passed to the GPRs. The IJ information is packed in the IJ buffer 4 quads at a time or two clocks. The sequencer allows at any given time as many as four quads to interpolate a parameter. They all have to come from the same primitive. Then the sequencer controls the write mask to the GPRs to write the valid data in.

{ISSUE : Do we do the center + centroid approach using both IJ buffers?}

3. Instruction Store

There is going to be only one instruction store for the whole chip. It will contain 4096 instructions of 96 bits each.

It is likely to be a 1 port memory; we use 1 clock to load the ALU instruction, 1 clocks to load the Fetch instruction, 1 clock to load 2 control flow instructions and 1 clock to write instructions.

The instruction store is loaded by the CP thru the register mapped registers.

The next picture shows the various modes the CP can load the memory. The Sequencer has to keep track of the loading modes in order to wrap around the correct boundaries. The wrap-around points are arbitrary and they are specified in the VS_BASE and PIX_BASE control registers. The VS_BASE and PS_BASE context registers are used to specify for each context where its shader is in the instruction memory.

For the Real time commands the story is quite the same but for some small differences. There are no wrap-around points for real time so the driver must be careful not to overwrite regular shader data. The shared code (shared subroutines) uses the same path as real time.

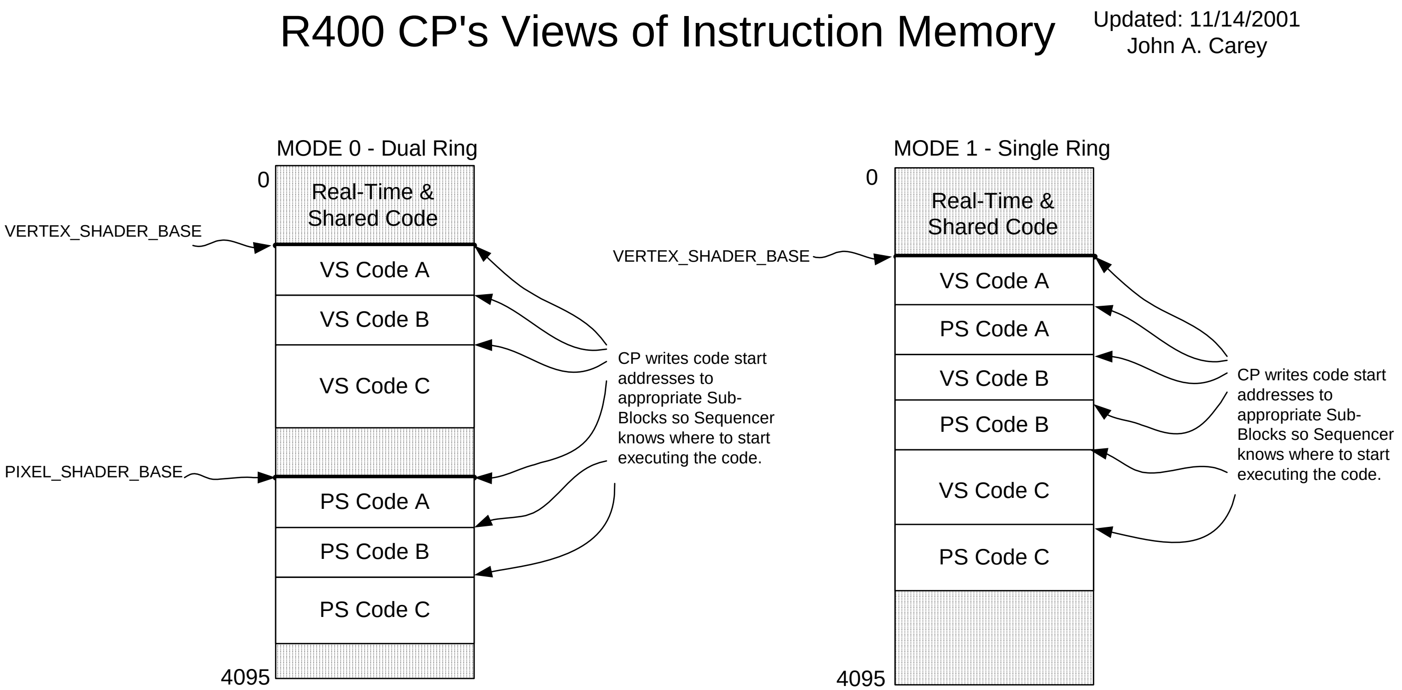

Figure 7: The CP's view of the instruction memory

4. Sequencer Instructions

All control flow instructions and move instructions are handled by the sequencer only. The ALUs will perform NOPs during this time (MOV PV,PV, PS,PS) if they have nothing else to do.

5. Constant Stores

5.1 Memory organizations

A likely size for the ALU constant store is 1024x128 bits. The read BW from the ALU constant store is 128 bits/clock and the write bandwidth is 32 bits/clock (directed by the CP bus size not by memory ports).

The maximum logical size of the constant store for a given shader is 256 constants. Or 512 for the pixel/vertex shader pair. The size of the re-mapping table is 128 lines (each line addresses 4 constants). The write granularity is 4 constants or 512 bits. It takes 16 clocks to write the four constants. Real time requires 256 lines in the physical memory (this is physically register mapped).

The texture state is also kept in a similar memory. The size of this memory is 128x192 bits. The memory thus holds 128 texture states (192 bits per state). The logical size exposes 32 different states total, which are going to be shared between the pixel and the vertex shader. The size of the re-mapping table to for the texture state memory is 32 lines (each line addresses 1 texture state lines in the real memory). The CP write granularity is 1 texture state lines (or 192 bits). The driver sends 512 bits but the CP ignores the top 320 bits. It thus takes 6 clocks to write the texture state. Real time requires 32 lines in the physical memory (this is physically register mapped).

The control flow constant memory doesn't sit behind a renaming table. It is register mapped and thus the driver must reload its content each time there is a ~~state~~ change in the control flow constants. Its size is 320*32 because it must hold 8 copies of the 32 dwords of control flow constants and the loop construct constants must be aligned.

The constant re-mapping tables for texture state and ALU constants are logically register mapped for regular mode and physically register mapped for RT operation.

5.2 Management of the Control Flow Constants

Formatted: Bullets and Numbering

The control flow constants are register mapped, thus the CP writes to the according register to set the constant, the SQ decodes the address and writes to the block pointed by its current base pointer (CF_WR_BASE). On the read side, one level of indirection is used. A register (SQ_CONTEXT_MISC.CF_RD_BASE) keeps the current base pointer to the control flow block. This register is copied whenever there is a state change. Should the CP write to CF after the state change, the base register is updated with the (current pointer number +1)% number of states. This way, if the CP doesn't write to CF the state is going to use the previous CF constants.

~~5.2~~5.3 Management of the re-mapping tables

Formatted: Bullets and Numbering

~~5.2.1~~5.3.1 *R400 Constant management*

The sequencer is responsible to manage two re-mapping tables (one for the constant store and one for the texture state). On a state change (by the driver), the sequencer will broadside copy the contents of its re-mapping tables to a new one. We have 8 different re-mapping tables we can use concurrently.

The constant memory update will be incremental, the driver only need to update the constants that actually changed between the two state changes.

For this model to work in its simplest form, the requirement is that the physical memory MUST be at least twice as large as the logical address space + the space allocated for Real Time. In our case, since the logical address space

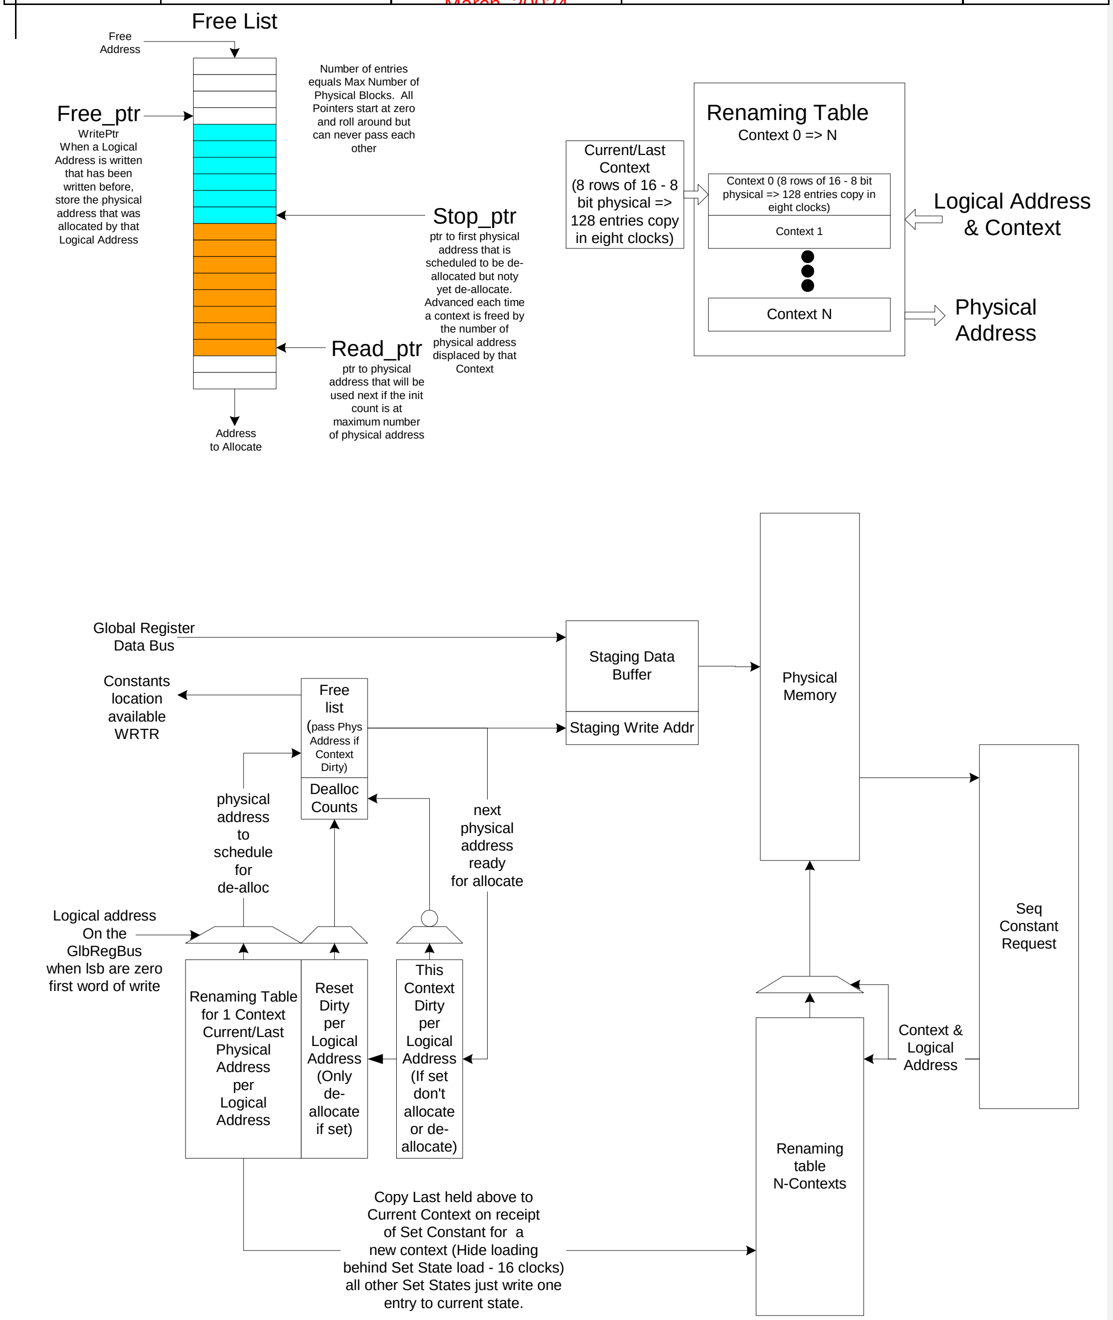
is 512 and the reserved RT space can be up to 256 entries, the memory must be of sizes 1280 and above. Similarly the size of the texture store must be of 32*2+32 = 96 entries and above.

~~5.2.2~~5.3.2 Proposal for R400LE constant management

Formatted: Bullets and Numbering

To make this scheme work with only 512+256 = 768 entries, upon reception of a CONTROL packet of state + 1, the sequencer would check for SQ_IDLE and PA_IDLE and if both are idle will erase the content of state to replace it with the new state (this is depicted in Figure 9: De-allocation mechanism~~Figure 9: De-allocation mechanism~~~~Figure 9: De-allocation mechanism~~). Note that in the case a state is cleared a value of 0 is written to the corresponding de-allocation counter location so that when the SQ is going to report a state change, nothing will be de-allocated upon the first report.

The second path sets all context dirty bits that were used in the current state to 1 (thus allowing the new state to reuse these physical addresses if needed).



Free List
Free Address
Free_ptr
WritePtr
When a Logical Address is written that has been written before, store the physical address that was allocated by that Logical Address
Number of entries equals Max Number of Physical Blocks. All Pointers start at zero and roll around but can never pass each other
Stop_ptr
ptr to first physical address that is scheduled to be de-allocated but noty yet de-allocate. Advanced each time a context is freed by the number of physical address displaced by that Context
Read_ptr
ptr to physical address that will be used next if the init count is at maximum number of physical address
Address to Allocate
Current/Last Context (8 rows of 16 - 8 bit physical => 128 entries copy in eight clocks)
Renaming Table
Context 0 => N
Context 0 (8 rows of 16 - 8 bit physical => 128 entries copy in eight clocks)
Context 1
Context N

Staging Write Addr
Physical Memory
Constants location available WRTR
Free list (pass Phys Address if Context Dirty)
Dealloc Counts
physical address to schedule for de-alloc
next physical address ready for allocate
Logical address On the GlbRegBus when lsb are zero first word of write
Renaming Table for 1 Context Current/Last Physical Address per Logical Address
Reset Dirty per Logical Address (Only de-allocate if set)
This Context Dirty per Logical Address (If set don't allocate or de-allocate)
Seq Constant Request
Context & Logical Address
Renaming table N-Contexts
Copy Last held above to Current Context on receipt of Set Constant for a new context (Hide loading behind Set State load - 16 clocks) all other Set States just write one entry to current state.

Figure 8: Constant management

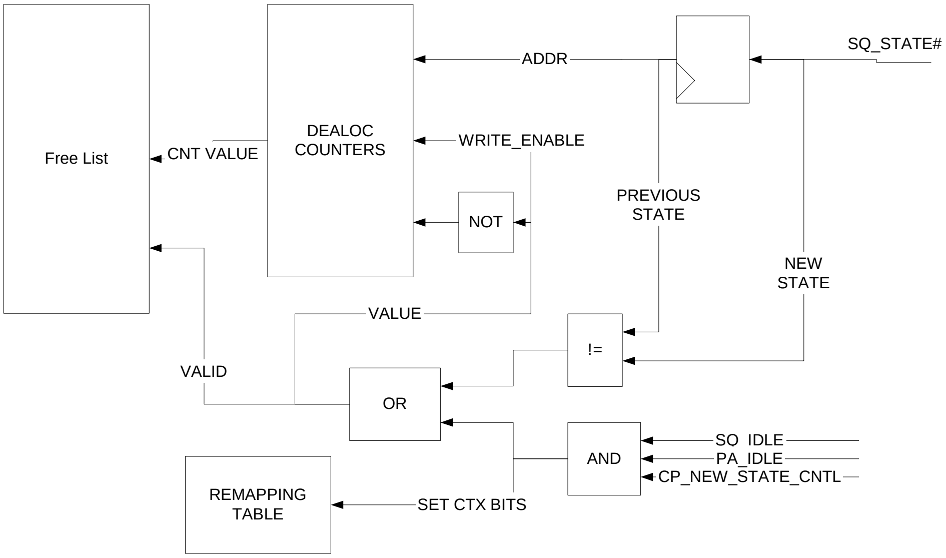

Figure 9: De-allocation mechanism for R400LE

~~5.2.3~~5.3.3 *Dirty bits*

Formatted: Bullets and Numbering

Two sets of dirty bits will be maintained per logical address. The first one will be set to zero on reset and set when the logical address is addressed. The second one will be set to zero whenever a new context is written and set for each address written while in this context. The reset dirty is not set, then writing to that logical address will not require de-allocation of whatever address stored in the renaming table. If it is set and the context dirty is not set, then the physical address store needs to be de-allocated and a new physical address is necessary to store the incoming data. If they are both set, then the data will be written into the physical address held in the renaming for the current logical address. No de-allocation or allocation takes place. This will happen when the driver does a set constant twice to the same logical address between context changes. NOTE: It is important to detect and prevent this, failure to do it will allow multiple writes to allocate all physical memory and thus hang because a context will not fit for rendering to start and thus free up space.

~~5.2.4~~5.3.4 *Free List Block*

Formatted: Bullets and Numbering

A free list block that would consist of a counter (called the IFC or Initial Free Counter) that would reset to zero and incremented every time a chunk of physical memory is used until they have all been used once. This counter would be checked each time a physical block is needed, and if the original ones have not been used up, us a new one, else check the free list for an available physical block address. The count is the physical address for when getting a chunk from the counter.

Storage of a free list big enough to store all physical block addresses.

Maintain three pointers for the free list that are reset to zero. The first one we will call write_ptr. This pointer will identify the next location to write the physical address of a block to be de-allocated. Note: we can never free more physical memory locations than we have. Once recording address the pointer will be incremented to walk the free list like a ring.

The second pointer will be called stop_ptr. The stop_ptr pointer will be advanced by the number of address chunks de-allocates when a context finishes. The address between the stop_ptr and write_ptr cannot be reused because they are still in use. But as soon as the context using then is dismissed the stop_ptr will be advanced.

The third pointer will be called read_ptr. This pointer will point will point to the next address that can be used for allocation as long as the read_ptr does not equal the stop_ptr and the IFC is at its maximum count.

~~5.2.5~~5.3.5 *De-allocate Block*

Formatted: Bullets and Numbering

This block will maintain a free physical address block count for each context. While in current context, a count shall be maintained specifying how many blocks were written into the free list at the write_ptr pointer. This count will be reset upon reset or when this context is active on the back and different than the previous context. It is actually a count of blocks in the previous context that will no longer be used. This count will be used to advance the write_ptr pointer to make available the set of physical blocks freed when the previous context was done. This allows the discard or de-allocation of any number of blocks in one clock.

~~5.2.6~~5.3.6 *Operation of Incremental model*

Formatted: Bullets and Numbering

The basic operation of the model would start with the write_ptr, stop_ptr, read_ptr pointers in the free list set to zero and the free list counter is set to zero. Also all the dirty bits and the previous context will be initialized to zero. When the first set constants happen, the reset dirty bit will not be set, so we will allocate a physical location from the free list counter because its not at the max value. The data will be written into physical address zero. Both the additional copy of the renaming table and the context zeros of the big renaming table will be updated for the logical address that was written by set start with physical address of 0. This process will be repeated for any logical address that are not dirty until the context changes. If a logical address is hit that has its dirty bits set while in the same context, both dirty bits would be set, so the new data will be over-written to the last physical address assigned for this logical address. When the first draw command of the context is detected, the previous context stored in the additional renaming table will be copied to the larger renaming table in the current (new) context location. Then the set constant logical address with be loaded with a new physical address during the copy and if the reset dirty was set, the physical address it replaced in the renaming table would be entered at the write_ptr pointer location on the free list and the write_ptr will be incremented. The de-allocation counter for the previous context (eight) will be incremented. This as set states come in for this context one of the following will happen:

1.) No dirty bits are set for the logical address being updated. A line will be allocated of the free-list counter or the free list at read_ptr pointer if read_ptr != to stop_ptr .
2.) Reset dirty set and Context dirty not set. A new physical address is allocated, the physical address in the renaming table is put on the free list at write_ptr and it is incremented along with the de-allocate counter for the last context.
3.) Context dirty is set then the data will be written into the physical address specified by the logical address.

This process will continue as long as set states arrive. This block will provide backpressure to the CP whenever he has not free list entries available (counter at max and stop_ptr == read_ptr). The command stream will keep a count of contexts of constants in use and prevent more than max constants contexts from being sent.

Whenever a draw packet arrives, the content of the re-mapping table is written to the correct re-mapping table for the context number. Also if the next context uses less constants than the current one all exceeding lines are moved to the free list to be de-allocated later. This happens in parallel with the writing of the re-mapping table to the correct memory.

Now preferable when the constant context leaves the last ALU clause it will be sent to this block and compared with the previous context that left. (Init to zero) If they differ than the older context will no longer be referenced and thus can be de-allocated in the physical memory. This is accomplished by adding the number of blocks freed this context to the stop_ptr pointer. This will make all the physical addresses used by this context available to the read_ptr allocate pointer for future allocation.

This device allows representation of multiple contexts of constants data with N copies of the logical address space. It also allows the second context to be represented as the first set plus some new additional data by just storing the delta's. It allows memory to be efficiently used and when the constants updates are small it can store multiple context. However, if the updates are large, less contexts will be stored and potentially performance will be degraded. Although it will still perform as well as a ring could in this case.

~~5.3~~5.4 Constant Store Indexing

Formatted: Bullets and Numbering

In order to do constant store indexing, the sequencer must be loaded first with the indexes (that come from the GPRs). There are 144 wires from the exit of the SP to the sequencer (9 bits pointers x 16 vertexes/clock). Since the data must pass thru the Shader pipe for the float to fixed conversion, there is a latency of 4 clocks (1 instruction)

between the time the sequencer is loaded and the time one can index into the constant store. The assembly will look like this

```
MOVA  R1.X,R2.X       // Loads the sequencer with the content of R2.X, also copies the content of R2.X into R1.X
NOP                   // latency of the float to fixed conversion
ADD   R3,R4,C0[R2.X]// Uses the state from the sequencer to add R4 to C0[R2.X] into R3
```

Note that we don't really care about what is in the brackets because we use the state from the MOVA instruction. R2.X is just written again for the sake of simplicity and coherency.

The storage needed in the sequencer in order to support this feature is 2*64*9 bits = 1152 bits.

~~5.4~~5.5 Real Time Commands

Formatted: Bullets and Numbering

The real time commands constants are written by the CP using the register mapped registers allocated for RT. It works is the same way than when dealing with regular constant loads BUT in this case the CP is not sending a logical address but rather a physical address and the reads are not passing thru the re-mapping table but are directly read from the memory. The boundary between the two zones is defined by the CONST_EO_RT control register. Similarly, for the fetch state, the boundary between the two zones is defined by the TSTATE_EO_RT control register.

~~5.5~~5.6 Constant Waterfalling

Formatted: Bullets and Numbering

In order to have a reasonable performance in the case of constant store indexing using the address register, we are going to have the possibility of using the physical memory port for read only. This way we can read 1 constant per clock and thus have a worst-case waterfall mode of 1 vertex per clock. There is a small synchronization issue related with this as we need for the SQ to make sure that the constants where actually written to memory (not only sent to the sequencer) before it can allow the first vector of pixels or vertices of the state to go thru the ALUs. To do so, the sequencer keeps 8 bits (one per render state) and sets the bits whenever the last render state is written to memory and clears the bit whenever a state is freed.

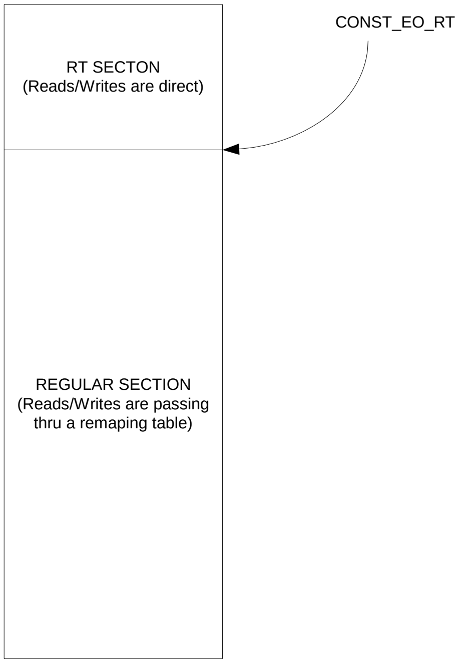

Figure 10: The instruction store

6. Looping and Branches

Loops and branches are planned to be supported and will have to be dealt with at the sequencer level. We plan on supporting constant loops and branches using a control program.

6.1 The controlling state.

The R400 controling state consists of:

Boolean[256:0]
Loop_count[7:0][31:0]
Loop_Start[7:0][31:0]
Loop_Step[7:0][31:0]

That is 256 Booleans and 32 loops.

We have a stack of 4 elements for nested calls of subroutines and 4 loop counters to allow for nested loops.

This state is available on a per shader program basis.

6.2 The Control Flow Program

Examples of control flow programs are located in the R400 programming guide document.

The basic model is as follows:

The render state defined the clause boundaries:

Vertex_shader_fetch[7:0][7:0]	// eight 8 bit pointers to the location where each clauses control program is located
Vertex_shader_alu[7:0][7:0]	// eight 8 bit pointers to the location where each clauses control program is located
Pixel_shader_fetch[7:0][7:0]	// eight 8 bit pointers to the location where each clauses control program is located
Pixel_shader_alu[7:0][7:0]	// eight 8 bit pointers to the location where each clauses control program is located

A pointer value of FF means that the clause doesn't contain any instructions.

The control program for a given clause is executed to completion before moving to another clause, (with the exception of the pick two nature of the alu execution). The control program is the only program aware of the clause boundaries.

The control program has ~~eleven~~ nine basic instructions:

Execute
Conditional_execute
Conditional_Execute_Predicates
Conditional_jump
Conditionnal_Call
Return
Loop_start
Loop_end
~~End_of_clause~~
~~Conditional_End_of_clause~~
NOP

Execute, causes the specified number of instructions in instruction store to be executed.
Conditional_execute checks a condition first, and if true, causes the specified number of instructions in instruction store to be executed.
Loop_start resets the corresponding loop counter to the start value on the first pass after it checks for the end condition and if met jumps over to a specified address.
Loop_end increments (decrements?) the loop counter and jumps back the specified number of instructions.

Conditionnal_Call jumps to an address and pushes the IP counter on the stack if the condition is met. On the return instruction, the IP is popped from the stack.
Conditional_execute_Predicates executes a block of instructions if all bits in the predicate vectors meet the condition.
~~End_of_clause marks the end of a clause.~~
~~Conditional_End_of_clause marks the end of a clause if the condition is met.~~
Conditional_jumps jumps to an address if the condition is met.
NOP is a regular NOP

NOTE THAT ALL JUMPS MUST JUMP TO EVEN CFP ADDRESSES since there are two control flow instructions per memory line. Thus the compiler must insert NOPs where needed to align the jumps on even CFP addresses.

Also if the jump is logically bigger than pshader_cntl_size (or vshader_cntl_size) we break the program (clause) and set the debug registers. If an execute or conditional_execute is lower than cntl_size or bigger than size we also break the program (clause) and set the debug registers.

We have to fit instructions into 48 bits in order to be able to put two control flow instruction per line in the instruction store.

Note that whenever a field is marked as RESERVED, it is assumed that all the bits of the field are cleared (0).

Execute					
47	46… 42	41~~41 … 24~~	40 … 24	23 … 12	11 … 0
Addressing	00001	Last~~RESERVED~~	RESERVED	Instruction count	Exec Address

Execute up to 4k instructions at the specified address in the instruction memory. If Last is set, this is the last group of instructions of the clause.

NOP			
47	46 … 42	41~~41 … 0~~	40 … 0
Addressing	00010	Last~~RESERVED~~	RESERVED

This is a regular NOP. If Last is set, this is the last instruction of the clause.

Conditional_Execute							
47	46 … 42	41	40 … 33	32	31 … 24	23 … 12	11 … 0
Addressing	00011	~~RESERVED~~ Last	Boolean address	Condition	RESERVED	Instruction count	Exec Address

If the specified Boolean (8 bits can address 256 Booleans) meets the specified condition then execute the specified instructions (up to 4k instructions). If Last is set, then if the condition is met, this is the last group of instructions to be executed in the clause. If the condition is not met, we go on to the next control flow instruction.

Conditional_Execute_Predicates								
47	46 … 42	41 ~~… 35~~	40 … 35	34 … 33	32	31 … 24	23 … 12	11 … 0
Addressing	00100	Last ~~RESERVED~~	RESERVED	Predicate vector	Condition	RESERVED	Instruction count	Exec Address

Check the AND/OR of all current predicate bits. If AND/OR matches the condition execute the specified number of instructions. We need to AND/OR this with the kill mask in order not to consider the pixels that aren't valid. If Last is set, then if the condition is met, this is the last group of instructions to be executed in the clause. If the condition is not met, we go on to the next control flow instruction.

Loop_Start				
47	46 … 42	41 … 17	16 … 12	11 … 0
Addressing	00101	RESERVED	loop ID	Jump address

Loop Start. Compares the loop iterator with the end value. If loop condition not met jump to the address. Forward jump only. Also computes the index value. The loop id must match between the start to end, and also indicates which control flow constants should be used with the loop.

Loop_End				
47	46 … 42	41 … 17	16 … 12	11 … 0
Addressing	00110	RESERVED	loop ID	start address

Loop end. Increments the counter by one, compares the loop count with the end value. If loop condition met, continue, else, jump BACK to the start of the loop.

The way this is described does not prevent nested loops, and the inclusion of the loop id make this easy to do.

Conditionnal_Call						
47	46 … 42	41 … 35	34 … 33	32	31 … 12	11 … 0
Addressing	00111	RESERVED	Predicate vector	Condition	RESERVED	Jump address

If the condition is met, jumps to the specified address and pushes the control flow program counter on the stack.

Return		
47	46 … 42	41 … 0
Addressing	01000	RESERVED

Pops the topmost address from the stack and jumps to that address. If nothing is on the stack, the program will just continue to the next instruction.

Conditionnal_Jump							
47	46 … 42	41	40 … 33	32	31	30 … 12	11 … 0
Addressing	01001	RESERVED	Boolean address	Condition	FW only	RESERVED	Jump address

If condition met, jumps to the address. FORWARD jump only allowed if bit 31 set. Bit 31 is only an optimization for the compiler and should NOT be exposed to the API.

~~This is an optimization in the case of very short shaders (where the control flow instruction can't be hidden anymore and thus are not free. In this case, if the condition is met, the clause is ended, else we continue the execution of the clause.~~

~~Marks the end of a clause.~~

To prevent infinite loops, we will keep 9 bits loop iterators instead of 8 (we are only able to loop 256 times). If the counter goes higher than 255 then the loop_end or the loop_start instruction is going to break the loop and set the debug GPRs.

6.3 Data dependant predicate instructions

Data dependant conditionals will be supported in the R400. The only way we plan to support those is by supporting three vector/scalar predicate operations of the form:

PRED_SETE_# - similar to SETE except that the result is 'exported' to the sequencer.
PRED_SETNE_# - similar to SETNE except that the result is 'exported' to the sequencer.
PRED_SETGT_# - similar to SETGT except that the result is 'exported' to the sequencer
PRED_SETGTE_# - similar to SETGTE except that the result is 'exported' to the sequencer

For the scalar operations only we will also support the two following instructions:
PRED_SETE0_# – SETE0
PRED_SETE1_# – SETE1

The export is a single bit - 1 or 0 that is sent using the same data path as the MOVA instruction. The sequencer will maintain 4 sets of 64 bit predicate vectors (in fact 8 sets because we interleave two programs but only 4 will be exposed) and use it to control the write masking. This predicate is not maintained across clause boundaries. The # sign is used to specify which predicate set you want to use 0 thru 3.

Then we have two conditional execute bits. The first bit is a conditional execute “on” bit and the second bit tells us if we execute on 1 or 0. For example, the instruction:

P0_ADD_# R0,R1,R2

Is only going to write the result of the ADD into those GPRs whose predicate bit is 0. Alternatively, P1_ADD_# would only write the results to the GPRs whose predicate bit is set. The use of the P0 or P1 without precharging the sequencer with a PRED instruction is undefined.

{Issue: do we have to have a NOP between PRED and the first instruction that uses a predicate?}

6.4 HW Detection of PV,PS

Because of the control program, the compiler cannot detect statically dependant instructions. In the case of non-masked writes and subsequent reads the sequencer will insert uses of PV,PS as needed. This will be done by comparing the read address and the write address of consecutive instructions. For masked writes, the sequencer will insert NOPs wherever there is a dependant read/write.

The sequencer will also have to insert NOPs between PRED_SET and MOVA instructions and their uses.

6.5 Register file indexing

Because we can have loops in fetch clause, we need to be able to index into the register file in order to retrieve the data created in a fetch clause loop and use it into an ALU clause. The instruction will include the base address for register indexing and the instruction will contain these controls:

Bit7	Bit 6	
0	0	'absolute register'
0	1	'relative register'
1	0	'previous vector'
1	1	'previous scalar'

In the case of an absolute register we just take the address as is. In the case of a relative register read we take the base address and we add to it the loop_index and this becomes our new address that we give to the shader pipe.

The sequencer is going to keep a loop index computed as such:

Index = Loop_iterator*Loop_step + Loop_start.

We loop until loop_iterator = loop_count. Loop_step is a signed value [-128…127]. The computed index value is a 10 bit counter that is also signed. Its real range is [-256,256]. The tenth bit is only there so that we can provide an out of range value to the “indexing logic” so that it knows when the provided index is out of range and thus can make the necessary arrangements.

6.6 Predicated Instruction support for Texture clauses

For texture clauses, we support the following optimization: we keep 1 bit (thus 4 bits for the four predicate vectors) per predicate vector in the reservation stations. A value of 1 means that one ore more elements in the vector have a value of one (thus we have to do the texture fetches for the whole vector). A value of 0 means that no elements in the vector have his predicate bit set and we can thus skip over the texture fetch. **We have to make sure the invalid pixels aren't considered with this optimization.**

6.7 Debugging the Shaders

In order to be able to debug the pixel/vertex shaders efficiently, we provide 2 methods.

6.7.1 *Method 1: Debugging registers*

Current plans are to expose 2 debugging, or error notification, registers:
1. address register where the first error occurred
2. count of the number of errors

The sequencer will detect the following groups of errors:
- count overflow
- constant indexing overflow
- register indexing overflow

Compiler recognizable errors:
- jump errors
    relative jump address > size of the control flow program
- call stack
    call with stack full
    return with stack empty

A jump error will always cause the program to break. In this case, a break means that a clause will halt execution, but allowing further clauses to be executed.

With all the other errors, program can continue to run, potentially to worst-case limits. The program will only break if the DB_PROB_BREAK register is set.

If indexing outside of the constant or the register range, causing an overflow error, the hardware is specified to return the value with an index of 0. This could be exploited to generate error tokens, by reserving and initializing the 0th register (or constant) for errors.

{ISSUE : Interrupt to the driver or not?}

6.7.2 *Method 2: Exporting the values in the GPRs (12)*

The sequencer will have a count register and an address register for this mode and 3 bits per clause specifying the execution mode for each clause. The modes can be :

1) Normal
2) Debug Kill
3) Debug Addr + Count

Under the normal mode execution follows the normal course. Under the kill mode, all control flow instructions are executed but all normal shader instructions of the clause are replaced by NOPs. Only debug_export instructions of clause 7 will be executed under the debug kill setting. Under the other mode, normal execution is done until we reach an address specified by the address register and instruction count (useful for loops) specified by the count register. After we have hit the instruction n times (n=count) we switch the clause to the kill mode.

Under the debug mode (debug kill OR debug Addr + count), it is assumed that clause 7 is always exporting 12 debug vectors and that all other exports to the SX block (position, color, z, ect) will been turned off (changed into NOPs) by the sequencer (even if they occur before the address stated by the ADDR debug register).

7. Pixel Kill Mask

A vector of 64 bits is kept by the sequencer per group of pixels/vertices. Its purpose is to optimize the texture fetch requests and allow the shader pipe to kill pixels using the following instructions:

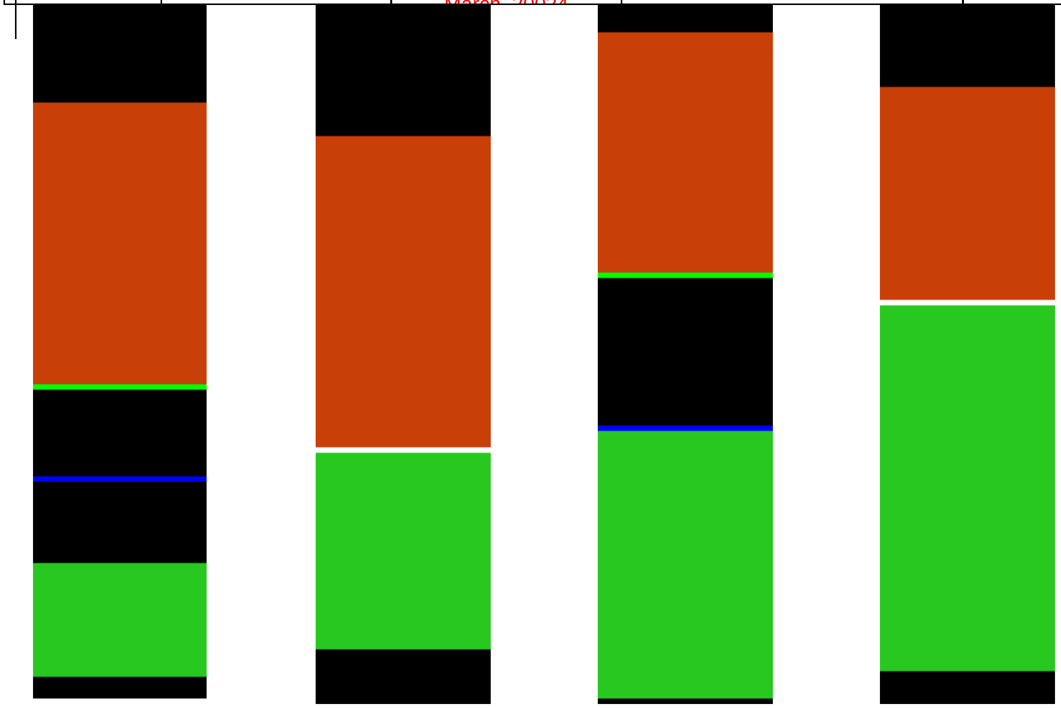
MASK_SETE
MASK_SETNE
MASK_SETGT
MASK_SETGTE

8. Multipass vertex shaders (HOS)

Multipass vertex shaders are able to export from the 6 last clauses but to memory ONLY.

9. Register file allocation

The register file allocation for vertices and pixels can either be static or dynamic. In both cases, the register file in managed using two round robins (one for pixels and one for vertices). In the dynamic case the boundary between pixels and vertices is allowed to move, in the static case it is fixed to 128-VERTEX_REG_SIZE for vertices and PIXEL_REG_SIZE for pixels.



Above is an example of how the algorithm works. Vertices come in from top to bottom; pixels come in from bottom to top. Vertices are in orange and pixels in green. The blue line is the tail of the vertices and the green line is the tail of the pixels. Thus anything between the two lines is shared. When pixels meets vertices the line turns white and the boundary is static until both vertices and pixels share the same "unallocated bubble". Then the boundary is allowed to move again. The numbering of the GPRs starts from the bottom of the picture at index 0 and goes up to the top at index 127.

10. Fetch Arbitration

The fetch arbitration logic chooses one of the 8 potentially pending fetch clauses to be executed. The choice is made by looking at the fifos from 7 to 0 and picking the first one ready to execute. Once chosen, the clause state machine will send one 2x2 fetch per clock (or 4 fetches in one clock every 4 clocks) until all the fetch instructions of the clause are sent. This means that there cannot be any dependencies between two fetches of the same clause.

The arbitrator will not wait for the fetches to return prior to selecting another clause for execution. The fetch pipe will be able to handle up to X(?) in flight fetches and thus there can be a fair number of active clauses waiting for their fetch return data.

11. ALU Arbitration

ALU arbitration proceeds in almost the same way than fetch arbitration. The ALU arbitration logic chooses one of the 8 potentially pending ALU clauses to be executed. The choice is made by looking at the fifos from 7 to 0 and picking the first one ready to execute. There are two ALU arbiters, one for the even clocks and one for the odd clocks. For example, here is the sequencing of two interleaved ALU clauses (E and O stands for Even and Odd sets of 4 clocks):

Einst0 Oinst0 Einst1 Oinst1 Einst2 Oinst2 Einst0 Oinst3 Einst1 Oinst4 Einst2 Oinst0…
Proceeding this way hides the latency of 8 clocks of the ALUs. Also note that the interleaving also occurs across clause boundaries.

12. Handling Stalls

When the output file is full, the sequencer prevents the ALU arbitration logic from selecting the last clause (this way nothing can exit the shader pipe until there is place in the output file. If the packet is a vertex packet and the position buffer is full (POS_FULL) then the sequencer also prevents a thread from entering the exporting clause (3?). The sequencer will set the OUT_FILE_FULL signal n clocks before the output file is actually full and thus the ALU arbiter will be able read this signal and act accordingly by not preventing exporting clauses to proceed.

13. Content of the reservation station FIFOs

The reservation FIFOs contain the state of the vector of pixels and vertices. We have two sets of those: one for pixels, and one for vertices. They contain 3 bits of Render State 7 bits for the base address of the GPRs, some bits for LOD correction and coverage mask information in order to fetch fetch for only valid pixels, the quad address.

14. The Output File

The output file is where pixels are put before they go to the RBs. The write BW to this store is 256 bits/clock. Just before this output file are staging registers with write BW 512 bits/clock and read BW 256 bits/clock. The staging registers are 4x128 (and there are 16 of those on the whole chip).

15. IJ Format

The IJ information sent by the PA is of this format on a per quad basis:

We have a vector of IJ's (one IJ per pixel at the centroid of the fragment or at the center of the pixel depending on the mode bit). The interpolation is done at a different precision across the 2x2. The upper left pixel's parameters are always interpolated at full 20x24 mantissa precision. Then the result of the interpolation along with the difference in IJ in reduced precision is used to interpolate the parameter for the other three pixels of the 2x2. Here is how we do it:

Assuming P0 is the interpolated parameter at Pixel 0 having the barycentric coordinates I(0), J(0) and so on for P1,P2 and P3. Also assuming that A is the parameter value at V0 (interpolated with I), B is the parameter value at V1 (interpolated with J) and C is the parameter value at V2 (interpolated with (1-I-J).

$$\Delta 01I = I(1) - I(0)$$
$$\Delta 01J = J(1) - J(0)$$
$$\Delta 02I = I(2) - I(0)$$
$$\Delta 02J = J(2) - J(0)$$
$$\Delta 03I = I(3) - I(0)$$
$$\Delta 03J = J(3) - J(0)$$

P0	P1
P2	P3

$$P0 = C + I(0)*(A-C) + J(0)*(B-C)$$
$$P1 = P0 + \Delta 01I*(A-C) + \Delta 01J*(B-C)$$
$$P2 = P0 + \Delta 02I*(A-C) + \Delta 02J*(B-C)$$
$$P3 = P0 + \Delta 03I*(A-C) + \Delta 03J*(B-C)$$

P0 is computed at 20x24 mantissa precision and P1 to P3 are computed at 8X24 mantissa precision. So far no visual degradation of the image was seen using this scheme.

Multiplies (Full Precision): 2
Multiplies (Reduced precision): 6
Subtracts 19x24 (Parameters): 2

Adds: 8

FORMAT OF P0's IJ : Mantissa 20 Exp 4 for I + Sign
Mantissa 20 Exp 4 for J + Sign

FORMAT of Deltas (x3):Mantissa 8 Exp 4 for I + Sign
Mantissa 8 Exp 4 for J + Sign

Total number of bits : 20*2 + 8*6 + 4*8 + 4*2 = 128

All numbers are kept using the un-normalized floating point convention: if exponent is different than 0 the number is normalized if not, then the number is un-normalized. The maximum range for the IJs (Full precision) is +/- 63 and the range for the Deltas is +/- 127.

15.1 Interpolation of constant attributes

Because of the floating point imprecision, we need to take special provisions if all the interpolated terms are the same or if two of the barycentric coordinates are the same.

We start with the premise that if A = B and B = C and C = A, then P0,1,2,3 = A. Since one or more of the IJ terms may be zero, so we extend this to:

```
if (A=B and B=C and C=A)
   P0,1,2,3 = A;
else if ((I = 0) or (J = 0)) and
          ((J = 0) or (1-I-J = 0)) and
          ((1-J-I = 0) or (I = 0))) {
                if(I != 0) {
                    P0 = A;
                } else if(J != 0) {
                    P0 = B;
                } else {
                    P0 = C;
               }
             //rest of the quad interpolated normally
}
else
{
             normal interpolation
}
```

16. Staging Registers

In order for the reuse of the vertices to be 14, the sequencer will have to re-order the data sent IN ORDER by the VGT for it to be aligned with the parameter cache memory arrangement. Given the following group of vertices sent by the VGT:

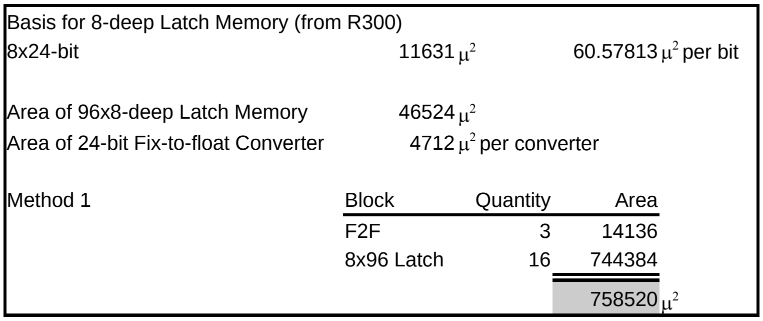
0 1 2 3 4 5 6 7 8 9 10 11 12 13 14 15 || 16 17 18 19 20 21 22 23 24 25 26 27 28 29 30 31 || 32 33 34 35 36 37 38 39 40 41 42 43 44 45 46 47 || 48 49 50 51 52 53 54 55 56 57 58 59 60 61 62 63

The sequencer will re-arrange them in this fashion:

0 1 2 3 16 17 18 19 32 33 34 35 48 49 50 51 || 4 5 6 7 20 21 22 23 36 37 38 39 52 53 54 55 || 8 9 10 11 24 25 26 27 40 41 42 43 56 57 58 59 || 12 13 14 15 28 29 30 31 44 45 46 47 60 61 62 63

The || markers show the SP divisions. In the event a shader pipe is broken, the VGT will send padding to account for the missing pipe. For example, if SP1 is broken, vertices 4 5 6 7 20 21 22 23 36 37 38 39 52 53 54 55 will still be sent by the VGT to the SQ **BUT** will not be processed by the SP and thus should be considered invalid (by the SU and VGT).

The most straightforward, *non-compressed* interface method would be to convert, in the VGT, the data to 32-bit floating point prior to transmission to the VSISRs. In this scenario, the data would be transmitted to (and stored in) the VSISRs in full 32-bit floating point. This method requires three 24-bit fixed-to-float converters in the VGT. Unfortunately, it also requires and additional 3,072 bits of storage across the VSISRs. This interface is illustrated in Figure 12~~Figure 12Figure 12~~. The area of the fixed-to-float converters and the VSISRs for this method is roughly estimated as 0.759sqmm using the R300 process. The gate count estimate is shown in Figure 11~~Figure 11Figure 11~~.



Basis for 8-deep Latch Memory (from R300)			
8x24-bit	11631 μ^2		60.57813 μ^2 per bit
Area of 96x8-deep Latch Memory	46524 μ^2		
Area of 24-bit Fix-to-float Converter	4712 μ^2 per converter		
Method 1	Block	Quantity	Area
	F2F	3	14136
	8x96 Latch	16	744384
			758520 μ^2

Figure 11:Area Estimate for VGT to Shader Interface

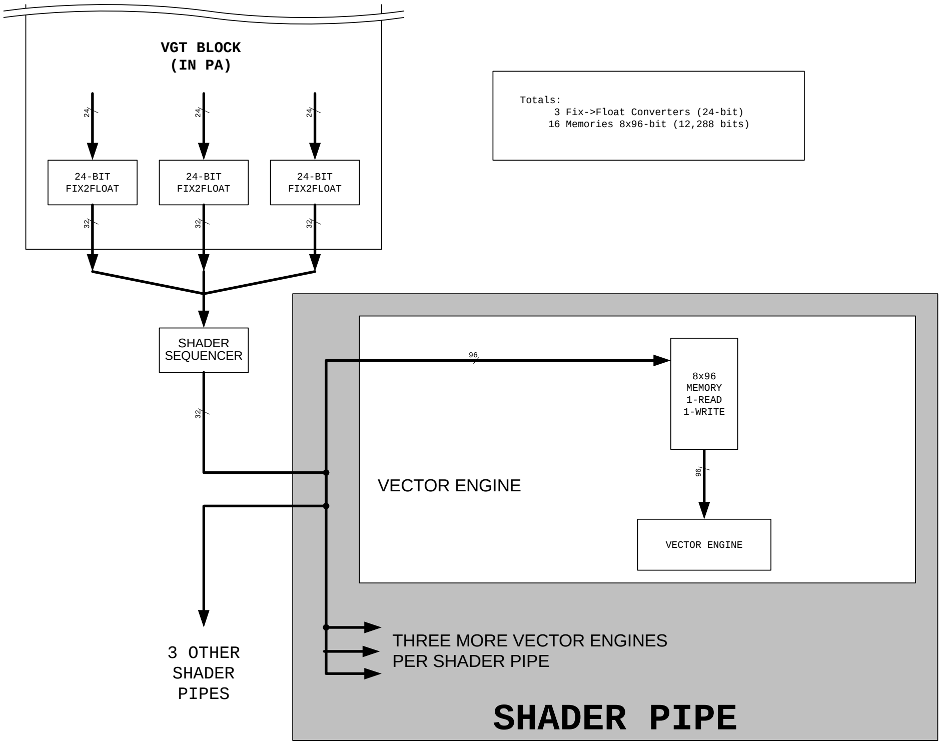


Figure 12:VGT to Shader Interface

17. The parameter cache

The parameter cache is where the vertex shaders export their data. It consists of 16 128x128 memories (1R/1W). The reuse engine will make it so that all vertexes of a given primitive will hit different memories. The allocation method for these memories is a simple round robin. The parameter cache pointers are mapped in the following way: 4MSBs are the memory number and the 7 LSBs are the address within this memory.

MEMORY NUMBER 4 bits	ADDRESS 7 bits

The PA generates the parameter cache addresses as the positions come from the SQ. All it needs to do is keep a Current_Location pointer (7 bits only) and as the positions comes increment the memory number. When the memory number field wraps around, the PA increments the Current_Location by VS_EXPORT_COUNT_7 (a snooped register from the SQ). As an example, say the memories are all empty to begin with and the vertex shader is exporting 8 parameters per vertex (VS_EXPORT_COUNT_7 = 8). The first position received is going to have the PC address 00000000000 the second one 00010000000, third one 00100000000 and so on up to 11110000000. Then the next position received (the 17th) is going to have the address 00000001000, the 18th 00010001000, the 19th 00100001000 and so on. The Current_location is NEVER reset BUT on chip resets. The only thing to be careful about is that if the SX doesn't send you a full group of positions (<64) then you need to fill the address space so that the next group starts correctly aligned (for example if you receive only 33 positions then you need to add 2*VS_EXPORT_COUNT_7to Current_Location and reset the memory count to 0 before the next vector begins).

18. Vertex position exporting

On clause 3 the vertex shader can export to the PA both the vertex position and the point sprite. It can also do so at clause 7 if not done at clause 3. The storage needed to perform the position export is at least 64x128 memories for the position and 64x32 memories for the sprite size. It is going to be taken in the pixel output fifo from the SX blocks. The clause where the position export occurs is specified by the EXPORT_LATE register. If turned on, it means that the export is going to occur at ALU clause 7 if unset position export occurs at clause 3.

19. Exporting Arbitration

Here are the rules for co-issuing exporting ALU clauses.

1) Position exports and position exports cannot be co-issued.

All other types of exports can be co-issued as long as there is place in the receiving buffer.

{ISSUE: Do we move the parameter caches to the SX?}

20. Export Types

The export type (or the location where the data should be put) is specified using the destination address field in the ALU instruction. Here is a list of all possible export modes:

20.1 Vertex Shading

0:15	- 16 parameter cache
16:31	- Empty (Reserved?)
32:43	- 12 vertex exports to the frame buffer and index
44:47	- Empty
48:59	- 12 debug export (interpret as normal vertex export)
60	- export addressing mode
61	- Empty
62	- position
63	- sprite size export that goes with position export (point_h,point_w,edgeflag,misc)

20.2 Pixel Shading

0	- Color for buffer 0 (primary)
1	- Color for buffer 1
2	- Color for buffer 2
3	- Color for buffer 3
4:7	- Empty
8	- Buffer 0 Color/Fog (primary)
9	- Buffer 1 Color/Fog
10	- Buffer 2 Color/Fog
11	- Buffer 3 Color/Fog
12:15	- Empty
16:31	- Empty (Reserved?)
32:43	- 12 exports for multipass pixel shaders.
44:47	- Empty
48:59	- 12 debug exports (interpret as normal pixel export)
60	- export addressing mode
61:62	- Empty
63	- Z for primary buffer (Z exported to 'alpha' component)

21. Special Interpolation modes

21.1 Real time commands

We are unable to use the parameter memory since there is no way for a command stream to write into it. Instead we need to add three 16x128 memories (one for each of three vertices x 16 interpolants). These will be mapped onto the register bus and written by type 0 packets, and output to the the parameter busses (the sequencer and/or PA need to be able to address the reatime parameter memory as well as the regular parameter store. For higher performance we should be able able to view them as two banks of 16 and do double buffering allowing one to be loaded, while the other is rasterized with. Most overlay shaders will need 2 or 4 scalar coordinates, one option might be to restrict the memory to 16x64 or 32x64 allowing only two interpolated scalars per cycle, the only problem I see with this is, if we view support for 16 vector-4 interpolants important (true only if we map Microsoft's high priority stream to the realtime stream), then the PA/sequencer need to support a realtime-specific mode where we need to address 32 vectors of parameters instead of 16. This mode is triggered by the primitive type: REAL TIME. The actual memories are in the in the SX blocks. The parameter data memories are hooked on the RBBM bus and are loaded by the CP using register mapped memory.

21.2 Sprites/ XY screen coordinates/ FB information

When working with sprites, one may want to overwrite the parameter 0 with SC generated data. Also, XY screen coordinates may be needed in the shader program. This functionality is controlled by the gen_I0 register (in SQ) in conjunction with the SND_XY register (in SC). Also it is possible to send the faceness information (for OGL front/back special operations) to the shader using the same control register. Here is a list of all the modes and how they interact together:

Gen_st is a bit taken from the interface between the SC and the SQ. This is the MSB of the primitive type. If the bit is set, it means we are dealing with Point AA, Line AA or sprite and in this case the vertex values are going to generated between 0 and 1.

Param_Gen_I0 disable, snd_xy disable, no gen_st – I0 = No modification
Param_Gen_I0 disable, snd_xy disable, gen_st – I0 = No modification
Param_Gen_I0 disable, snd_xy enable, no gen_st – I0 = No modification
Param_Gen_I0 disable, snd_xy enable, gen_st – I0 = No modification
Param_Gen_I0 enable, snd_xy disable, no gen_st – I0 = garbage, garbage, garbage, faceness
Param_Gen_I0 enable, snd_xy disable, gen_st – I0 = garbage, garbage, s, t
Param_Gen_I0 enable, snd_xy enable, no gen_st – I0 = screen x, screen y, garbage, faceness
Param_Gen_I0 enable, snd_xy enable, gen_st – I0 = screen x, screen y, s, t

21.3 Auto generated counters

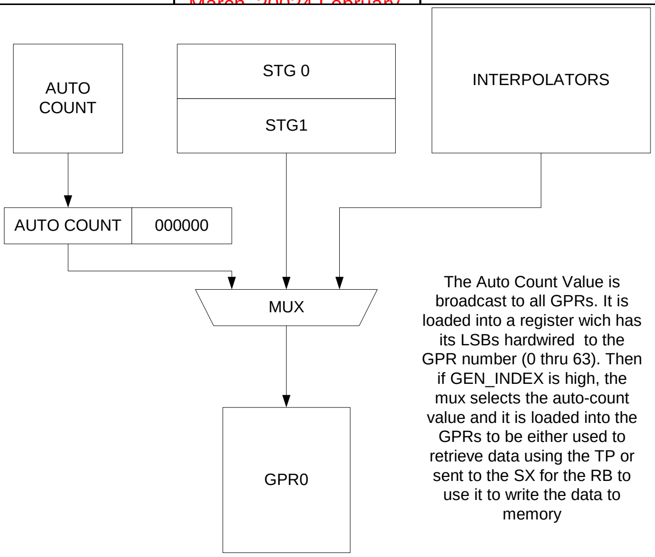
In the cases we are dealing with multipass shaders, the sequencer is going to generate a vector count to be able to both use this count to write the 1st pass data to memory and then use the count to retrieve the data on the 2nd pass. The count is always generated in the same way but it is passed to the shader in a slightly different way depending on the shader type (pixel or vertex). This is toggled on and off using the GEN_INDEX register. The sequencer is going to keep two counters, one for pixels and one for vertices. Every time a full vector of vertices or pixels is written to the GPRs the counter is incremented. Every time a state change is detected, the corresponding counter is reset. While there is only one count broadcast to the GPRs, the LSB are hardwired to specific values making the index different for all elements in the vector.

21.3.1 *Vertex shaders*

In the case of vertex shaders, if GEN_INDEX is set, the data will be put into the x field of the third register (it means that the compiler must allocate 3 GPRs in all multipass vertex shader modes).

21.3.2 *Pixel shaders*

In the case of pixel shaders, if GEN_INDEX is set and Param_Gen_I0 is enabled, the data will be put in the x field of the 2nd register (R1.x), else if GEN_INDEX is set the data will be put into the x field of the 1st register (R0.x).



The Auto Count Value is broadcast to all GPRs. It is loaded into a register wich has its LSBs hardwired to the GPR number (0 thru 63). Then if GEN_INDEX is high, the mux selects the auto-count value and it is loaded into the GPRs to be either used to retrieve data using the TP or sent to the SX for the RB to use it to write the data to memory

Figure 13: GPR input mux Control

22. State management

Every clock, the sequencer will report to the CP the oldest states still in the pipe. These are the states of the programs as they enter the last ALU clause.

22.1 Parameter cache synchronization

In order for the sequencer not to begin a group of pixels before the associated group of vertices has finished, the sequencer will keep a 6 bit count per state (for a total of 8 counters). These counters are initialized to 0 and every time a vertex shader exports its data TO THE PARAMETER CACHE, the corresponding pointer is incremented. When the SC sends a new vector of pixels with the SC_SQ_new_vector bit asserted, the sequencer will first check if the count is greater than 0 before accepting the transmission (it will in fact accept the transmission but then lower its ready to receive). Then the sequencer waits for the count to go to one and decrements it. The sequencer can then issue the group of pixels to the interpolators. Every time the state changes, the new state counter is initialized to 0.

23. XY Address imports

The SC will be able to send the XY addresses to the GPRs. It does so by interleaving the writes of the IJs (to the IJ buffer) with XY writes (to the XY buffer). Then when writing the data to the GPRs, the sequencer is going to interpolate the IJ data or pass the XY data thru a Fix→float converter and expander and write the converted values to the GPRs. The Xys are currently SCREEN SPACE COORDINATES. The values in the XY buffers will wrap. See section 21.2 for details on how to control the interpolation in this mode.

23.1 Vertex indexes imports

In order to import vertex indexes, we have 16 8x96 staging registers. These are loaded one line at a time by the VGT block (96 bits). They are loaded in floating point format and can be transferred in 4 or 8 clocks to the GPRs.

24. Registers

24.1 Control

REG_DYNAMIC	Dynamic allocation (pixel/vertex) of the register file on or off.
REG_SIZE_PIX	Size of the register file's pixel portion (minimal size when dynamic allocation turned on)
REG_SIZE_VTX	Size of the register file's vertex portion (minimal size when dynamic allocation turned on)
ARBITRATION_POLICY	policy of the arbitration between vertexes and pixels
INST_STORE_ALLOC	interleaved, separate
INST_BASE_VTX	start point for the vertex instruction store (RT always ends at vertex_base and Begins at 0)
INST_BASE_PIX	start point for the pixel shader instruction store
ONE_THREAD	debug state register. Only allows one program at a time into the GPRs
ONE_ALU	debug state register. Only allows one ALU program at a time to be executed (instead of 2)
INSTRUCTION	This is where the CP puts the base address of the instruction writes and type (auto-incremented on reads/writes) Register mapped
CONSTANTS	512*4 ALU constants + 32*6 Texture state 32 bits registers (logically mapped)
CONSTANTS_RT	256*4 ALU constants + 32*6 texture states? (physically mapped)
CONSTANT_EO_RT	This is the size of the space reserved for real time in the constant store (from 0 to CONSTANT_EO_RT). The re-mapping table operates on the rest of the memory
TSTATE_EO_RT	This is the size of the space reserved for real time in the fetch state store (from 0 to TSTATE_EO_RT). The re-mapping table operates on the rest of the memory
EXPORT_LATE	Controls whether or not we are exporting position from clause 3. If set, position exports occur at clause 7.

24.2 Context

VS_FETCH_{0…7}	eight 8 bit pointers to the location where each clauses control program is located
VS_ALU_{0…7}	eight 8 bit pointers to the location where each clauses control program is located
PS_FETCH_{0…7}	eight 8 bit pointers to the location where each clauses control program is located
PS_ALU_{0…7}	eight 8 bit pointers to the location where each clauses control program is located
PS_BASE	base pointer for the pixel shader in the instruction store
VS_BASE	base pointer for the vertex shader in the instruction store
VS_CF_SIZE	size of the vertex shader (# of instructions in control program/2)
PS_CF_SIZE	size of the pixel shader (# of instructions in control program/2)
PS_SIZE	size of the pixel shader (cntl+instructions)
VS_SIZE	size of the vertex shader (cntl+instructions)
PS_NUM_REG	number of GPRs to allocate for pixel shader programs
VS_NUM_REG	number of GPRs to allocate for vertex shader programs
PARAM_SHADE	One 16 bit register specifying which parameters are to be gouraud shaded (0 = flat, 1 = gouraud)
PROVO_VERT	0 : vertex 0, 1: vertex 1, 2: vertex 2, 3: Last vertex of the primitive
PARAM_WRAP	64 bits: for which parameters (and channels (xyzw)) do we do the cyl wrapping (0=linear, 1=cylindrical).
PS_EXPORT_MODE	0xxxx : Normal mode 1xxxx : Multipass mode If normal, bbbz where bbb is how many colors (0-4) and z is export z or not If multipass 1-12 exports for color.
VS_EXPORT_MASK	which of the last 6 ALU clauses is exporting (multipass only)
VS_EXPORT_MODE	0: position (1 vector), 1: position (2 vectors), 3:multipass
VS_EXPORT _COUNT_{0…6}	Six 4 bit counters representing the # of interpolated parameters exported in clause 7 (located in VS_EXPORT_COUNT_6) OR # of exported vectors to memory per clause in multipass mode (per clause)
PARAM_GEN_I0	Do we overwrite or not the parameter 0 with XY data and generated T and S values

GEN_INDEX	Auto generates an address from 0 to XX. Puts the results into R0-1 for pixel shaders and R2 for vertex shaders
CONST_BASE_VTX (9 bits)	Logical Base address for the constants of the Vertex shader
CONST_BASE_PIX (9 bits)	Logical Base address for the constants of the Pixel shader
CONST_SIZE_PIX (8 bits)	Size of the logical constant store for pixel shaders
CONST_SIZE_VTX (8 bits)	Size of the logical constant store for vertex shaders
INST_PRED_OPTIMIZE	Turns on the predicate bit optimization (if of, conditional_execute_predicates is always executed).
CF_BOOLEANS	256 boolean bits
CF_LOOP_COUNT	32x8 bit counters (number of times we traverse the loop)
CF_LOOP_START	32x8 bit counters (init value used in index computation)
CF_LOOP_STEP	32x8 bit counters (step value used in index computation)

25. DEBUG Registers

25.1 Context

DB_PROB_ADDR	instruction address where the first problem occurred
DB_PROB_COUNT	number of problems encountered during the execution of the program
DB_PROB_BREAK	break the clause if an error is found.
DB_INST_COUNT	instruction counter for debug method 2
DB_BREAK_ADDR	break address for method number 2
DB_CLAUSE _MODE_ALU_{0…7}	clause mode for debug method 2 (0: normal, 1: addr, 2: kill)
DB_CLAUSE _MODE_FETCH_{0…7}	clause mode for debug method 2 (0: normal, 1: addr, 2: kill)

25.2 Control

DB_ALUCST_MEMSIZE	Size of the physical ALU constant memory
DB_TSTATE_MEMSIZE	Size of the physical texture state memory

26. Interfaces

26.1 External Interfaces

Whenever an x is used, it means that the bus is broadcast to all units of the same name. For example, if a bus is named SQ→SPx it means that SQ is going to broadcast the same information to all SP instances.

26.1.1 *SC to SQ : IJ Control bus*

This is the control information sent to the sequencer in order to control the IJ fifos and all other information needed to execute a shader program on the sent pixels. This information is sent over 2 clocks, if SENDXY is asserted the next control packet is going to be ignored and XY information is going to be sent on the IJ bus (for the quads that where just sent). All pixels from the group of quads are from the same primitive, all quads of a vector are from the same render state.

Name	Direction	Bits	Description
SC_SQ_q_wr_mask	SC→SQ	4	Quad Write mask left to right
SC_SQ_lod_correct	SC→SQ	24	LOD correction per quad (6 bits per quad)
SC_SQ_param_ptr0	SC→SQ	11	P Store pointer for vertex 0
SC_SQ_param_ptr1	SC→SQ	11	P Store pointer for vertex 1
SC_SQ_param_ptr2	SC→SQ	11	P Store pointer for vertex 2
SC_SQ_end_of_vect	SC→SQ	1	End of the vector
SC_SQ_store_dealloc	SC→SQ	1	Deallocation token for the P Store
SC_SQ_state	SC→SQ	3	State/constant pointer
SC_SQ_valid_pixel	SC→SQ	16	Valid bits for all pixels
SC_SQ_null_prim	SC→SQ	1	Null Primitive (for PC deallocation purposes)
SC_SQ_end_of_prim	SC→SQ	1	End Of the primitive
SC_SQ_send_xy	SC→SQ	1	Sending XY information [XY information is going to be sent on the next clock]
SC_SQ_prim_type	SC→SQ	3	Real time command need to load tex cords from alternate buffer. Line AA, Point AA and Sprite reads their parameters from GEN_T and GEN_S GPRs. 000 : Normal 011 : Real Time 100 : Line AA 101 : Point AA 110 : Sprite
SC_SQ_new_vector	SC→SQ	1	This primitive comes from a new vector of vertices. Make sure that the corresponding vertex shader has finished before starting the group of pixels.
SC_SQ_RTRn	SQ→SC	1	Stalls the PA in n clocks
SC_SQ_RTS	SC→SQ	1	SC ready to send data

26.1.2 *SQ to SP: Interpolator bus*

Name	Direction	Bits	Description
SQ_SPx_interp_prim_type	SQ→SPx	3	Type of the primitive 000 : Normal 011 : Real Time 100 : Line AA 101 : Point AA 110 : Sprite
SQ_SPx_interp_ijline	SQ→SPx	2	Line in the IJ/XY buffer to use to interpolate
SQ_SPx_interp_buff_swap	SQ→SPx	1	Swap the IJ/XY buffers at the end of the interpolation
SQ_SPx_interp_gen_I0	SQ→SPx	1	Generate I0 or not. This tells the interpolators not to use the parameter cache but rather overwrite the data with interpolated 1 and 0. Overwrite if gen_I0 is high.

26.1.3 *SQ to SX: Interpolator bus*

Name	Direction	Bits	Description
SQ_SPx_interp_flat_vtx	SQ→SPx	2	Provoking vertex for flat shading
SQ_SPx_interp_flat_gouraud	SQ→SPx	1	Flat or gouraud shading
SQ_SPx_interp_cyl_wrap	SQ→SPx	4	Wich channel needs to be cylindrical wrapped
SQ_SXx_mux0	SQ→SXx	11	Parameter Cache Pointer
SQ_SXx_mux1	SQ→SXx	11	Parameter Cache Pointer
SQ_SXx_mux2	SQ→SXx	11	Parameter Cache Pointer
SQ_SXx_RT_switch	SQ→SXx	1	Selects between RT and Normal data

~~26.1.4SQ to SP: Parameter Cache Read control bus~~

Formatted: Bullets and Numbering

~~The four following interfaces (SQ→SP, SQ→SX,SP→SX and SX→Interpolators) are all SYNCHRONIZED together.~~

~~26.1.4 SQ to SX: Parameter Cache Mux control Bus~~

~~26.1.6~~26.1.4 SQ to SP: Staging Register Data

Formatted: Bullets and Numbering

This is a broadcast bus that sends the VSISR information to the staging registers of the shader pipes.

Name	Direction	Bits	Description
SQ_SPx_vgt_vsisr_data	SQ→SPx	96	Pointers of indexes or HOS surface information
SQ_SPx_vgt_vsisr_double	SQ→SPx	1	0: Normal 96 bits per vert 1: double 192 bits per vert
SQ_SP0_data_valid	SQ→SP0	1	Data is valid
SQ_SP1_data_valid	SQ→SP1	1	Data is valid
SQ_SP2_data_valid	SQ→SP2	1	Data is valid
SQ_SP3_data_valid	SQ→SP3	1	Data is valid

~~26.1.7~~26.1.5 PA to SQ : Vertex interface

Formatted: Bullets and Numbering

~~26.1.7.1~~26.1.5.1 Interface Signal Table

The area difference between the two methods is not sufficient to warrant complicating the interface or the state requirements of the VSISRs. **Therefore, the POR for this interface is that the VGT will transmit the data to the VSISRs (via the Shader Sequencer) in full, 32-bit floating-point format.** The VGT can transmit up to six 32-bit floating-point values to each VSISR where four or more values require two transmission clocks. The data bus is 96 bits wide.

Name	Bits	Description
PA_SQ_vgt_vsisr_data	96	Pointers of indexes or HOS surface information
PA_SQ_vgt_vsisr_double	1	0: Normal 96 bits per vert 1: double 192 bits per vert
PA_SQ_vgt_end_of_vector	1	Indicates the last VSISR data set for the current process vector (for double vector data, "end_of_vector" is set on the second vector)
PA_SQ_vgt_vsisr_valid	1	Vsisr data is valid
PA_SQ_vgt_state	3	Render State (6*3+3 for constants). This signal is guaranteed to be correct when “PA_SQ_vgt_end_of_vector” is high.
PA_SQ_vgt_send	1	Data on the VGT_SQ is valid receive (see write-up for standard R400 SEND/RTR interface handshaking)
SQ_PA_vgt_rtr	1	Ready to receive (see write-up for standard R400 SEND/RTR interface handshaking)

~~26.1.8~~26.1.6 SQ to CP: State report

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
SQ_CP_vrtx_ state	SEQ→CP	3	Oldest vertex state still in the pipe
SQ_CP_pix_state	SEQ→CP	3	Oldest pixel state still in the pipe

~~26.1.9~~26.1.7 SQ to SX: Control bus

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
SQ_SXx_exp_Pixel	SQ→SXx	1	1: Pixel 0: Vertex
SQ_SXx_exp_start	SQ→SXx	1	Raised to indicate that the SQ is starting an exporting clause
SQ_SXx_exp_Clause	SQ→SXx	3	Clause number, which is needed for vertex clauses
SQ_SXx_exp_State	SQ→SXx	3	State ID~~, which is needed for vertex clauses~~
SQ_SXx_exp_VDest	SQ→SXx	6	Export Destination
SQ_SXx_exp_exportID	SQ→SXx	1	ALU ID

These fields are sent synchronously with SP export data, described in SP0→SX0 interface
~~{ISSUE: Where are the PC pointers}~~

~~26.1.10~~26.1.8 SX to SQ : Output file control

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
SXx_SQ_Export_count_rdy	SXx→SQ	1	Raised by SX0 to indicate that the following two fields reflect the result of the most recent export
SXx_SQ_Export_Position	SXx→SQ	1	Specifies whether there is room for another position.
SXx_SQ_Export_Buffer	SXx→SQ	7	Specifies the space available in the output buffers. 0: buffers are full 1: 2K-bits available (32-bits for each of the 64 pixels in a clause) ... 64: 128K-bits available (16 128-bit entries for each of 64 pixels) 65-127: RESERVED

~~26.1.11~~26.1.9 SQ to TP: Control bus

Formatted: Bullets and Numbering

Once every clock, the fetch unit sends to the sequencer on which clause it is now working and if the data in the GPRs is ready or not. This way the sequencer can update the fetch counters for the reservation station fifos. The sequencer also provides the instruction and constants for the fetch to execute and the address in the register file where to write the fetch return data.

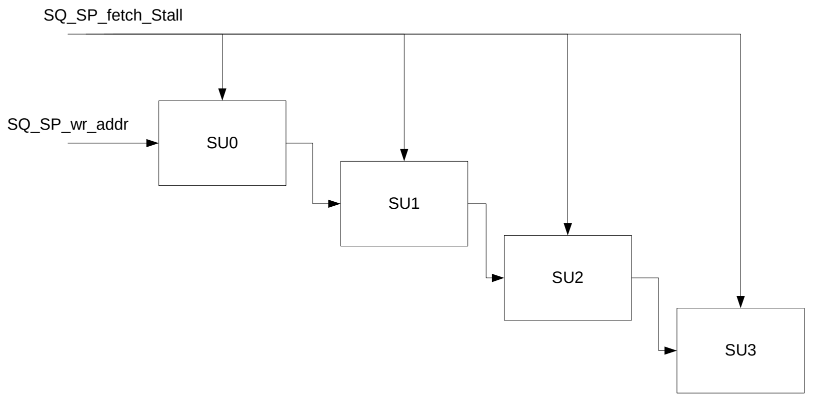
Name	Direction	Bits	Description
TPx_SQ_data_rdy	TPx→ SQ	1	Data ready
TPx_SQ_clause_num	TPx→ SQ	3	Clause number
TPx_SQ_Type	TPx→ SQ	1	Type of data sent (0:PIXEL, 1:VERTEX)
SQ_TPx_const	SQ→TPx	48	Fetch state sent over 4 clocks (192 bits total)
SQ_TPx_instuct	SQ→TPx	24	Fetch instruction sent over 4 clocks
SQ_TPx_end_of_clause	SQ→TPx	1	Last instruction of the clause
SQ_TPx_Type	SQ→TPx	1	Type of data sent (0:PIXEL, 1:VERTEX)
SQ_TPx_phase	SQ→TPx	2	Write phase signal
SQ_TP0_lod_correct	SQ→TP0	6	LOD correct 3 bits per comp 2 components per quad
SQ_TP0_pmask	SQ→TP0	4	Pixel mask 1 bit per pixel
SQ_TP1_lod_correct	SQ→TP1	6	LOD correct 3 bits per comp 2 components per quad
SQ_TP1_pmask	SQ→TP1	4	Pixel mask 1 bit per pixel
SQ_TP2_lod_correct	SQ→TP2	6	LOD correct 3 bits per comp 2 components per quad
SQ_TP2_pmask	SQ→TP2	4	Pixel mask 1 bit per pixel

SQ_TP3_lod_correct	SQ→TP3	6	LOD correct 3 bits per comp 2 components per quad
SQ_TP3_pmask	SQ→TP3	4	Pixel mask 1 bit per pixel
SQ_TPx_clause_num	SQ→TPx	3	Clause number
SQ_TPx_write_gpr_index	SQ->TPx	7	Index into Register file for write of returned Fetch Data

Formatted: Bullets and Numbering

~~26.1.12~~26.1.10 TP to SQ: Texture stall

The TP sends this signal to the SQ when its input buffer is full. The SQ is going to send it to the SP X clocks after reception (maximum of 3 clocks of pipeline delay).



Name	Direction	Bits	Description
TP_SQ_fetch_stall	TP→ SQ	1	Do not send more texture request if asserted

Formatted: Bullets and Numbering

~~26.1.13~~26.1.11 SQ to SP: Texture stall

Name	Direction	Bits	Description
SQ_SPx_fetch_stall	SQ→SPx	1	Do not send more texture request if asserted

Formatted: Bullets and Numbering

~~26.1.14~~26.1.12 SQ to SP: GPR, Parameter cache control and auto counter

Name	Direction	Bits	Description
SQ_SPx_wr_addr	SQ→SPx	7	Write address
SQ_SPx_gpr_rd_addr	SQ→SPx	7	Read address
SQ_SPx_gpr_re_addr	SQ→SPx	1	Read Enable
SQ_SPx_gpr_we_addr	SQ→SPx	1	Write Enable for the GPRs
SQ_SPx_gpr_phase_mux	SQ→SPx	2	The phase mux (arbitrates between inputs, ALU SRC reads and writes)
SQ_SPx_channel_mask	SQ→SPx	4	The channel mask
SQ_SP0_pixel_mask	SQ→SP0	4	The pixel mask
SQ_SP1_pixel_mask	SQ→SP1	4	The pixel mask
SQ_SP2_pixel_mask	SQ→SP2	4	The pixel mask
SQ_SP3_pixel_mask	SQ→SP3	4	The pixel mask
SQ_SPx_pc_we_addr	SQ→SPx	1	Write Enable for the parameter caches
SQ_SPx_gpr_input_mux	SQ→SPx	2	When the phase mux selects the inputs this tells from which source to read from: Interpolated data, VTX0, VTX1, autogen counter.
SQ_SPx_index_count	SQ→SPx	12?	Index count, common for all shader pipes

~~26.1.15~~26.1.13 SQ to SPx: Instructions

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
SQ_SPx_instruct_start	SQ→SPx	1	Instruction start
SQ_SP_instruct	SQ→SPx	21	Transferred over 4 cycles 0: SRC A Select 2:0 SRC A Argument Modifier 3:3 SRC A swizzle 11:4 ~~Unused~~ VectorDst ~~20~~17:12 Unused 20:18 -- - 1: SRC B Select 2:0 SRC B Argument Modifier 3:3 SRC B swizzle 11:4 ScalarDst 17:12 Unused 20:18 ~~Unused 20:12~~ -- - 2: SRC C Select 2:0 SRC C Argument Modifier 3:3 SRC C swizzle 11:4 Unused 20:12 -- - 3: Vector Opcode 4:0 Scalar Opcode 10:5 Vector Clamp 11:11 Scalar Clamp 12:12 Vector Write Mask 16:13 Scalar Write Mask 20:17
SQ_SPx_stall	SQ→SPx	1	Stall signal
SQ_SPx_export_count	SQ→SPx	3	Each set of four pixels or vectors is exported over eight clocks. This field specifies where the SP is in that sequence.
SQ_SPx_export_last	SQ→SPx	1	Asserted on the first shader count of the last export of the clause
SQ_SP0_export_pvalid	SQ→SP0	4	Result of pixel kill in the shader pipe, which must be output for all pixel exports (depth and all color buffers). 4x4 because 16 pixels are computed per clock
SQ_SP0_export_wvalid	SQ→SP0	2	Specifies whether to write low and/or high 32-bit word of the 64-bit export data from each of the 16 pixels or vectors
SQ_SP1_ export_pvalid	SQ→SP1	4	Result of pixel kill in the shader pipe, which must be output for all pixel exports (depth and all color buffers). 4x4 because 16 pixels are computed per clock
SQ_SP1_ export_wvalid	SQ→SP1	2	Specifies whether to write low and/or high 32-bit word of the 64-bit export data from each of the 16 pixels or vectors
SQ_SP2_ export_pvalid	SQ→SP2	4	Result of pixel kill in the shader pipe, which must be output for all pixel exports (depth and all color buffers). 4x4 because 16 pixels are computed per clock
SQ_SP2_ export_wvalid	SQ→SP2	2	Specifies whether to write low and/or high 32-bit word of the 64-bit export data from each of the 16 pixels or vectors

SQ_SP3_ export_pvalid	SQ→SP3	4	Result of pixel kill in the shader pipe, which must be output for all pixel exports (depth and all color buffers). 4x4 because 16 pixels are computed per clock
SQ_SP3_ export_wvalid	SQ→SP3	2	Specifies whether to write low and/or high 32-bit word of the 64-bit export data from each of the 16 pixels or vectors

~~26.1.16~~26.1.14 *SP to SQ: Constant address load/ Predicate Set*

Formatted: Bullets and Numbering

Name	**Direction**	**Bits**	**Description**
SP0_SQ_const_addr	SP0→SQ	36	Constant address load / predicate vector load (4 bits only) to the sequencer
SP0_SQ_valid	SP0→SQ	1	Data valid
SP1_SQ_const_addr	SP1→SQ	36	Constant address load / predicate vector load (4 bits only) to the sequencer
SP1_SQ_valid	SP1→SQ	1	Data valid
SP2_SQ_const_addr	SP2→SQ	36	Constant address load / predicate vector load (4 bits only) to the sequencer
SP2_SQ_valid	SP2→SQ	1	Data valid
SP3_SQ_const_addr	SP3→SQ	36	Constant address load / predicate vector load (4 bits only) to the sequencer
SP3_SQ_valid	SP3→SQ	1	Data valid

~~26.1.17~~26.1.15 *SQ to SPx: constant broadcast*

Formatted: Bullets and Numbering

Name	**Direction**	**Bits**	**Description**
SQ_SPx_constant	SQ→SPx	128	Constant broadcast

~~26.1.18~~26.1.16 *SP0 to SQ: Kill vector load*

Formatted: Bullets and Numbering

Name	**Direction**	**Bits**	**Description**
SP0_SQ_kill_vect	SP0→SQ	4	Kill vector load
SP1_SQ_kill_vect	SP1→SQ	4	Kill vector load
SP2_SQ_kill_vect	SP2→SQ	4	Kill vector load
SP3_SQ_kill_vect	SP3→SQ	4	Kill vector load

~~26.1.19~~26.1.17 *SQ to CP: RBBM bus*

Formatted: Bullets and Numbering

Name	**Direction**	**Bits**	**Description**
SQ_RBB_rs	SQ→CP	1	Read Strobe
SQ_RBB_rd	SQ→CP	32	Read Data
SQ_RBBM_nrtrtr	SQ→CP	1	Optional
SQ_RBBM_rtr	SQ→CP	1	Real-Time (Optional)

~~26.1.20~~26.1.18 *CP to SQ: RBBM bus*

Formatted: Bullets and Numbering

Name	**Direction**	**Bits**	**Description**
rbbm_we	CP→SQ	1	Write Enable
rbbm_a	CP→SQ	15	Address -- Upper Extent is TBD (16:2)
rbbm_wd	CP→SQ	32	Data
rbbm_be	CP→SQ	4	Byte Enables
rbbm_re	CP→SQ	1	Read Enable
rbb_rs0	CP→SQ	1	Read Return Strobe 0
rbb_rs1	CP→SQ	1	Read Return Strobe 1
rbb_rd0	CP→SQ	32	Read Data 0
rbb_rd1	CP→SQ	32	Read Data 0
RBBM_SQ_soft_reset	CP→SQ	1	Soft Reset

27. Examples of program executions

27.1.1 *Sequencer Control of a Vector of Vertices*

1. PA sends a vector of 64 vertices (actually vertex indices – 32 bits/index for 2048 bit total) to the RE's Vertex FIFO
   - state pointer as well as tag into position cache is sent along with vertices
   - space was allocated in the position cache for transformed position before the vector was sent
   - **also before the vector is sent to the RE, the CP has loaded the global instruction store with the vertex shader program (using the MH?)**
   - The vertex program is assumed to be loaded when we receive the vertex vector.
     - the SEQ then accesses the IS base for this shader using the local state pointer (provided to all sequencers by the RBBM when the CP is done loading the program)
2. SEQ arbitrates between the Pixel FIFO and the Vertex FIFO – basically the Vertex FIFO always has priority
   - at this point the vector is removed from the Vertex FIFO
   - the arbiter is not going to select a vector to be transformed if the parameter cache is full unless the pipe as nothing else to do (ie no pixels are in the pixel fifo).
3. SEQ allocates space in the SP register file for index data plus GPRs used by the program
   - the number of GPRs required by the program is stored in a local state register, which is accessed using the state pointer that came down with the vertices
   - SEQ will not send vertex data until space in the register file has been allocated
4. SEQ sends the vector to the SP register file over the RE_SP interface (which has a bandwidth of 2048 bits/cycle)
   - the 64 vertex indices are sent to the 64 register files over 4 cycles
     - RF0 of SU0, SU1, SU2, and SU3 is written the first cycle
     - RF1 of SU0, SU1, SU2, and SU3 is written the second cycle
     - RF2 of SU0, SU1, SU2, and SU3 is written the third cycle
     - RF3 of SU0, SU1, SU2, and SU3 is written the fourth cycle
   - the index is written to the least significant 32 bits **(floating point format?) (what about compound indices)** of the 128-bit location within the register file (w); the remaining data bits are set to zero (x, y, z)
5. SEQ constructs a control packet for the vector and sends it to the first reservation station (the FIFO in front of fetch state machine 0, or TSM0 FIFO)
   - the control packet contains the state pointer, the tag to the position cache and a register file base pointer.
6. TSM0 accepts the control packet and fetches the instructions for fetch clause 0 from the global instruction store
   - TSM0 was first selected by the TSM arbiter before it could start
7. all instructions of fetch clause 0 are issued by TSM0
8. the control packet is passed to the next reservation station (the FIFO in front of ALU state machine 0, or ASM0 FIFO)
   - TSM0 does not wait for requests made to the Fetch Unit to complete; it passes the register file write index for the fetch data to the TU, which will write the data to the RF as it is received
   - once the TU has written all the data to the register files, it increments a counter that is associated with ASM0 FIFO; a count greater than zero indicates that the ALU state machine can go ahead start to execute the ALU clause
9. ASM0 accepts the control packet (after being selected by the ASM arbiter) and gets the instructions for ALU clause 0 from the global instruction store
10. all instructions of ALU clause 0 are issued by ASM0, then the control packet is passed to the next reservation station (the FIFO in front of fetch state machine 1, or TSM1 FIFO)
11. the control packet continues to travel down the path of reservation stations until all clauses have been executed
    - position can be exported in ALU clause 3 (or 4?); the data (and the tag) is sent over a position bus (which is shared with all four shader pipes) back to the PA's position cache
    - A parameter cache pointer is also sent along with the position data. This tells to the PA where the data is going to be in the parameter cache.
      - there is a position export FIFO in the SP that buffers position data before it gets sent back to the PA

    - the ASM arbiter will prevent a packet from starting an exporting clause if the position export FIFO is full
- parameter data is exported in clause 7 (as well as position data if it was not exported earlier)
    - parameter data is sent to the Parameter Cache over a dedicated bus
    - the SEQ allocates storage in the Parameter Cache, and the SEQ deallocates that space when there is no longer a need for the parameters (it is told by the PA when using a token).
    - the ASM arbiter will prevent a packet from starting on ASM7 if the parameter cache (or the position buffer if position is being exported) is full

12. after the shader program has completed, the SEQ will free up the GPRs so that they can be used by another shader program

27.1.2 *Sequencer Control of a Vector of Pixels*

1. **As with vertex shader programs, pixel shaders are loaded into the global instruction store by the CP**
    - At this point it is assumed that the pixel program is loaded into the instruction store and thus ready to be read.
2. the RE's Pixel FIFO is loaded with the barycentric coordinates for pixel quads by the detailed walker
    - the state pointer and the LOD correction bits are also placed in the Pixel FIF0
    - the Pixel FIFO is wide enough to source four quad's worth of barycentrics per cycle
3. SEQ arbitrates between Pixel FIFO and Vertex FIFO – when there are no vertices pending OR there is no space left in the register files for vertices, the Pixel FIFO is selected
4. SEQ allocates space in the SP register file for all the GPRs used by the program
    - the number of GPRs required by the program is stored in a local state register, which is accessed using the state pointer
    - SEQ will not allow interpolated data to be sent to the shader until space in the register file has been allocated
5. SEQ controls the transfer of interpolated data to the SP register file over the RE_SP interface (which has a bandwidth of 2048 bits/cycle). See interpolated data bus diagrams for details.
6. SEQ constructs a control packet for the vector and sends it to the first reservation station (the FIFO in front of fetch state machine 0, or TSM0 FIFO)
    - note that there is a separate set of reservation stations/arbiters/state machines for vertices and for pixels
    - the control packet contains the state pointer, the register file base pointer, and the LOD correction bits
    - all other information (such as quad address for example) travels in a separate FIFO
7. TSM0 accepts the control packet and fetches the instructions for fetch clause 0 from the global instruction store
    - TSM0 was first selected by the TSM arbiter before it could start
8. all instructions of fetch clause 0 are issued by TSM0
9. the control packet is passed to the next reservation station (the FIFO in front of ALU state machine 0, or ASM0 FIFO)
    - TSM0 does not wait for fetch requests made to the Fetch Unit to complete; it passes the register file write index for the fetch data to the TU, which will write the data to the RF as it is received
    - once the TU has written all the data for a particular clause to the register files, it increments a counter that is associated with the ASM0 FIFO; a count greater than zero indicates that the ALU state machine can go ahead and pop the FIFO and start to execute the ALU clause
10. ASM0 accepts the control packet (after being selected by the ASM arbiter) and gets the instructions for ALU clause 0 from the global instruction store
11. all instructions of ALU clause 0 are issued by ASM0, then the control packet is passed to the next reservation station (the FIFO in front of fetch state machine 1, or TSM1 FIFO)
12. the control packet continues to travel down the path of reservation stations until all clauses have been executed
    - pixel data is exported in the last ALU clause (clause 7)
        - it is sent to an output FIFO where it will be picked up by the render backend
        - the ASM arbiter will prevent a packet from starting on ASM7 if the output FIFO is full
13. after the shader program has completed, the SEQ will free up the GPRs so that they can be used by another shader program

27.1.3 *Notes*

14. The state machines and arbiters will operate ahead of time so that they will be able to immediately start the real threads or stall.
15. The register file base pointer for a vector needs to travel with the vector through the reservation stations, but the instruction store base pointer does not – this is because the RF pointer is different for all threads, but the IS pointer is only different for each state and thus can be accessed via the state pointer.

28. Open issues

Need to do some testing on the size of the register file as well as on the register file allocation method (dynamic VS static).

Saving power?

Parameter caches in SX?

Using both IJ buffers for center + centroid interpolation?

R400 Sequencer Specification

SQ

Version 1.9~~8~~

Overview: This is an architectural specification for the R400 Sequencer block (SEQ). It provides an overview of the required capabilities and expected uses of the block. It also describes the block interfaces, internal sub-blocks, and provides internal state diagrams.

Revision Changes:

Rev 0.1 (Laurent Lefebvre) Date: May 7, 2001	First draft.
Rev 0.2 (Laurent Lefebvre) Date : July 9, 2001	Changed the interfaces to reflect the changes in the SP. Added some details in the arbitration section.
Rev 0.3 (Laurent Lefebvre) Date : August 6, 2001	Reviewed the Sequencer spec after the meeting on August 3, 2001.
Rev 0.4 (Laurent Lefebvre) Date : August 24, 2001	Added the dynamic allocation method for register file and an example (written in part by Vic) of the flow of pixels/vertices in the sequencer.
Rev 0.5 (Laurent Lefebvre) Date : September 7, 2001	Added timing diagrams (Vic)
Rev 0.6 (Laurent Lefebvre) Date : September 24, 2001	Changed the spec to reflect the new R400 architecture. Added interfaces.
Rev 0.7 (Laurent Lefebvre) Date : October 5, 2001	Added constant store management, instruction store management, control flow management and data dependant predication.
Rev 0.8 (Laurent Lefebvre) Date : October 8, 2001	Changed the control flow method to be more flexible. Also updated the external interfaces.
Rev 0.9 (Laurent Lefebvre) Date : October 17, 2001	Incorporated changes made in the 10/18/01 control flow meeting. Added a NOP instruction, removed the conditional_execute_or_jump. Added debug registers.
Rev 1.0 (Laurent Lefebvre) Date : October 19, 2001	Refined interfaces to RB. Added state registers.
Rev 1.1 (Laurent Lefebvre) Date : October 26, 2001	Added SEQ→SP0 interfaces. Changed delta precision. Changed VGT→SP0 interface. Debug Methods added.
Rev 1.2 (Laurent Lefebvre) Date : November 16, 2001	Interfaces greatly refined. Cleaned up the spec.
Rev 1.3 (Laurent Lefebvre) Date : November 26, 2001	Added the different interpolation modes.
Rev 1.4 (Laurent Lefebvre) Date : December 6, 2001	Added the auto incrementing counters. Changed the VGT→SQ interface. Added content on constant management. Updated GPRs.
Rev 1.5 (Laurent Lefebvre) Date : December 11, 2001	Removed from the spec all interfaces that weren't directly tied to the SQ. Added explanations on constant management. Added PA→SQ synchronization fields and explanation.
Rev 1.6 (Laurent Lefebvre) Date : January 7, 2002	Added more details on the staging register. Added detail about the parameter caches. Changed the call instruction to a Conditionnal_call instruction. Added details on constant management and updated the diagram.
Rev 1.7 (Laurent Lefebvre) Date : February 4, 2002	Added Real Time parameter control in the SX interface. Updated the control flow section.
Rev 1.8 (Laurent Lefebvre) Date : March 4, 2002	New interfaces to the SX block. Added the end of clause modifier, removed the end of clause instructions.
Rev 1.9 (Laurent Lefebvre) Date :	Rearangement of the CF instruction bits in order to ensure byte alignment

1. Overview

The sequencer is based on the R300 design. It chooses two ALU clauses and a fetch clause to execute, and executes all of the instructions in a clause before looking for a new clause of the same type. Two ALU clauses are executed interleaved to hide the ALU latency. Each vector will have eight fetch and eight ALU clauses, but clauses do not need to contain instructions. A vector of pixels or vertices ping-pongs along the sequencer FIFO, bouncing from fetch reservation station to alu reservation station. A FIFO exists between each reservation stage, holding up vectors until the vector currently occupying a reservation station has left. A vector at a reservation station can be chosen to execute. The sequencer looks at all eight alu reservation stations to choose an alu clause to execute and all eight fetch stations to choose a fetch clause to execute. The arbitrator will give priority to clauses/reservation stations closer to the bottom of the pipeline. It will not execute an alu clause until the fetch fetches initiated by the previous fetch clause have completed. There are two separate sets of reservation stations, one for pixel vectors and one for vertices vectors. This way a pixel can pass a vertex and a vertex can pass a pixel.

To support the shader pipe the sequencer also contains the shader instruction cache, constant store, control flow constants and texture state. The four shader pipes also execute the same instruction thus there is only one sequencer for the whole chip.

The sequencer first arbitrates between vectors of 64 vertices that arrive directly from primitive assembly and vectors of 16 quads (64 pixels) that are generated in the scan converter.

The vertex or pixel program specifies how many GPRs it needs to execute. The sequencer will not start the next vector until the needed space is available in the GPRs.

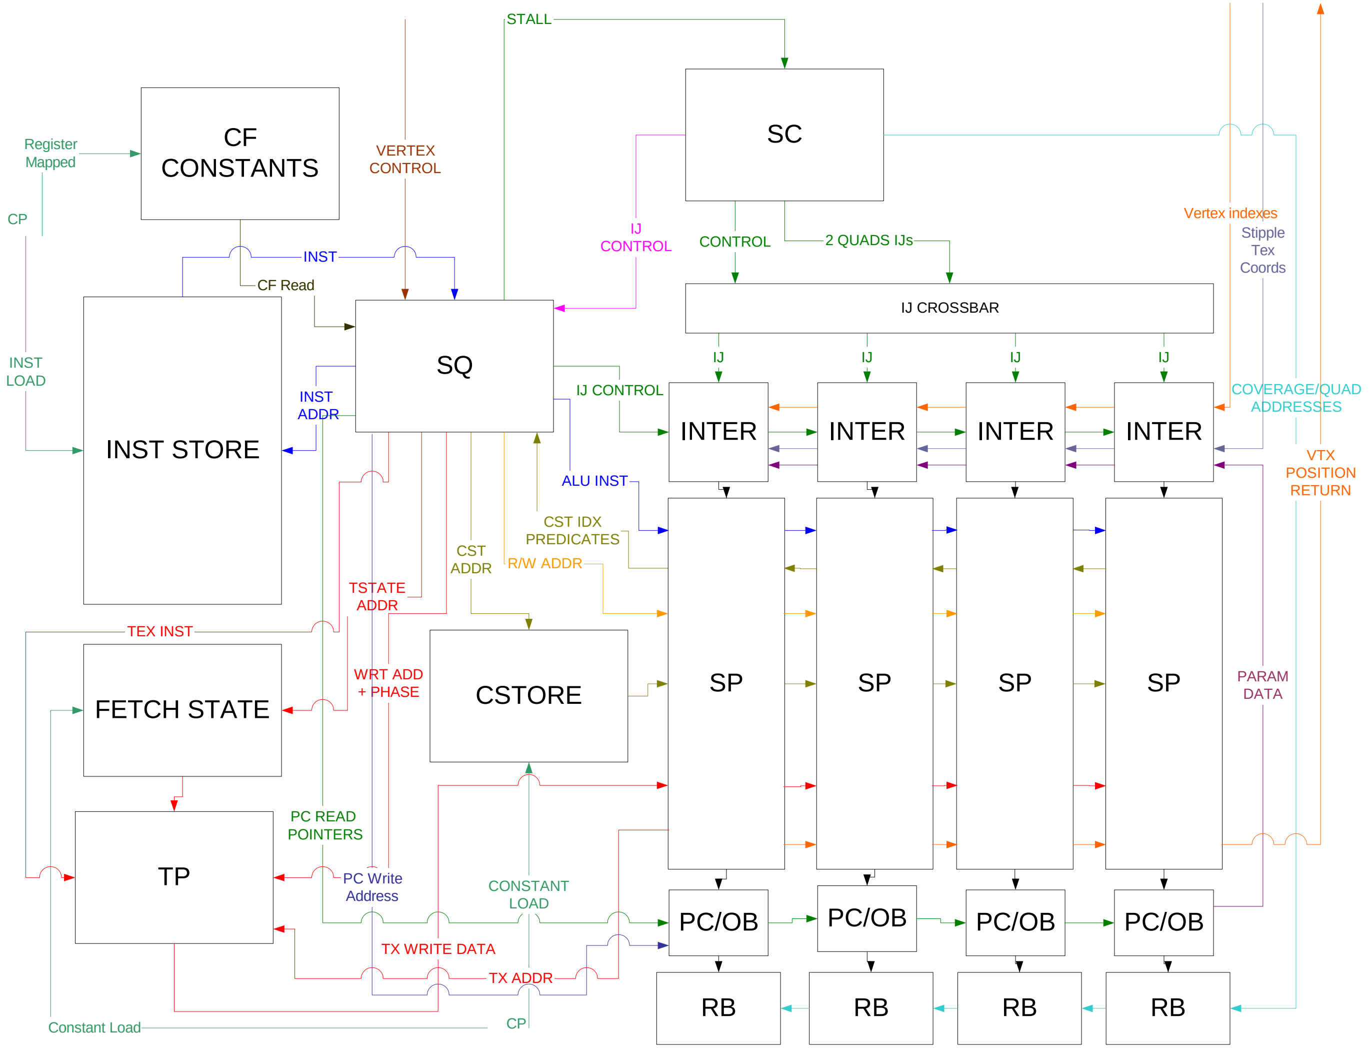

Figure 1: General Sequencer overview

Figure 2: Reservation stations and arbiters

There are two sets of the above figure, one for vertices and one for pixels.

Depending on the arbitration state, the sequencer will either choose a vertex or a pixel packet. The control packet consists of 3 bits of state, 7 bits for the base address of the Shader program and some information on the coverage to determine fetch LOD plus other various small state bits.

On receipt of a packet, the input state machine (not pictured but just before the first FIFO) allocated enough space in the GPRs to store the interpolated values and temporaries. Following this, the barycentric coordinates (and XY screen position if needed) are sent to the interpolator, which will use them to interpolate the parameters and place the results into the GPRs. Then, the input state machine stacks the packet in the first FIFO.

On receipt of a command, the level 0 fetch machine issues a fetch request to the TP and corresponding GPR address for the fetch address (ta). A small command (tcmd) is passed to the fetch system identifying the current level number (0) as well as the GPR write address for the fetch return data. One fetch request is sent every 4 clocks causing the texturing of sixteen 2x2s worth of data (or 64 vertices). Once all the requests are sent the packet is put in FIFO 1.

Upon receipt of the return data, the fetch unit writes the data to the register file using the write address that was provided by the level 0 fetch machine and sends the clause number (0) to the level 0 fetch state machine to signify that the write is done and thus the data is ready. Then, the level 0 fetch machine increments the counter of FIFO 1 to signify to the ALU 0 that the data is ready to be processed.

On receipt of a command, the level 0 ALU machine first decrements the input FIFO 1 counter and then issues a complete set of level 0 shader instructions. For each instruction, the ALU state machine generates 3 source addresses, one destination address and an instruction. Once the last instruction has been issued, the packet is put into FIFO 2.

There will always be two active ALU clauses at any given time (and two arbiters). One arbiter will arbitrate over the odd instructions (4 clocks cycles) and the other one will arbitrate over the even instructions (4 clocks cycles). The only constraints between the two arbiters is that they are not allowed to pick the same clause number as the other one is currently working on if the packet is not of the same type (render state).

If the packet is a vertex packet, upon reaching ALU clause 3, it can export the position if the position is ready. So the arbiter must prevent ALU clause 3 to be selected if the positional buffer is full (or can't be accessed). Along with the positional data, if needed the sprite size and/or edge flags can also be sent.

A special case is for multipass vertex shaders, which can export 12 parameters per last 6 clauses to the output buffer. If the output buffer is full or doesn't have enough space the sequencer will prevent such a vertex group to enter an exporting clause.

Multipass pixel shaders can export 12 parameters to memory from the last clause only (7).

All other clauses process in the same way until the packet finally reaches the last ALU machine (7).

Only one pair of interleaved ALU state machines may have access to the register file address bus or the instruction decode bus at one time. Similarly, only one fetch state machine may have access to the register file address bus at one time. Arbitration is performed by three arbiter blocks (two for the ALU state machines and one for the fetch state machines). The arbiters always favor the higher number state machines, preventing a bunch of half finished jobs from clogging up the register files.

1.2 Data Flow graph (SP)

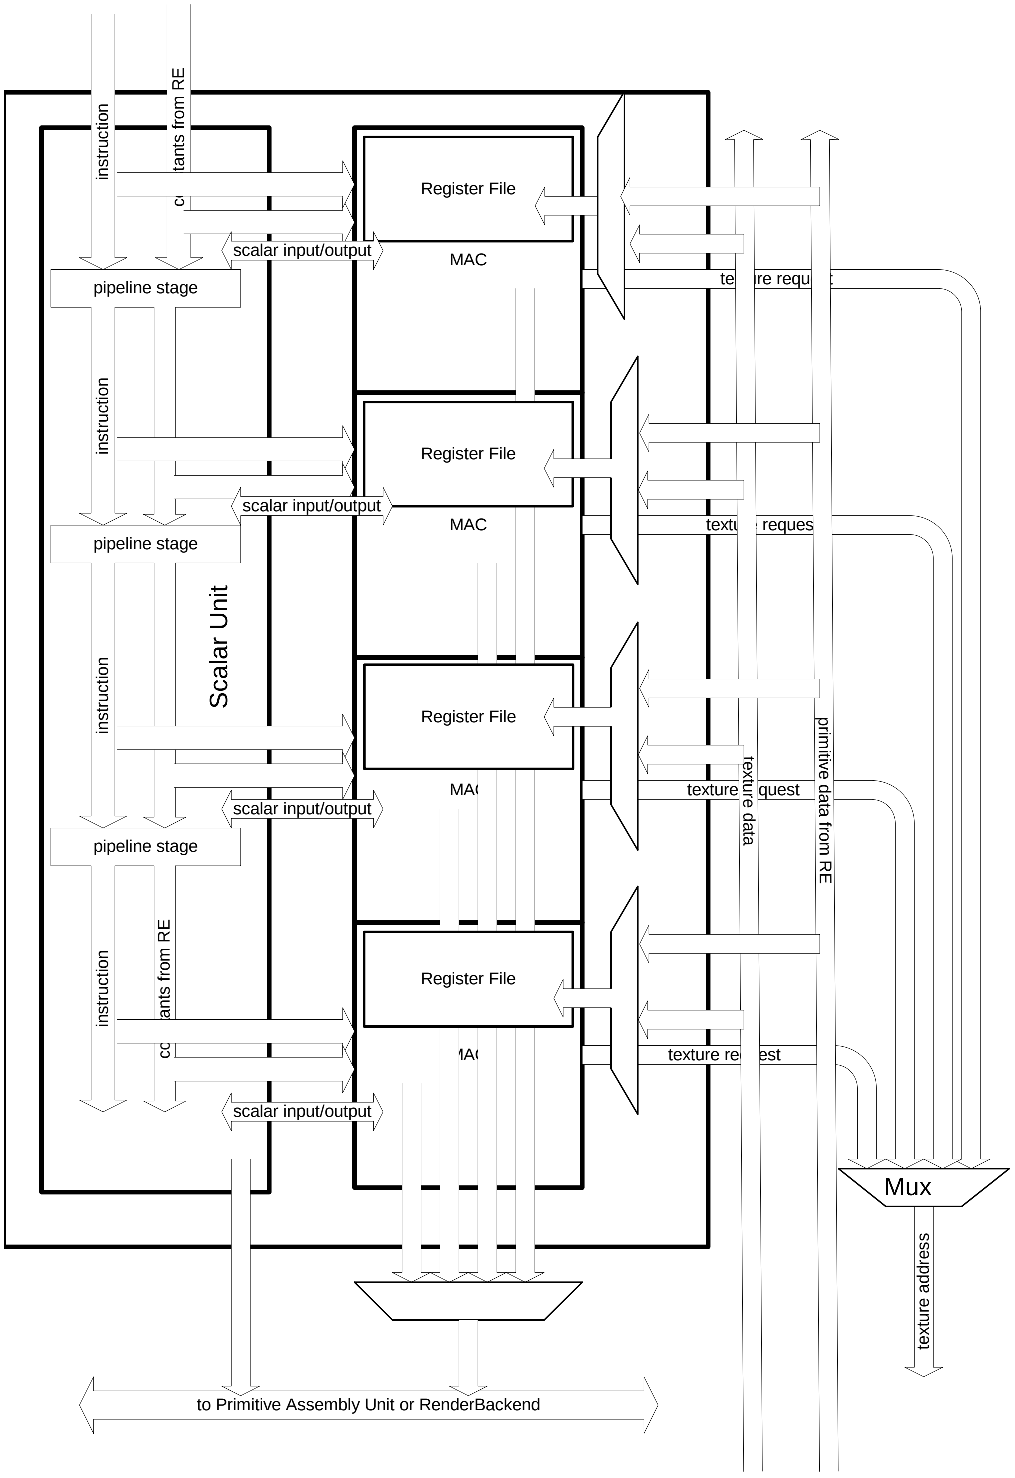

Figure 3: The shader Pipe

The gray area represents blocks that are replicated 4 times per shader pipe (16 times on the overall chip).

1.3 Control Graph

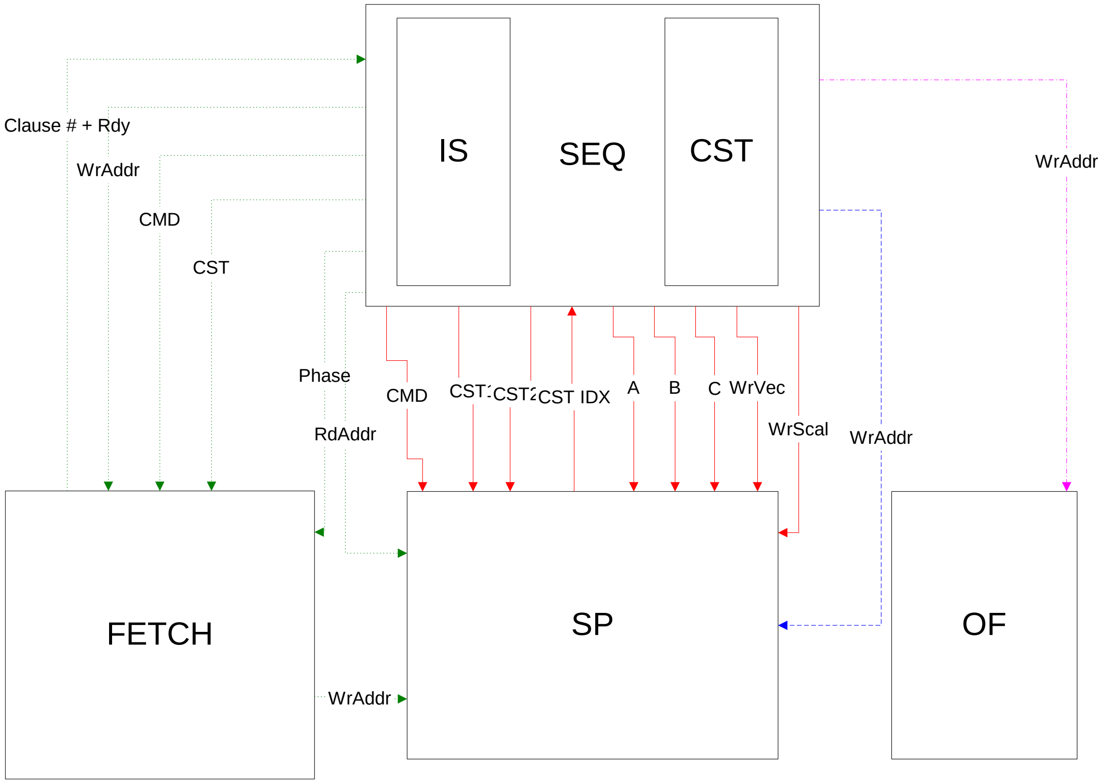

Figure 4: Sequencer Control interfaces

In green is represented the Fetch control interface, in red the ALU control interface, in blue the Interpolated/Vector control interface and in purple is the output file control interface.

2. Interpolated data bus

The interpolators contain an IJ buffer to pack the information as much as possible before writing it to the register file.

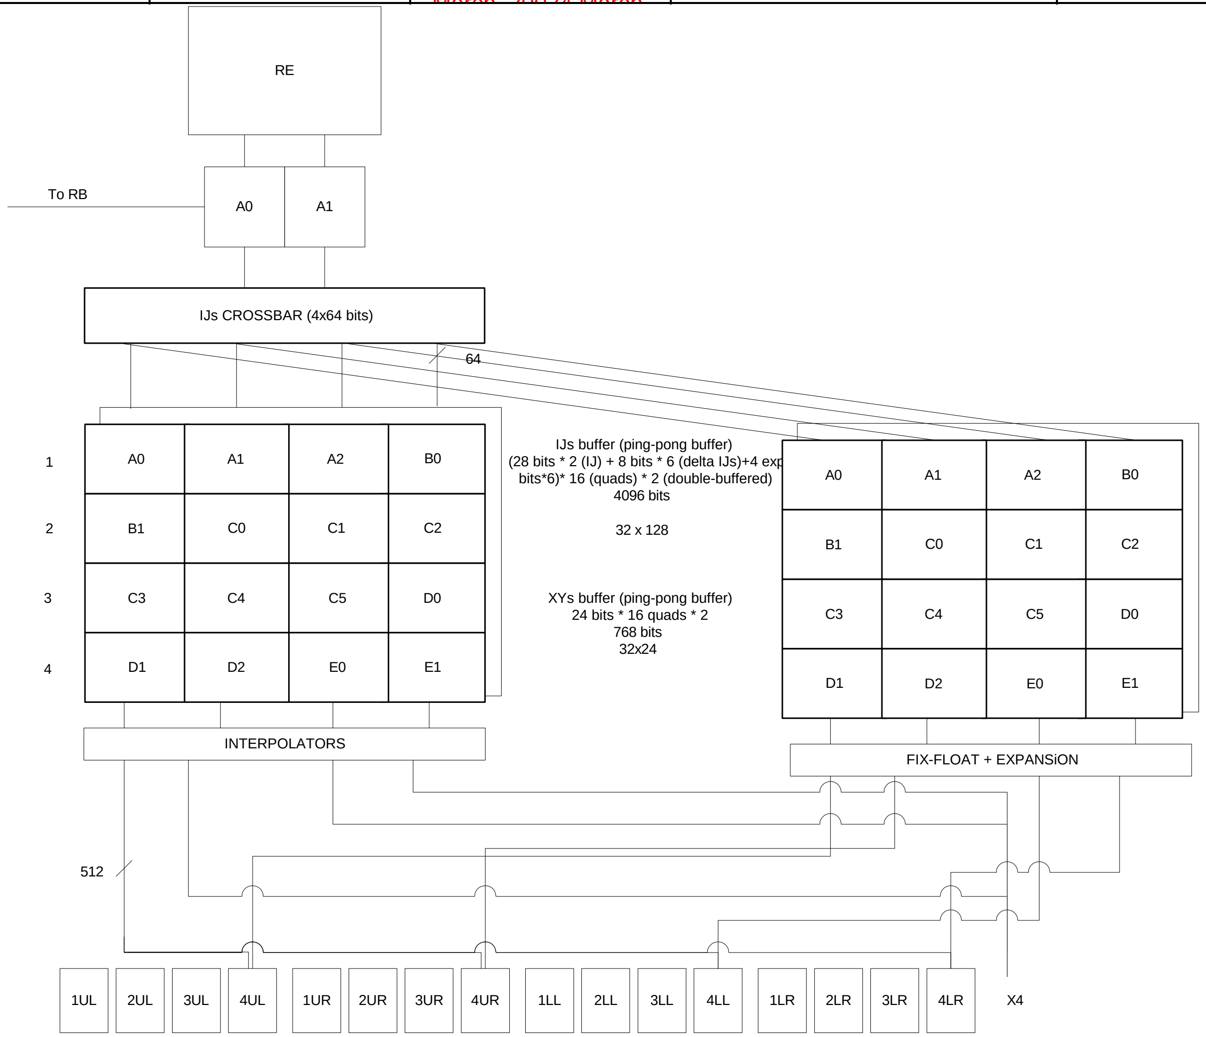

Figure 5: Interpolation buffers

Figure 6: Interpolation timing diagram

Above is an example of a tile the sequencer might receive from the SC. The write side is how the data get stacked into the XY and IJ buffers, the read side is how the data is passed to the GPRs. The IJ information is packed in the IJ buffer 4 quads at a time or two clocks. The sequencer allows at any given time as many as four quads to interpolate a parameter. They all have to come from the same primitive. Then the sequencer controls the write mask to the GPRs to write the valid data in.

{ISSUE : Do we do the center + centroid approach using both IJ buffers?}

3. Instruction Store

There is going to be only one instruction store for the whole chip. It will contain 4096 instructions of 96 bits each.

It is likely to be a 1 port memory; we use 1 clock to load the ALU instruction, 1 clocks to load the Fetch instruction, 1 clock to load 2 control flow instructions and 1 clock to write instructions.

The instruction store is loaded by the CP thru the register mapped registers.

The next picture shows the various modes the CP can load the memory. The Sequencer has to keep track of the loading modes in order to wrap around the correct boundaries. The wrap-around points are arbitrary and they are specified in the VS_BASE and PIX_BASE control registers. The VS_BASE and PS_BASE context registers are used to specify for each context where its shader is in the instruction memory.

For the Real time commands the story is quite the same but for some small differences. There are no wrap-around points for real time so the driver must be careful not to overwrite regular shader data. The shared code (shared subroutines) uses the same path as real time.

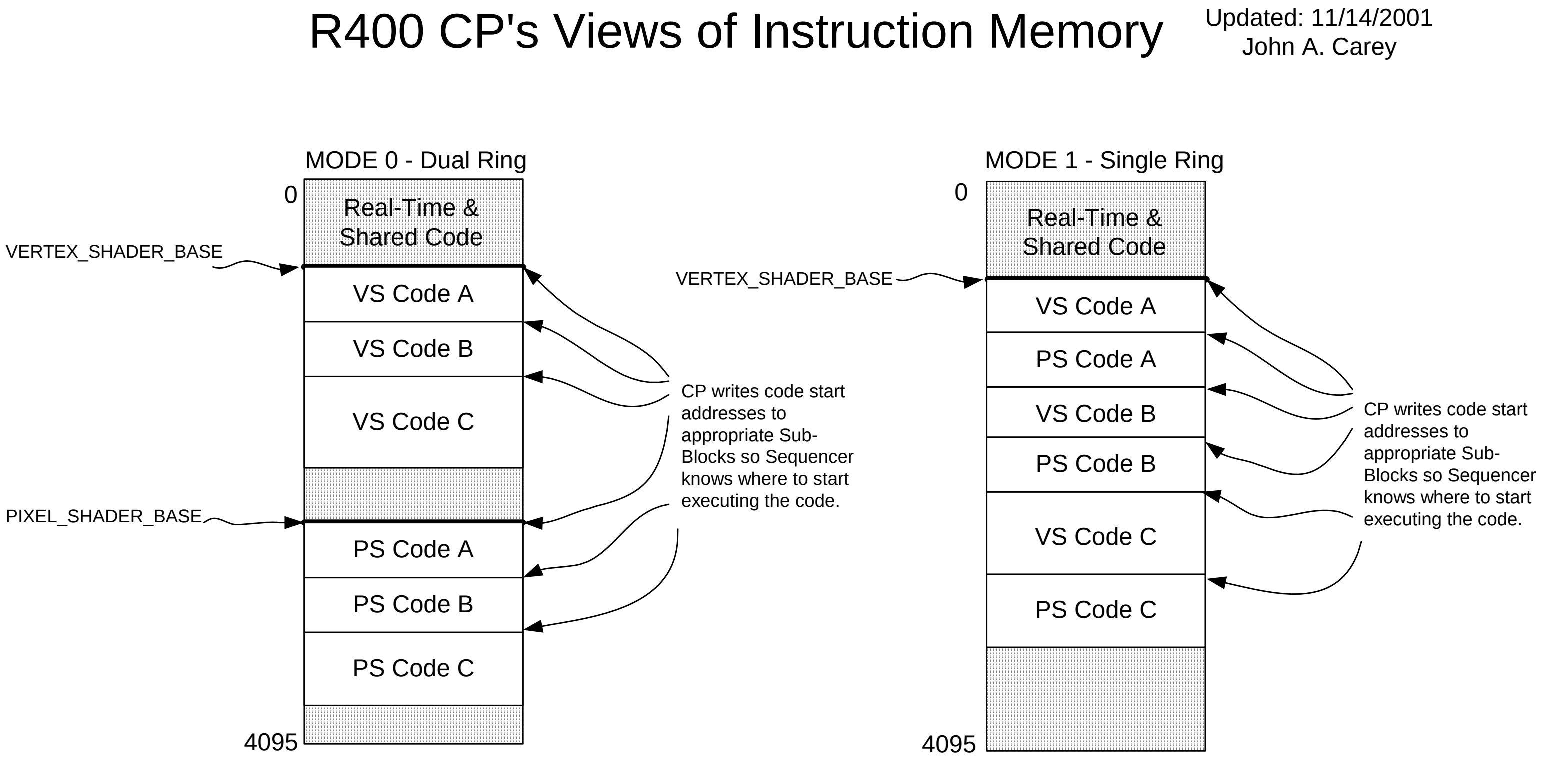

Figure 7: The CP's view of the instruction memory

4. Sequencer Instructions

All control flow instructions and move instructions are handled by the sequencer only. The ALUs will perform NOPs during this time (MOV PV,PV, PS,PS) if they have nothing else to do.

5. Constant Stores

5.1 Memory organizations

A likely size for the ALU constant store is 1024x128 bits. The read BW from the ALU constant store is 128 bits/clock and the write bandwidth is 32 bits/clock (directed by the CP bus size not by memory ports).

The maximum logical size of the constant store for a given shader is 256 constants. Or 512 for the pixel/vertex shader pair. The size of the re-mapping table is 128 lines (each line addresses 4 constants). The write granularity is 4 constants or 512 bits. It takes 16 clocks to write the four constants. Real time requires 256 lines in the physical memory (this is physically register mapped).

The texture state is also kept in a similar memory. The size of this memory is ~~128x192~~ 320x96 bits (128 texture states for regular mode, 32 states for RT). The memory thus holds 128 texture states (192 bits per state). The logical size exposes 32 different states total, which are going to be shared between the pixel and the vertex shader. The size of the re-mapping table to for the texture state memory is 32 lines (each line addresses 1 texture state lines in the real memory). The CP write granularity is 1 texture state lines (or 192 bits). The driver sends 512 bits but the CP ignores the top 320 bits. It thus takes 6 clocks to write the texture state. Real time requires 32 lines in the physical memory (this is physically register mapped).

The control flow constant memory doesn't sit behind a renaming table. It is register mapped and thus the driver must reload its content each time there is a change in the control flow constants. Its size is 320*32 because it must hold 8 copies of the 32 dwords of control flow constants and the loop construct constants must be aligned.

The constant re-mapping tables for texture state and ALU constants are logically register mapped for regular mode and physically register mapped for RT operation.

5.2 Management of the Control Flow Constants

The control flow constants are register mapped, thus the CP writes to the according register to set the constant, the SQ decodes the address and writes to the block pointed by its current base pointer (CF_WR_BASE). On the read side, one level of indirection is used. A register (SQ_CONTEXT_MISC.CF_RD_BASE) keeps the current base pointer to the control flow block. This register is copied whenever there is a state change. Should the CP write to CF after the state change, the base register is updated with the (current pointer number +1)% number of states. This way, if the CP doesn't write to CF the state is going to use the previous CF constants.

5.3 Management of the re-mapping tables

5.3.1 *R400 Constant management*

The sequencer is responsible to manage two re-mapping tables (one for the constant store and one for the texture state). On a state change (by the driver), the sequencer will broadside copy the contents of its re-mapping tables to a new one. We have 8 different re-mapping tables we can use concurrently.

The constant memory update will be incremental, the driver only need to update the constants that actually changed between the two state changes.

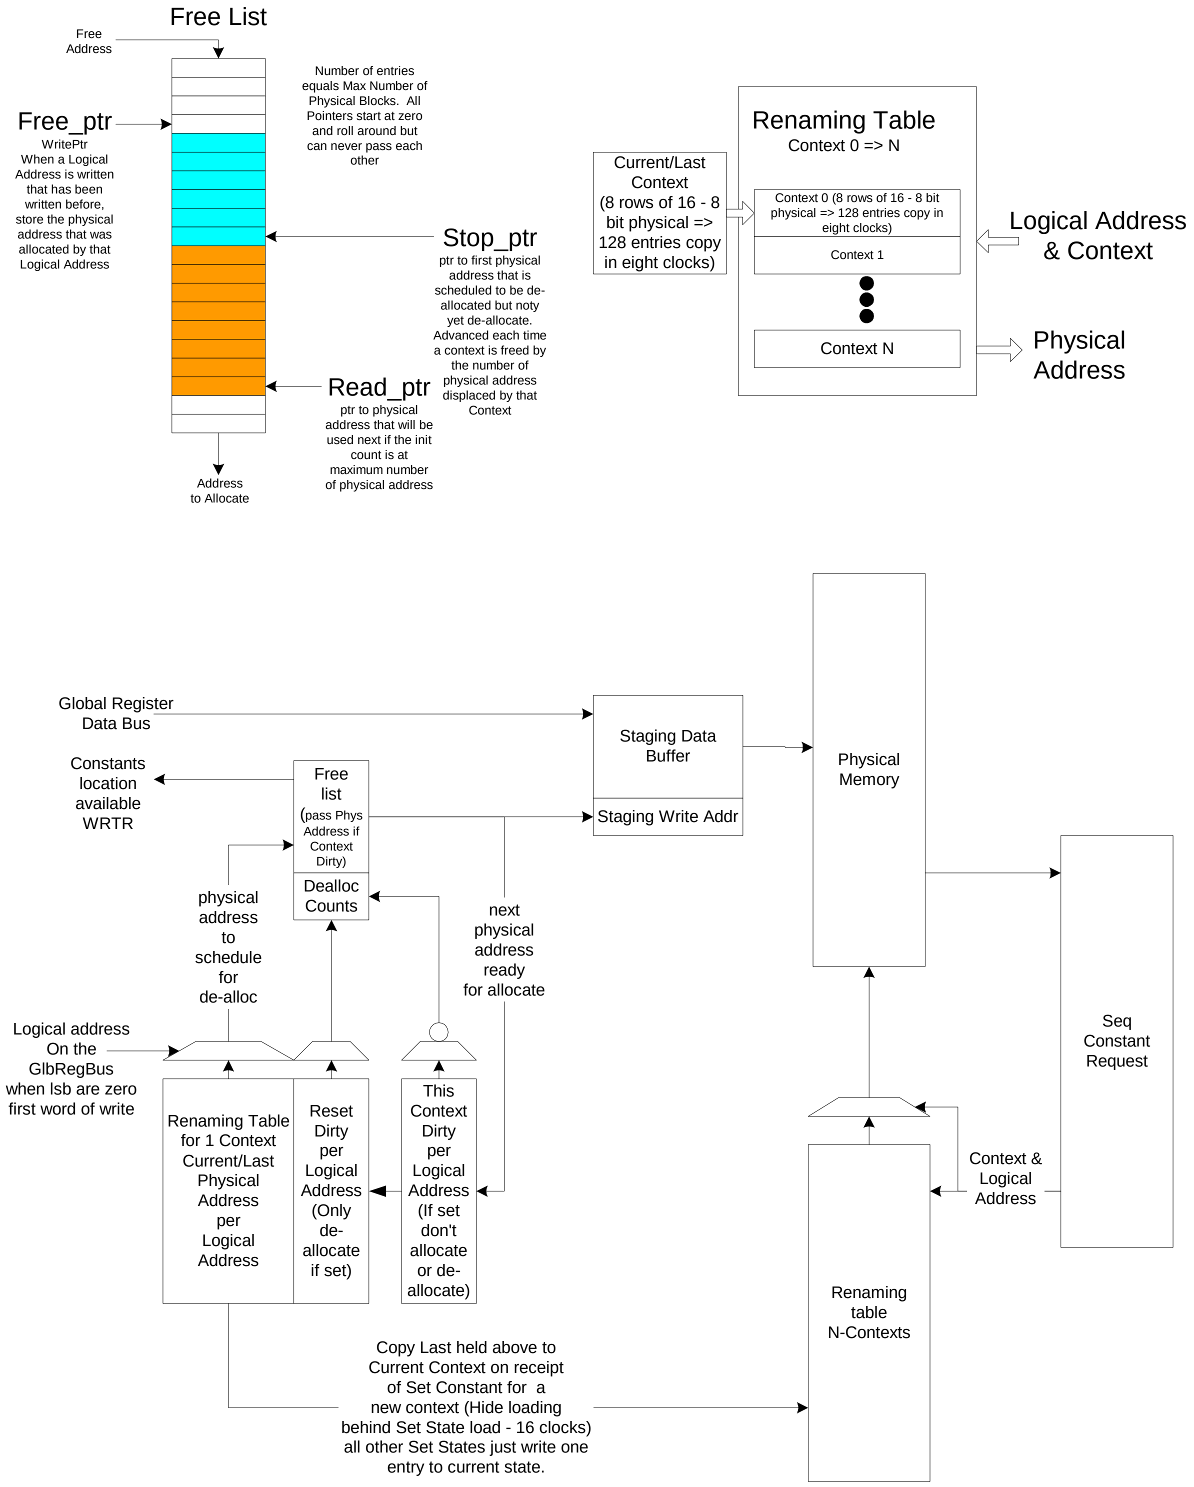
For this model to work in its simplest form, the requirement is that the physical memory MUST be at least twice as large as the logical address space + the space allocated for Real Time. In our case, since the logical address space

is 512 and the reserved RT space can be up to 256 entries, the memory must be of sizes 1280 and above. Similarly the size of the texture store must be of 32*2+32 = 96 entries and above.

5.3.2 *Proposal for R400LE constant management*

To make this scheme work with only 512+256 = 768 entries, upon reception of a CONTROL packet of state + 1, the sequencer would check for SQ_IDLE and PA_IDLE and if both are idle will erase the content of state to replace it with the new state (this is depicted in Figure 9: De-allocation mechanism~~Figure 9: De-allocation mechanism~~~~Figure 9: De-allocation mechanism~~). Note that in the case a state is cleared a value of 0 is written to the corresponding de-allocation counter location so that when the SQ is going to report a state change, nothing will be de-allocated upon the first report.

The second path sets all context dirty bits that were used in the current state to 1 (thus allowing the new state to reuse these physical addresses if needed).



Free List
Free Address
Free_ptr
WritePtr
When a Logical Address is written that has been written before, store the physical address that was allocated by that Logical Address
Number of entries equals Max Number of Physical Blocks. All Pointers start at zero and roll around but can never pass each other
Stop_ptr
ptr to first physical address that is scheduled to be de-allocated but noty yet de-allocate. Advanced each time a context is freed by the number of physical address displaced by that Context
Read_ptr
ptr to physical address that will be used next if the init count is at maximum number of physical address
Address to Allocate

Copy Last held above to Current Context on receipt of Set Constant for a new context (Hide loading behind Set State load - 16 clocks) all other Set States just write one entry to current state.

Figure 8: Constant management

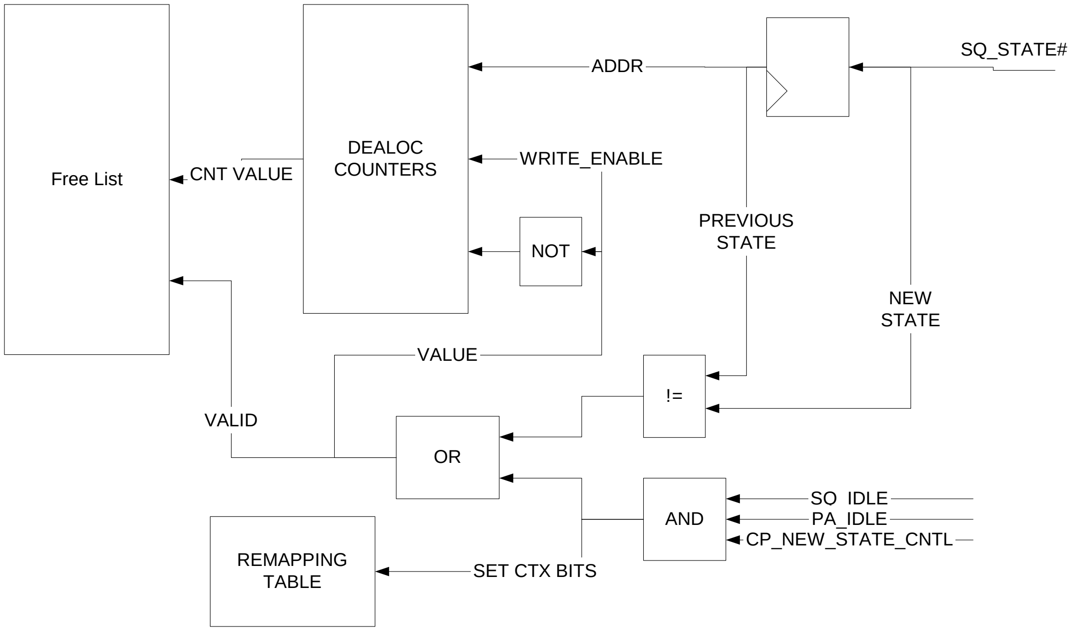

Figure 9: De-allocation mechanism for R400LE

5.3.3 *Dirty bits*

Two sets of dirty bits will be maintained per logical address. The first one will be set to zero on reset and set when the logical address is addressed. The second one will be set to zero whenever a new context is written and set for each address written while in this context. The reset dirty is not set, then writing to that logical address will not require de-allocation of whatever address stored in the renaming table. If it is set and the context dirty is not set, then the physical address store needs to be de-allocated and a new physical address is necessary to store the incoming data. If they are both set, then the data will be written into the physical address held in the renaming for the current logical address. No de-allocation or allocation takes place. This will happen when the driver does a set constant twice to the same logical address between context changes. NOTE: It is important to detect and prevent this, failure to do it will allow multiple writes to allocate all physical memory and thus hang because a context will not fit for rendering to start and thus free up space.

5.3.4 *Free List Block*

A free list block that would consist of a counter (called the IFC or Initial Free Counter) that would reset to zero and incremented every time a chunk of physical memory is used until they have all been used once. This counter would be checked each time a physical block is needed, and if the original ones have not been used up, us a new one, else check the free list for an available physical block address. The count is the physical address for when getting a chunk from the counter.

Storage of a free list big enough to store all physical block addresses.

Maintain three pointers for the free list that are reset to zero. The first one we will call write_ptr. This pointer will identify the next location to write the physical address of a block to be de-allocated. Note: we can never free more physical memory locations than we have. Once recording address the pointer will be incremented to walk the free list like a ring.

The second pointer will be called stop_ptr. The stop_ptr pointer will be advanced by the number of address chunks de-allocates when a context finishes. The address between the stop_ptr and write_ptr cannot be reused because they are still in use. But as soon as the context using then is dismissed the stop_ptr will be advanced.

The third pointer will be called read_ptr. This pointer will point will point to the next address that can be used for allocation as long as the read_ptr does not equal the stop_ptr and the IFC is at its maximum count.

5.3.5 *De-allocate Block*

This block will maintain a free physical address block count for each context. While in current context, a count shall be maintained specifying how many blocks were written into the free list at the write_ptr pointer. This count will be reset upon reset or when this context is active on the back and different than the previous context. It is actually a count of blocks in the previous context that will no longer be used. This count will be used to advance the write_ptr pointer to make available the set of physical blocks freed when the previous context was done. This allows the discard or de-allocation of any number of blocks in one clock.

5.3.6 *Operation of Incremental model*

The basic operation of the model would start with the write_ptr, stop_ptr, read_ptr pointers in the free list set to zero and the free list counter is set to zero. Also all the dirty bits and the previous context will be initialized to zero. When the first set constants happen, the reset dirty bit will not be set, so we will allocate a physical location from the free list counter because its not at the max value. The data will be written into physical address zero. Both the additional copy of the renaming table and the context zeros of the big renaming table will be updated for the logical address that was written by set start with physical address of 0. This process will be repeated for any logical address that are not dirty until the context changes. If a logical address is hit that has its dirty bits set while in the same context, both dirty bits would be set, so the new data will be over-written to the last physical address assigned for this logical address. When the first draw command of the context is detected, the previous context stored in the additional renaming table will be copied to the larger renaming table in the current (new) context location. Then the set constant logical address with be loaded with a new physical address during the copy and if the reset dirty was set, the physical address it replaced in the renaming table would be entered at the write_ptr pointer location on the free list and the write_ptr will be incremented. The de-allocation counter for the previous context (eight) will be incremented. This as set states come in for this context one of the following will happen:

1.) No dirty bits are set for the logical address being updated. A line will be allocated of the free-list counter or the free list at read_ptr pointer if read_ptr != to stop_ptr .
2.) Reset dirty set and Context dirty not set. A new physical address is allocated, the physical address in the renaming table is put on the free list at write_ptr and it is incremented along with the de-allocate counter for the last context.
3.) Context dirty is set then the data will be written into the physical address specified by the logical address.

This process will continue as long as set states arrive. This block will provide backpressure to the CP whenever he has not free list entries available (counter at max and stop_ptr == read_ptr). The command stream will keep a count of contexts of constants in use and prevent more than max constants contexts from being sent.

Whenever a draw packet arrives, the content of the re-mapping table is written to the correct re-mapping table for the context number. Also if the next context uses less constants than the current one all exceeding lines are moved to the free list to be de-allocated later. This happens in parallel with the writing of the re-mapping table to the correct memory.

Now preferable when the constant context leaves the last ALU clause it will be sent to this block and compared with the previous context that left. (Init to zero) If they differ than the older context will no longer be referenced and thus can be de-allocated in the physical memory. This is accomplished by adding the number of blocks freed this context to the stop_ptr pointer. This will make all the physical addresses used by this context available to the read_ptr allocate pointer for future allocation.

This device allows representation of multiple contexts of constants data with N copies of the logical address space. It also allows the second context to be represented as the first set plus some new additional data by just storing the delta's. It allows memory to be efficiently used and when the constants updates are small it can store multiple context. However, if the updates are large, less contexts will be stored and potentially performance will be degraded. Although it will still perform as well as a ring could in this case.

5.4 Constant Store Indexing

In order to do constant store indexing, the sequencer must be loaded first with the indexes (that come from the GPRs). There are 144 wires from the exit of the SP to the sequencer (9 bits pointers x 16 vertexes/clock). Since the data must pass thru the Shader pipe for the float to fixed conversion, there is a latency of 4 clocks (1 instruction)

between the time the sequencer is loaded and the time one can index into the constant store. The assembly will look like this

```
MOVA  R1.X,R2.X        // Loads the sequencer with the content of R2.X, also copies the content of R2.X into R1.X
NOP                    // latency of the float to fixed conversion
ADD   R3,R4,C0[R2.X]// Uses the state from the sequencer to add R4 to C0[R2.X] into R3
```

Note that we don’t really care about what is in the brackets because we use the state from the MOVA instruction. R2.X is just written again for the sake of simplicity and coherency.

The storage needed in the sequencer in order to support this feature is 2*64*9 bits = 1152 bits.

5.5 Real Time Commands

The real time commands constants are written by the CP using the register mapped registers allocated for RT. It works is the same way than when dealing with regular constant loads BUT in this case the CP is not sending a logical address but rather a physical address and the reads are not passing thru the re-mapping table but are directly read from the memory. The boundary between the two zones is defined by the CONST_EO_RT control register. Similarly, for the fetch state, the boundary between the two zones is defined by the TSTATE_EO_RT control register.

5.6 Constant Waterfalling

In order to have a reasonable performance in the case of constant store indexing using the address register, we are going to have the possibility of using the physical memory port for read only. This way we can read 1 constant per clock and thus have a worst-case waterfall mode of 1 vertex per clock. There is a small synchronization issue related with this as we need for the SQ to make sure that the constants where actually written to memory (not only sent to the sequencer) before it can allow the first vector of pixels or vertices of the state to go thru the ALUs. To do so, the sequencer keeps 8 bits (one per render state) and sets the bits whenever the last render state is written to memory and clears the bit whenever a state is freed.

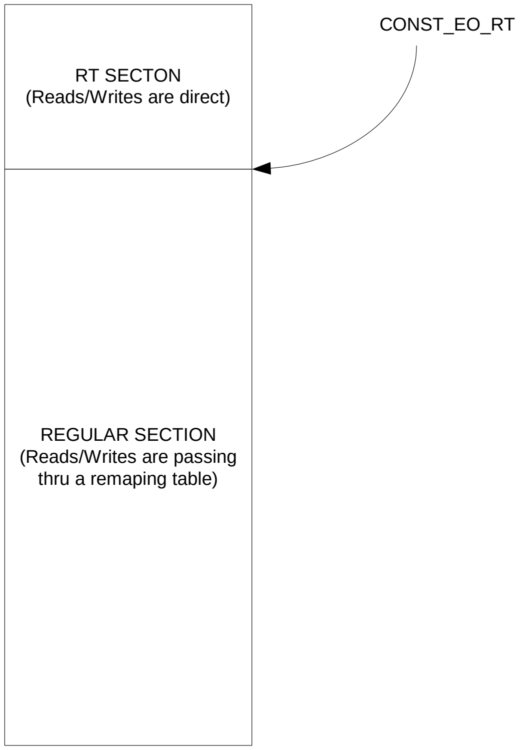

Figure 10: The instruction store

6. Looping and Branches

Loops and branches are planned to be supported and will have to be dealt with at the sequencer level. We plan on supporting constant loops and branches using a control program.

6.1 The controlling state.

The R400 controling state consists of:

Boolean[256:0]
Loop_count[7:0][31:0]
Loop_Start[7:0][31:0]
Loop_Step[7:0][31:0]

That is 256 Booleans and 32 loops.

We have a stack of 4 elements for nested calls of subroutines and 4 loop counters to allow for nested loops.

This state is available on a per shader program basis.

6.2 The Control Flow Program

Examples of control flow programs are located in the R400 programming guide document.

The basic model is as follows:

The render state defined the clause boundaries:

Vertex_shader_fetch[7:0][7:0]	// eight 8 bit pointers to the location where each clauses control program is located
Vertex_shader_alu[7:0][7:0]	// eight 8 bit pointers to the location where each clauses control program is located
Pixel_shader_fetch[7:0][7:0]	// eight 8 bit pointers to the location where each clauses control program is located
Pixel_shader_alu[7:0][7:0]	// eight 8 bit pointers to the location where each clauses control program is located

A pointer value of FF means that the clause doesn't contain any instructions.

The control program for a given clause is executed to completion before moving to another clause, (with the exception of the pick two nature of the alu execution). The control program is the only program aware of the clause boundaries.

The control program has nine basic instructions:

Execute
Conditional_execute
Conditional_Execute_Predicates
Conditional_jump
Conditionnal_Call
Return
Loop_start
Loop_end
NOP

Execute, causes the specified number of instructions in instruction store to be executed.
Conditional_execute checks a condition first, and if true, causes the specified number of instructions in instruction store to be executed.
Loop_start resets the corresponding loop counter to the start value on the first pass after it checks for the end condition and if met jumps over to a specified address.
Loop_end increments (decrements?) the loop counter and jumps back the specified number of instructions.
Conditionnal_Call jumps to an address and pushes the IP counter on the stack if the condition is met. On the return instruction, the IP is popped from the stack.

Conditional_execute_Predicates executes a block of instructions if all bits in the predicate vectors meet the condition.
Conditional_jumps jumps to an address if the condition is met.
NOP is a regular NOP

NOTE THAT ALL JUMPS MUST JUMP TO EVEN CFP ADDRESSES since there are two control flow instructions per memory line. Thus the compiler must insert NOPs where needed to align the jumps on even CFP addresses.

Also if the jump is logically bigger than pshader_cntl_size (or vshader_cntl_size) we break the program (clause) and set the debug registers. If an execute or conditional_execute is lower than cntl_size or bigger than size we also break the program (clause) and set the debug registers.

We have to fit instructions into 48 bits in order to be able to put two control flow instruction per line in the instruction store.

A value of 1 in the Addressing means that the address specified in the Exec Address field (or in the jump address field) is an ABSOLUTE address. If the addressing field is cleared (should be the default) then the address is relative to the base of the current shader program.

Note that whenever a field is marked as RESERVED, it is assumed that all the bits of the field are cleared (0).

Execute					
47	46… 42	41	40 … 24	23 … 12	11 … 0
Addressing	00001	Last	RESERVED	Instruction count	Exec Address

Execute up to 4k instructions at the specified address in the instruction memory. If Last is set, this is the last group of instructions of the clause.

NOP			
47	46 … 42	41	40 … 0
Addressing	00010	Last	RESERVED

This is a regular NOP. If Last is set, this is the last instruction of the clause.

Conditional_Execute								
47	46 … 42	41	40	~~40~~ 39 … ~~33~~32	~~32~~31	~~31~~ 30 … 24	23 … 12	11 … 0
Addressing	00011	Last	RESERVED	Boolean address	Condition	RESERVED	Instruction count	Exec Address

If the specified Boolean (8 bits can address 256 Booleans) meets the specified condition then execute the specified instructions (up to 4k instructions). If Last is set, then if the condition is met, this is the last group of instructions to be executed in the clause. If the condition is not met, we go on to the next control flow instruction.

Conditional_Execute_Predicates								
47	46 … 42	41	~~40~~ 40 … ~~35~~34	~~34~~ 33 … ~~33~~32	~~32~~31	~~31~~ 30 … 24	23 … 12	11 … 0
Addressing	00100	Last	RESERVED	Predicate vector	Condition	RESERVED	Instruction count	Exec Address

Check the AND/OR of all current predicate bits. If AND/OR matches the condition execute the specified number of instructions. We need to AND/OR this with the kill mask in order not to consider the pixels that aren't valid. If Last is set, then if the condition is met, this is the last group of instructions to be executed in the clause. If the condition is not met, we go on to the next control flow instruction.

Loop_Start				
47	46 … 42	41 … 17	16 … 12	11 … 0

Addressing	00101	RESERVED	loop ID	Jump address

Loop Start. Compares the loop iterator with the end value. If loop condition not met jump to the address. Forward jump only. Also computes the index value. The loop id must match between the start to end, and also indicates which control flow constants should be used with the loop.

Loop_End				
47	46 … 42	41 … 17	16 … 12	11 … 0
Addressing	00110	RESERVED	loop ID	start address

Loop end. Increments the counter by one, compares the loop count with the end value. If loop condition met, continue, else, jump BACK to the start of the loop.

The way this is described does not prevent nested loops, and the inclusion of the loop id make this easy to do.

Conditionnal_Call						
47	46 … 42	41 … ~~35~~34	~~34~~ 33 … ~~33~~32	31~~2~~	~~31~~ 30 … 12	11 … 0
Addressing	00111	RESERVED	Predicate vector	Condition	RESERVED	Jump address

If the condition is met, jumps to the specified address and pushes the control flow program counter on the stack.

Return		
47	46 … 42	41 … 0
Addressing	01000	RESERVED

Pops the topmost address from the stack and jumps to that address. If nothing is on the stack, the program will just continue to the next instruction.

Conditionnal_Jump							
47	46 … 42	41 … 40~~1~~	~~40~~ 39 … ~~33~~32	~~32~~31	~~31~~30	~~30~~ 29 … 12	11 … 0
Addressing	01001	RESERVED	Boolean address	Condition	FW only	RESERVED	Jump address

If condition met, jumps to the address. FORWARD jump only allowed if bit 31 set. Bit 31 is only an optimization for the compiler and should NOT be exposed to the API.

To prevent infinite loops, we will keep 9 bits loop iterators instead of 8 (we are only able to loop 256 times). If the counter goes higher than 255 then the loop_end or the loop_start instruction is going to break the loop and set the debug GPRs.

6.3 Data dependant predicate instructions

Data dependant conditionals will be supported in the R400. The only way we plan to support those is by supporting three vector/scalar predicate operations of the form:

PRED_SETE_# - similar to SETE except that the result is 'exported' to the sequencer.
PRED_SETNE_# - similar to SETNE except that the result is 'exported' to the sequencer.
PRED_SETGT_# - similar to SETGT except that the result is 'exported' to the sequencer
PRED_SETGTE_# - similar to SETGTE except that the result is 'exported' to the sequencer

For the scalar operations only we will also support the two following instructions:
PRED_SETE0_# – SETE0

PRED_SETE1_# – SETE1

The export is a single bit - 1 or 0 that is sent using the same data path as the MOVA instruction. The sequencer will maintain 4 sets of 64 bit predicate vectors (in fact 8 sets because we interleave two programs but only 4 will be exposed) and use it to control the write masking. This predicate is not maintained across clause boundaries. The # sign is used to specify which predicate set you want to use 0 thru 3.

Then we have two conditional execute bits. The first bit is a conditional execute “on” bit and the second bit tells us if we execute on 1 or 0. For example, the instruction:

P0_ADD_# R0,R1,R2

Is only going to write the result of the ADD into those GPRs whose predicate bit is 0. Alternatively, P1_ADD_# would only write the results to the GPRs whose predicate bit is set. The use of the P0 or P1 without precharging the sequencer with a PRED instruction is undefined.

{Issue: do we have to have a NOP between PRED and the first instruction that uses a predicate?}

6.4 HW Detection of PV,PS

Because of the control program, the compiler cannot detect statically dependant instructions. In the case of non-masked writes and subsequent reads the sequencer will insert uses of PV,PS as needed. This will be done by comparing the read address and the write address of consecutive instructions. For masked writes, the sequencer will insert NOPs wherever there is a dependant read/write.

The sequencer will also have to insert NOPs between PRED_SET and MOVA instructions and their uses.

6.5 Register file indexing

Because we can have loops in fetch clause, we need to be able to index into the register file in order to retrieve the data created in a fetch clause loop and use it into an ALU clause. The instruction will include the base address for register indexing and the instruction will contain these controls:

Bit7	Bit 6	
0	0	'absolute register'
0	1	'relative register'
1	0	'previous vector'
1	1	'previous scalar'

In the case of an absolute register we just take the address as is. In the case of a relative register read we take the base address and we add to it the loop_index and this becomes our new address that we give to the shader pipe.

The sequencer is going to keep a loop index computed as such:

Index = Loop_iterator*Loop_step + Loop_start.

We loop until loop_iterator = loop_count. Loop_step is a signed value [-128…127]. The computed index value is a 10 bit counter that is also signed. Its real range is [-256,256]. The tenth bit is only there so that we can provide an out of range value to the “indexing logic” so that it knows when the provided index is out of range and thus can make the necessary arrangements.

6.6 Predicated Instruction support for Texture clauses

For texture clauses, we support the following optimization: we keep 1 bit (thus 4 bits for the four predicate vectors) per predicate vector in the reservation stations. A value of 1 means that one ore more elements in the vector have a value of one (thus we have to do the texture fetches for the whole vector). A value of 0 means that no elements in the vector have his predicate bit set and we can thus skip over the texture fetch. **We have to make sure the invalid pixels aren’t considered with this optimization.**

6.7 Debugging the Shaders

In order to be able to debug the pixel/vertex shaders efficiently, we provide 2 methods.

6.7.1 *Method 1: Debugging registers*

Current plans are to expose 2 debugging, or error notification, registers:
1. address register where the first error occurred
2. count of the number of errors

The sequencer will detect the following groups of errors:
- count overflow
- constant indexing overflow
- register indexing overflow

Compiler recognizable errors:
- jump errors
    relative jump address > size of the control flow program
- call stack
    call with stack full
    return with stack empty

A jump error will always cause the program to break. In this case, a break means that a clause will halt execution, but allowing further clauses to be executed.

With all the other errors, program can continue to run, potentially to worst-case limits. The program will only break if the DB_PROB_BREAK register is set.

If indexing outside of the constant or the register range, causing an overflow error, the hardware is specified to return the value with an index of 0. This could be exploited to generate error tokens, by reserving and initializing the 0th register (or constant) for errors.

{ISSUE : Interrupt to the driver or not?}

6.7.2 *Method 2: Exporting the values in the GPRs (12)*

The sequencer will have a count register and an address register for this mode and 3 bits per clause specifying the execution mode for each clause. The modes can be :

1) Normal
2) Debug Kill
3) Debug Addr + Count

Under the normal mode execution follows the normal course. Under the kill mode, all control flow instructions are executed but all normal shader instructions of the clause are replaced by NOPs. Only debug_export instructions of clause 7 will be executed under the debug kill setting. Under the other mode, normal execution is done until we reach an address specified by the address register and instruction count (useful for loops) specified by the count register. After we have hit the instruction n times (n=count) we switch the clause to the kill mode.

Under the debug mode (debug kill OR debug Addr + count), it is assumed that clause 7 is always exporting 12 debug vectors and that all other exports to the SX block (position, color, z, ect) will been turned off (changed into NOPs) by the sequencer (even if they occur before the address stated by the ADDR debug register).

7. Pixel Kill Mask

A vector of 64 bits is kept by the sequencer per group of pixels/vertices. Its purpose is to optimize the texture fetch requests and allow the shader pipe to kill pixels using the following instructions:

MASK_SETE
MASK_SETNE
MASK_SETGT

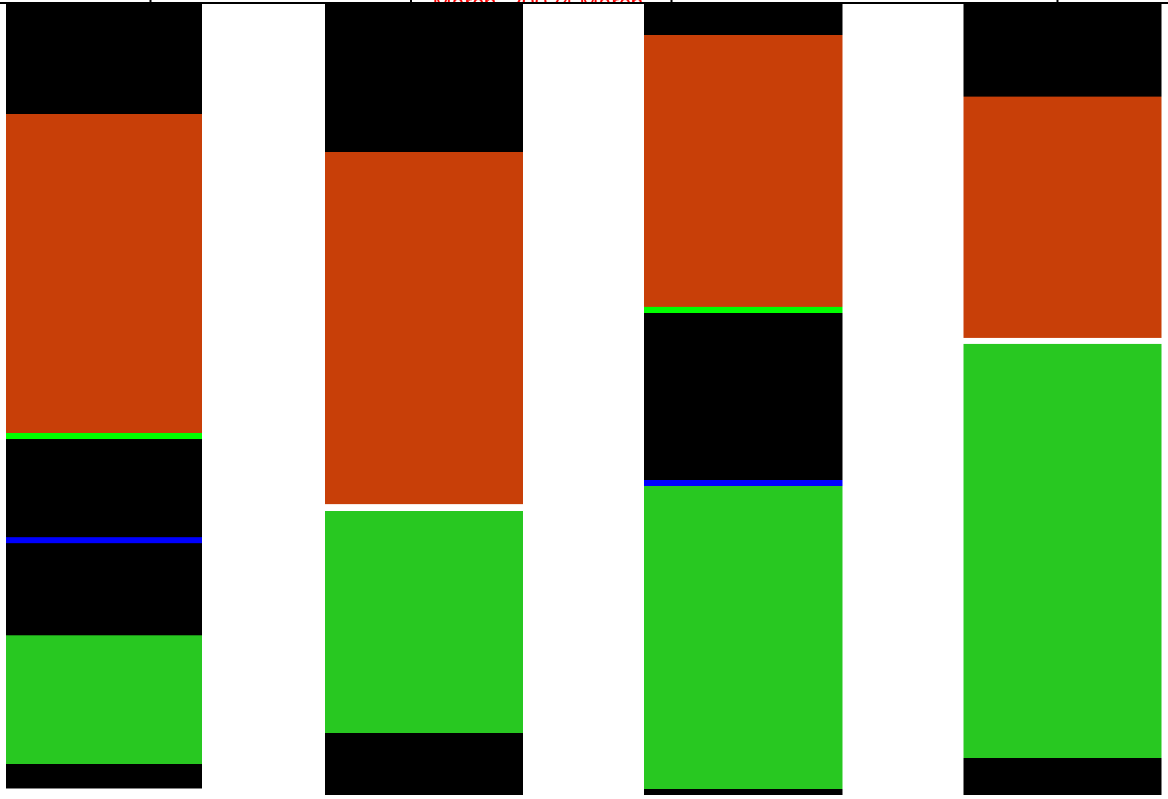
MASK_SETGTE

8. Multipass vertex shaders (HOS)

Multipass vertex shaders are able to export from the 6 last clauses but to memory ONLY.

9. Register file allocation

The register file allocation for vertices and pixels can either be static or dynamic. In both cases, the register file in managed using two round robins (one for pixels and one for vertices). In the dynamic case the boundary between pixels and vertices is allowed to move, in the static case it is fixed to 128-VERTEX_REG_SIZE for vertices and PIXEL_REG_SIZE for pixels.



Above is an example of how the algorithm works. Vertices come in from top to bottom; pixels come in from bottom to top. Vertices are in orange and pixels in green. The blue line is the tail of the vertices and the green line is the tail of the pixels. Thus anything between the two lines is shared. When pixels meets vertices the line turns white and the boundary is static until both vertices and pixels share the same "unallocated bubble". Then the boundary is allowed to move again. The numbering of the GPRs starts from the bottom of the picture at index 0 and goes up to the top at index 127.

10. Fetch Arbitration

The fetch arbitration logic chooses one of the 8 potentially pending fetch clauses to be executed. The choice is made by looking at the fifos from 7 to 0 and picking the first one ready to execute. Once chosen, the clause state machine will send one 2x2 fetch per clock (or 4 fetches in one clock every 4 clocks) until all the fetch instructions of the clause are sent. This means that there cannot be any dependencies between two fetches of the same clause.

The arbitrator will not wait for the fetches to return prior to selecting another clause for execution. The fetch pipe will be able to handle up to X(?) in flight fetches and thus there can be a fair number of active clauses waiting for their fetch return data.

11. ALU Arbitration

ALU arbitration proceeds in almost the same way than fetch arbitration. The ALU arbitration logic chooses one of the 8 potentially pending ALU clauses to be executed. The choice is made by looking at the fifos from 7 to 0 and picking the first one ready to execute. There are two ALU arbiters, one for the even clocks and one for the odd clocks. For example, here is the sequencing of two interleaved ALU clauses (E and O stands for Even and Odd sets of 4 clocks):

Einst0 Oinst0 Einst1 Oinst1 Einst2 Oinst2 Einst0 Oinst3 Einst1 Oinst4 Einst2 Oinst0…
Proceeding this way hides the latency of 8 clocks of the ALUs. Also note that the interleaving also occurs across clause boundaries.

12. Handling Stalls

When the output file is full, the sequencer prevents the ALU arbitration logic from selecting the last clause (this way nothing can exit the shader pipe until there is place in the output file. If the packet is a vertex packet and the position buffer is full (POS_FULL) then the sequencer also prevents a thread from entering the exporting clause (3?). The sequencer will set the OUT_FILE_FULL signal n clocks before the output file is actually full and thus the ALU arbiter will be able read this signal and act accordingly by not preventing exporting clauses to proceed.

13. Content of the reservation station FIFOs

The reservation FIFOs contain the state of the vector of pixels and vertices. We have two sets of those: one for pixels, and one for vertices. They contain 3 bits of Render State 7 bits for the base address of the GPRs, some bits for LOD correction and coverage mask information in order to fetch fetch for only valid pixels, the quad address.

14. The Output File

The output file is where pixels are put before they go to the RBs. The write BW to this store is 256 bits/clock. Just before this output file are staging registers with write BW 512 bits/clock and read BW 256 bits/clock. The staging registers are 4x128 (and there are 16 of those on the whole chip).

15. IJ Format

The IJ information sent by the PA is of this format on a per quad basis:

We have a vector of IJ's (one IJ per pixel at the centroid of the fragment or at the center of the pixel depending on the mode bit). The interpolation is done at a different precision across the 2x2. The upper left pixel's parameters are always interpolated at full 20x24 mantissa precision. Then the result of the interpolation along with the difference in IJ in reduced precision is used to interpolate the parameter for the other three pixels of the 2x2. Here is how we do it:

Assuming P0 is the interpolated parameter at Pixel 0 having the barycentric coordinates I(0), J(0) and so on for P1,P2 and P3. Also assuming that A is the parameter value at V0 (interpolated with I), B is the parameter value at V1 (interpolated with J) and C is the parameter value at V2 (interpolated with (1-I-J).

$$\Delta 01I = I(1) - I(0)$$
$$\Delta 01J = J(1) - J(0)$$
$$\Delta 02I = I(2) - I(0)$$
$$\Delta 02J = J(2) - J(0)$$
$$\Delta 03I = I(3) - I(0)$$
$$\Delta 03J = J(3) - J(0)$$

P0	P1
P2	P3

$$P0 = C + I(0) * (A - C) + J(0) * (B - C)$$
$$P1 = P0 + \Delta 01I * (A - C) + \Delta 01J * (B - C)$$
$$P2 = P0 + \Delta 02I * (A - C) + \Delta 02J * (B - C)$$
$$P3 = P0 + \Delta 03I * (A - C) + \Delta 03J * (B - C)$$

P0 is computed at 20x24 mantissa precision and P1 to P3 are computed at 8X24 mantissa precision. So far no visual degradation of the image was seen using this scheme.

Multiplies (Full Precision): 2
Multiplies (Reduced precision): 6
Subtracts 19x24 (Parameters): 2

Adds: 8

FORMAT OF P0's IJ : Mantissa 20 Exp 4 for I + Sign
Mantissa 20 Exp 4 for J + Sign

FORMAT of Deltas (x3):Mantissa 8 Exp 4 for I + Sign
Mantissa 8 Exp 4 for J + Sign

Total number of bits : 20*2 + 8*6 + 4*8 + 4*2 = 128

All numbers are kept using the un-normalized floating point convention: if exponent is different than 0 the number is normalized if not, then the number is un-normalized. The maximum range for the IJs (Full precision) is +/- 63 and the range for the Deltas is +/- 127.

15.1 Interpolation of constant attributes

Because of the floating point imprecision, we need to take special provisions if all the interpolated terms are the same or if two of the barycentric coordinates are the same.

We start with the premise that if A = B and B = C and C = A, then P0,1,2,3 = A. Since one or more of the IJ terms may be zero, so we extend this to:

```
if (A=B and B=C and C=A)
   P0,1,2,3 = A;
else if ((I = 0) or (J = 0)) and
          ((J = 0) or (1-I-J = 0)) and
          ((1-J-I = 0) or (I = 0))) {
                if(I != 0) {
                    P0 = A;
                } else if(J != 0) {
                    P0 = B;
                } else {
                    P0 = C;
               }
             //rest of the quad interpolated normally
}
else
{
             normal interpolation
}
```

16. Staging Registers

In order for the reuse of the vertices to be 14, the sequencer will have to re-order the data sent IN ORDER by the VGT for it to be aligned with the parameter cache memory arrangement. Given the following group of vertices sent by the VGT:

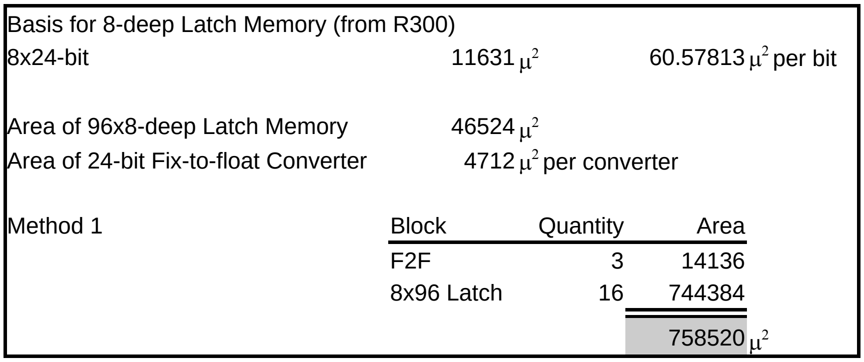
0 1 2 3 4 5 6 7 8 9 10 11 12 13 14 15 || 16 17 18 19 20 21 22 23 24 25 26 27 28 29 30 31 || 32 33 34 35 36 37 38 39 40 41 42 43 44 45 46 47 || 48 49 50 51 52 53 54 55 56 57 58 59 60 61 62 63

The sequencer will re-arrange them in this fashion:

0 1 2 3 16 17 18 19 32 33 34 35 48 49 50 51 || 4 5 6 7 20 21 22 23 36 37 38 39 52 53 54 55 || 8 9 10 11 24 25 26 27 40 41 42 43 56 57 58 59 || 12 13 14 15 28 29 30 31 44 45 46 47 60 61 62 63

The || markers show the SP divisions. In the event a shader pipe is broken, the VGT will send padding to account for the missing pipe. For example, if SP1 is broken, vertices 4 5 6 7 20 21 22 23 36 37 38 39 52 53 54 55 will still be sent by the VGT to the SQ **BUT** will not be processed by the SP and thus should be considered invalid (by the SU and VGT).

The most straightforward, *non-compressed* interface method would be to convert, in the VGT, the data to 32-bit floating point prior to transmission to the VSISRs. In this scenario, the data would be transmitted to (and stored in) the VSISRs in full 32-bit floating point. This method requires three 24-bit fixed-to-float converters in the VGT. Unfortunately, it also requires and additional 3,072 bits of storage across the VSISRs. This interface is illustrated in Figure 12~~Figure 12~~~~Figure 12~~. The area of the fixed-to-float converters and the VSISRs for this method is roughly estimated as 0.759sqmm using the R300 process. The gate count estimate is shown in Figure 11~~Figure 11~~~~Figure 11~~.



Basis for 8-deep Latch Memory (from R300)				
8x24-bit	11631 μ^2		60.57813 μ^2 per bit	
Area of 96x8-deep Latch Memory	46524 μ^2			
Area of 24-bit Fix-to-float Converter	4712 μ^2 per converter			
Method 1	Block	Quantity	Area	
	F2F	3	14136	
	8x96 Latch	16	744384	
			758520	μ^2

Figure 11:Area Estimate for VGT to Shader Interface

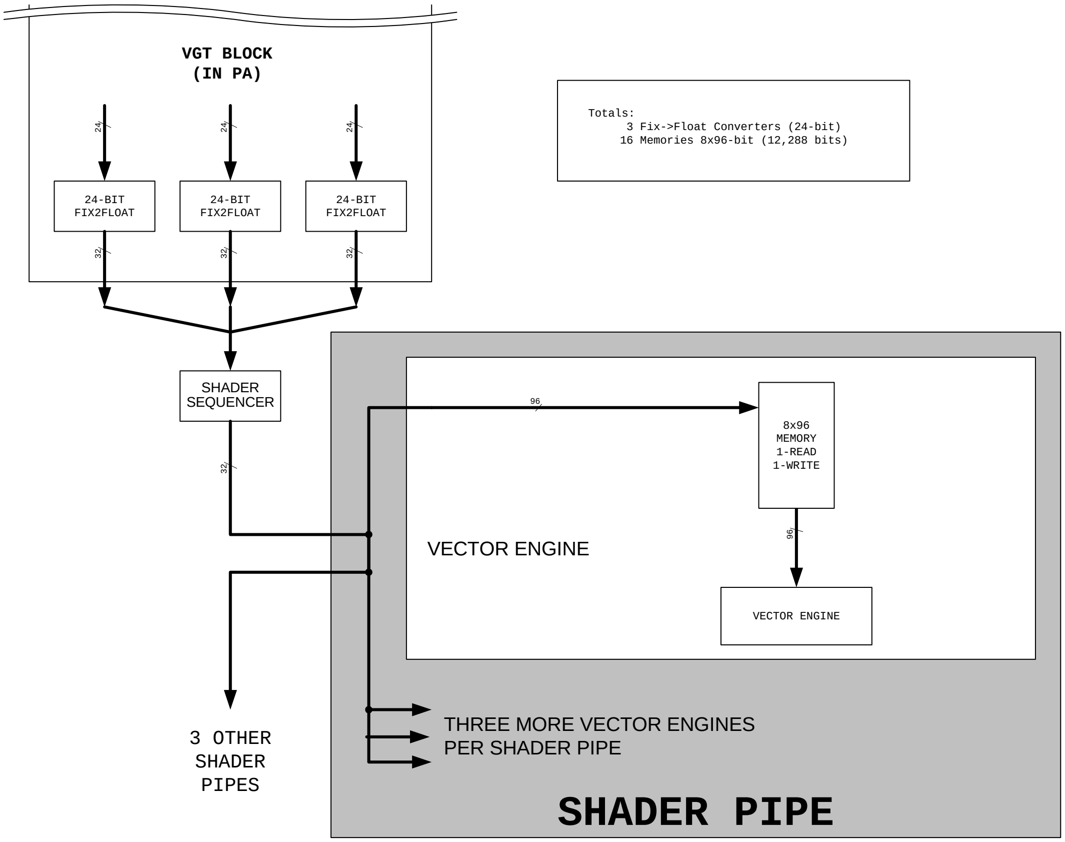


Figure 12:VGT to Shader Interface

17. The parameter cache

The parameter cache is where the vertex shaders export their data. It consists of 16 128x128 memories (1R/1W). The reuse engine will make it so that all vertexes of a given primitive will hit different memories. The allocation method for these memories is a simple round robin. The parameter cache pointers are mapped in the following way: 4MSBs are the memory number and the 7 LSBs are the address within this memory.

MEMORY NUMBER 4 bits	ADDRESS 7 bits

The PA generates the parameter cache addresses as the positions come from the SQ. All it needs to do is keep a Current_Location pointer (7 bits only) and as the positions comes increment the memory number. When the memory number field wraps around, the PA increments the Current_Location by VS_EXPORT_COUNT_7 (a snooped register from the SQ). As an example, say the memories are all empty to begin with and the vertex shader is exporting 8 parameters per vertex (VS_EXPORT_COUNT_7 = 8). The first position received is going to have the PC address 00000000000 the second one 00010000000, third one 00100000000 and so on up to 11110000000. Then the next position received (the 17th) is going to have the address 00000001000, the 18th 00010001000, the 19th 00100001000 and so on. The Current_location is NEVER reset BUT on chip resets. The only thing to be careful about is that if the SX doesn't send you a full group of positions (<64) then you need to fill the address space so that the next group starts correctly aligned (for example if you receive only 33 positions then you need to add 2*VS_EXPORT_COUNT_7to Current_Location and reset the memory count to 0 before the next vector begins).

18. Vertex position exporting

On clause 3 the vertex shader can export to the PA both the vertex position and the point sprite. It can also do so at clause 7 if not done at clause 3. The storage needed to perform the position export is at least 64x128 memories for the position and 64x32 memories for the sprite size. It is going to be taken in the pixel output fifo from the SX blocks. The clause where the position export occurs is specified by the EXPORT_LATE register. If turned on, it means that the export is going to occur at ALU clause 7 if unset position export occurs at clause 3.

19. Exporting Arbitration

Here are the rules for co-issuing exporting ALU clauses.

1) Position exports and position exports cannot be co-issued.

All other types of exports can be co-issued as long as there is place in the receiving buffer.

{ISSUE: Do we move the parameter caches to the SX?}

20. Export Types

The export type (or the location where the data should be put) is specified using the destination address field in the ALU instruction. Here is a list of all possible export modes:

20.1 Vertex Shading

0:15	- 16 parameter cache
16:31	- Empty (Reserved?)
32:43	- 12 vertex exports to the frame buffer and index
44:47	- Empty
48:59	- 12 debug export (interpret as normal vertex export)
60	- export addressing mode
61	- Empty
62	- position
63	- sprite size export that goes with position export (point_h,point_w,edgeflag,misc)

20.2 Pixel Shading

0	- Color for buffer 0 (primary)
1	- Color for buffer 1
2	- Color for buffer 2
3	- Color for buffer 3
4:7	- Empty
8	- Buffer 0 Color/Fog (primary)
9	- Buffer 1 Color/Fog
10	- Buffer 2 Color/Fog
11	- Buffer 3 Color/Fog
12:15	- Empty
16:31	- Empty (Reserved?)
32:43	- 12 exports for multipass pixel shaders.
44:47	- Empty
48:59	- 12 debug exports (interpret as normal pixel export)
60	- export addressing mode
61:62	- Empty
63	- Z for primary buffer (Z exported to 'alpha' component)

21. Special Interpolation modes

21.1 Real time commands

We are unable to use the parameter memory since there is no way for a command stream to write into it. Instead we need to add three 16x128 memories (one for each of three vertices x 16 interpolants). These will be mapped onto the register bus and written by type 0 packets, and output to the the parameter busses (the sequencer and/or PA need to be able to address the reatime parameter memory as well as the regular parameter store. For higher performance we should be able able to view them as two banks of 16 and do double buffering allowing one to be loaded, while the other is rasterized with. Most overlay shaders will need 2 or 4 scalar coordinates, one option might be to restrict the memory to 16x64 or 32x64 allowing only two interpolated scalars per cycle, the only problem I see with this is, if we view support for 16 vector-4 interpolants important (true only if we map Microsoft's high priority stream to the realtime stream), then the PA/sequencer need to support a realtime-specific mode where we need to address 32 vectors of parameters instead of 16. This mode is triggered by the primitive type: REAL TIME. The actual memories are in the in the SX blocks. The parameter data memories are hooked on the RBBM bus and are loaded by the CP using register mapped memory.

21.2 Sprites/ XY screen coordinates/ FB information

When working with sprites, one may want to overwrite the parameter 0 with SC generated data. Also, XY screen coordinates may be needed in the shader program. This functionality is controlled by the gen_I0 register (in SQ) in conjunction with the SND_XY register (in SC). Also it is possible to send the faceness information (for OGL front/back special operations) to the shader using the same control register. Here is a list of all the modes and how they interact together:

Gen_st is a bit taken from the interface between the SC and the SQ. This is the MSB of the primitive type. If the bit is set, it means we are dealing with Point AA, Line AA or sprite and in this case the vertex values are going to generated between 0 and 1.

Param_Gen_I0 disable, snd_xy disable, no gen_st – I0 = No modification
Param_Gen_I0 disable, snd_xy disable, gen_st – I0 = No modification
Param_Gen_I0 disable, snd_xy enable, no gen_st – I0 = No modification
Param_Gen_I0 disable, snd_xy enable, gen_st – I0 = No modification
Param_Gen_I0 enable, snd_xy disable, no gen_st – I0 = garbage, garbage, garbage, faceness
Param_Gen_I0 enable, snd_xy disable, gen_st – I0 = garbage, garbage, s, t
Param_Gen_I0 enable, snd_xy enable, no gen_st – I0 = screen x, screen y, garbage, faceness
Param_Gen_I0 enable, snd_xy enable, gen_st – I0 = screen x, screen y, s, t

21.3 Auto generated counters

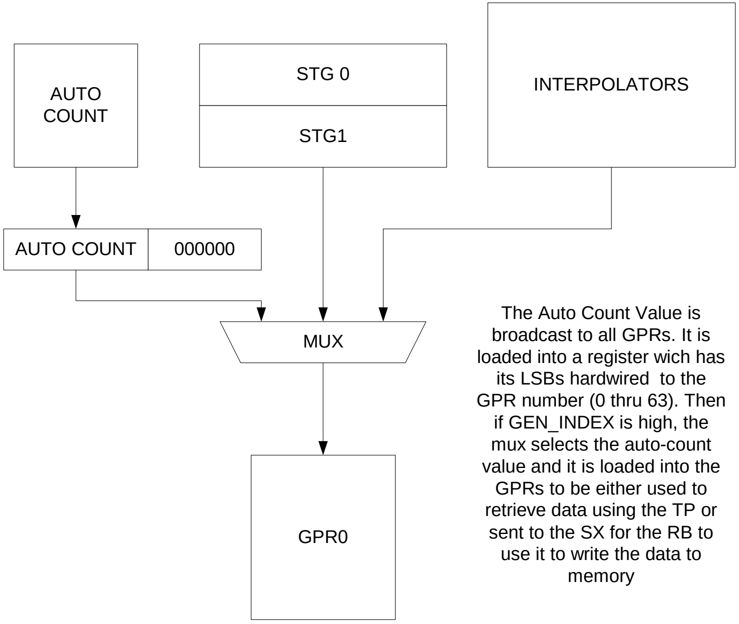
In the cases we are dealing with multipass shaders, the sequencer is going to generate a vector count to be able to both use this count to write the 1st pass data to memory and then use the count to retrieve the data on the 2nd pass. The count is always generated in the same way but it is passed to the shader in a slightly different way depending on the shader type (pixel or vertex). This is toggled on and off using the GEN_INDEX register. The sequencer is going to keep two counters, one for pixels and one for vertices. Every time a full vector of vertices or pixels is written to the GPRs the counter is incremented. Every time a state change is detected, the corresponding counter is reset. While there is only one count broadcast to the GPRs, the LSB are hardwired to specific values making the index different for all elements in the vector.

21.3.1 *Vertex shaders*

In the case of vertex shaders, if GEN_INDEX is set, the data will be put into the x field of the third register (it means that the compiler must allocate 3 GPRs in all multipass vertex shader modes).

21.3.2 *Pixel shaders*

In the case of pixel shaders, if GEN_INDEX is set and Param_Gen_I0 is enabled, the data will be put in the x field of the 2nd register (R1.x), else if GEN_INDEX is set the data will be put into the x field of the 1st register (R0.x).



The Auto Count Value is broadcast to all GPRs. It is loaded into a register wich has its LSBs hardwired to the GPR number (0 thru 63). Then if GEN_INDEX is high, the mux selects the auto-count value and it is loaded into the GPRs to be either used to retrieve data using the TP or sent to the SX for the RB to use it to write the data to memory

Figure 13: GPR input mux Control

22. State management

Every clock, the sequencer will report to the CP the oldest states still in the pipe. These are the states of the programs as they enter the last ALU clause.

22.1 Parameter cache synchronization

In order for the sequencer not to begin a group of pixels before the associated group of vertices has finished, the sequencer will keep a 6 bit count per state (for a total of 8 counters). These counters are initialized to 0 and every time a vertex shader exports its data TO THE PARAMETER CACHE, the corresponding pointer is incremented. When the SC sends a new vector of pixels with the SC_SQ_new_vector bit asserted, the sequencer will first check if the count is greater than 0 before accepting the transmission (it will in fact accept the transmission but then lower its ready to receive). Then the sequencer waits for the count to go to one and decrements it. The sequencer can then issue the group of pixels to the interpolators. Every time the state changes, the new state counter is initialized to 0.

23. XY Address imports

The SC will be able to send the XY addresses to the GPRs. It does so by interleaving the writes of the IJs (to the IJ buffer) with XY writes (to the XY buffer). Then when writing the data to the GPRs, the sequencer is going to interpolate the IJ data or pass the XY data thru a Fix→float converter and expander and write the converted values to the GPRs. The Xys are currently SCREEN SPACE COORDINATES. The values in the XY buffers will wrap. See section 21.2 for details on how to control the interpolation in this mode.

23.1 Vertex indexes imports

In order to import vertex indexes, we have 16 8x96 staging registers. These are loaded one line at a time by the VGT block (96 bits). They are loaded in floating point format and can be transferred in 4 or 8 clocks to the GPRs.

24. Registers

24.1 Control

REG_DYNAMIC	Dynamic allocation (pixel/vertex) of the register file on or off.
REG_SIZE_PIX	Size of the register file's pixel portion (minimal size when dynamic allocation turned on)
REG_SIZE_VTX	Size of the register file's vertex portion (minimal size when dynamic allocation turned on)
ARBITRATION_POLICY	policy of the arbitration between vertexes and pixels
INST_STORE_ALLOC	interleaved, separate
INST_BASE_VTX	start point for the vertex instruction store (RT always ends at vertex_base and Begins at 0)
INST_BASE_PIX	start point for the pixel shader instruction store
ONE_THREAD	debug state register. Only allows one program at a time into the GPRs
ONE_ALU	debug state register. Only allows one ALU program at a time to be executed (instead of 2)
INSTRUCTION	This is where the CP puts the base address of the instruction writes and type (auto-incremented on reads/writes) Register mapped
CONSTANTS	512*4 ALU constants + 32*6 Texture state 32 bits registers (logically mapped)
CONSTANTS_RT	256*4 ALU constants + 32*6 texture states? (physically mapped)
CONSTANT_EO_RT	This is the size of the space reserved for real time in the constant store (from 0 to CONSTANT_EO_RT). The re-mapping table operates on the rest of the memory
TSTATE_EO_RT	This is the size of the space reserved for real time in the fetch state store (from 0 to TSTATE_EO_RT). The re-mapping table operates on the rest of the memory
EXPORT_LATE	Controls whether or not we are exporting position from clause 3. If set, position exports occur at clause 7.

24.2 Context

VS_FETCH_{0…7}	eight 8 bit pointers to the location where each clauses control program is located
VS_ALU_{0…7}	eight 8 bit pointers to the location where each clauses control program is located
PS_FETCH_{0…7}	eight 8 bit pointers to the location where each clauses control program is located
PS_ALU_{0…7}	eight 8 bit pointers to the location where each clauses control program is located
PS_BASE	base pointer for the pixel shader in the instruction store
VS_BASE	base pointer for the vertex shader in the instruction store
VS_CF_SIZE	size of the vertex shader (# of instructions in control program/2)
PS_CF_SIZE	size of the pixel shader (# of instructions in control program/2)
PS_SIZE	size of the pixel shader (cntl+instructions)
VS_SIZE	size of the vertex shader (cntl+instructions)
PS_NUM_REG	number of GPRs to allocate for pixel shader programs
VS_NUM_REG	number of GPRs to allocate for vertex shader programs
PARAM_SHADE	One 16 bit register specifying which parameters are to be gouraud shaded (0 = flat, 1 = gouraud)
PROVO_VERT	0 : vertex 0, 1: vertex 1, 2: vertex 2, 3: Last vertex of the primitive
PARAM_WRAP	64 bits: for which parameters (and channels (xyzw)) do we do the cyl wrapping (0=linear, 1=cylindrical).
PS_EXPORT_MODE	0xxxx : Normal mode 1xxxx : Multipass mode If normal, bbbz where bbb is how many colors (0-4) and z is export z or not If multipass 1-12 exports for color.
~~VS_EXPORT_MASK~~	~~which of the last 6 ALU clauses is exporting (multipass only)~~
VS_EXPORT_MODE	0: position (1 vector), 1: position (2 vectors), 3:multipass
VS_EXPORT _COUNT_{0…6}	Six 4 bit counters representing the # of interpolated parameters exported in clause 7 (located in VS_EXPORT_COUNT_6) OR # of exported vectors to memory per clause in multipass mode (per clause)
PARAM_GEN_I0	Do we overwrite or not the parameter 0 with XY data and generated T and S values

GEN_INDEX	Auto generates an address from 0 to XX. Puts the results into R0-1 for pixel shaders and R2 for vertex shaders
CONST_BASE_VTX (9 bits)	Logical Base address for the constants of the Vertex shader
CONST_BASE_PIX (9 bits)	Logical Base address for the constants of the Pixel shader
CONST_SIZE_PIX (8 bits)	Size of the logical constant store for pixel shaders
CONST_SIZE_VTX (8 bits)	Size of the logical constant store for vertex shaders
INST_PRED_OPTIMIZE	Turns on the predicate bit optimization (if of, conditional_execute_predicates is always executed).
CF_BOOLEANS	256 boolean bits
CF_LOOP_COUNT	32x8 bit counters (number of times we traverse the loop)
CF_LOOP_START	32x8 bit counters (init value used in index computation)
CF_LOOP_STEP	32x8 bit counters (step value used in index computation)

25. DEBUG Registers

25.1 Context

DB_PROB_ADDR	instruction address where the first problem occurred
DB_PROB_COUNT	number of problems encountered during the execution of the program
DB_PROB_BREAK	break the clause if an error is found.
DB_INST_COUNT	instruction counter for debug method 2
DB_BREAK_ADDR	break address for method number 2
DB_CLAUSE_MODE_ALU_{0…7}	clause mode for debug method 2 (0: normal, 1: addr, 2: kill)
DB_CLAUSE_MODE_FETCH_{0…7}	clause mode for debug method 2 (0: normal, 1: addr, 2: kill)

25.2 Control

DB_ALUCST_MEMSIZE	Size of the physical ALU constant memory
DB_TSTATE_MEMSIZE	Size of the physical texture state memory

26. Interfaces

26.1 External Interfaces

Whenever an x is used, it means that the bus is broadcast to all units of the same name. For example, if a bus is named SQ→SPx it means that SQ is going to broadcast the same information to all SP instances.

26.1.1 *SC to SQ : IJ Control bus*

This is the control information sent to the sequencer in order to control the IJ fifos and all other information needed to execute a shader program on the sent pixels. This information is sent over 2 clocks, if SENDXY is asserted the next control packet is going to be ignored and XY information is going to be sent on the IJ bus (for the quads that where just sent). All pixels from the group of quads are from the same primitive, all quads of a vector are from the same render state.

Name	Direction	Bits	Description
SC_SQ_q_wr_mask	SC→SQ	4	Quad Write mask left to right
SC_SQ_lod_correct	SC→SQ	24	LOD correction per quad (6 bits per quad)
SC_SQ_param_ptr0	SC→SQ	11	P Store pointer for vertex 0
SC_SQ_param_ptr1	SC→SQ	11	P Store pointer for vertex 1
SC_SQ_param_ptr2	SC→SQ	11	P Store pointer for vertex 2
SC_SQ_end_of_vect	SC→SQ	1	End of the vector
SC_SQ_store_dealloc	SC→SQ	1	Deallocation token for the P Store
SC_SQ_state	SC→SQ	3	State/constant pointer
SC_SQ_valid_pixel	SC→SQ	16	Valid bits for all pixels
SC_SQ_null_prim	SC→SQ	1	Null Primitive (for PC deallocation purposes)
SC_SQ_end_of_prim	SC→SQ	1	End Of the primitive
SC_SQ_send_xy	SC→SQ	1	Sending XY information [XY information is going to be sent on the next clock]
SC_SQ_prim_type	SC→SQ	3	Real time command need to load tex cords from alternate buffer. Line AA, Point AA and Sprite reads their parameters from GEN_T and GEN_S GPRs. 000 : Normal 011 : Real Time 100 : Line AA 101 : Point AA 110 : Sprite
SC_SQ_new_vector	SC→SQ	1	This primitive comes from a new vector of vertices. Make sure that the corresponding vertex shader has finished before starting the group of pixels.
SC_SQ_RTRn	SQ→SC	1	Stalls the PA in n clocks
SC_SQ_RTS	SC→SQ	1	SC ready to send data

26.1.2 *SQ to SP: Interpolator bus*

Name	Direction	Bits	Description
SQ_SPx_interp_prim_type	SQ→SPx	3	Type of the primitive 000 : Normal 011 : Real Time 100 : Line AA 101 : Point AA 110 : Sprite
SQ_SPx_interp_ijline	SQ→SPx	2	Line in the IJ/XY buffer to use to interpolate
SQ_SPx_interp_mode	SQ→SPx	1	0: Use centroid buffer 1: Use center buffer
SQ_SPx_interp_buff_swap	SQ→SPx	1	Swap the IJ/XY buffers at the end of the interpolation
SQ_SPx_interp_gen_I0	SQ→SPx	1	Generate I0 or not. This tells the interpolators not to use the parameter cache but rather overwrite the data with interpolated 1 and 0. Overwrite if gen_I0 is high.

26.1.3 *SQ to SX: Interpolator bus*

Name	Direction	Bits	Description
SQ_SPx_interp_flat_vtx	SQ→SPx	2	Provoking vertex for flat shading
SQ_SPx_interp_flat_gouraud	SQ→SPx	1	Flat or gouraud shading
SQ_SPx_interp_cyl_wrap	SQ→SPx	4	Wich channel needs to be cylindrical wrapped
SQ_SXx_ptr1~~mux0~~	SQ→SXx	11	Parameter Cache Pointer
SQ_SXx_ptr2~~mux1~~	SQ→SXx	11	Parameter Cache Pointer
SQ_SXx_ptr3~~mux2~~	SQ→SXx	11	Parameter Cache Pointer
SQ_SXx_RT_switch	SQ→SXx	1	Selects between RT and Normal data
SQ_SXx_pc_wr_en	SQ→SXx	1	Write enable for the PC memories
SQ_SXx_pc_wr_addr	SQ→SXx	7	Write address for the PCs

26.1.4 SQ to SP: Staging Register Data

This is a broadcast bus that sends the VSISR information to the staging registers of the shader pipes.

Name	Direction	Bits	Description
SQ_SPx_vgt_vsisr_data	SQ→SPx	96	Pointers of indexes or HOS surface information
SQ_SPx_vgt_vsisr_double	SQ→SPx	1	0: Normal 96 bits per vert 1: double 192 bits per vert
SQ_SP0_data_valid	SQ→SP0	1	Data is valid
SQ_SP1_data_valid	SQ→SP1	1	Data is valid
SQ_SP2_data_valid	SQ→SP2	1	Data is valid
SQ_SP3_data_valid	SQ→SP3	1	Data is valid

26.1.5 PA to SQ : Vertex interface

26.1.5.1 Interface Signal Table

The area difference between the two methods is not sufficient to warrant complicating the interface or the state requirements of the VSISRs. **Therefore, the POR for this interface is that the VGT will transmit the data to the VSISRs (via the Shader Sequencer) in full, 32-bit floating-point format.** The VGT can transmit up to six 32-bit floating-point values to each VSISR where four or more values require two transmission clocks. The data bus is 96 bits wide.

Name	Bits	Description
PA_SQ_vgt_vsisr_data	96	Pointers of indexes or HOS surface information
PA_SQ_vgt_vsisr_double	1	0: Normal 96 bits per vert 1: double 192 bits per vert
PA_SQ_vgt_end_of_vector	1	Indicates the last VSISR data set for the current process vector (for double vector data, "end_of_vector" is set on the second vector)
PA_SQ_vgt_vsisr_valid	1	Vsisr data is valid
PA_SQ_vgt_state	3	Render State (6*3+3 for constants). This signal is guaranteed to be correct when “PA_SQ_vgt_end_of_vector” is high.
PA_SQ_vgt_send	1	Data on the VGT_SQ is valid receive (see write-up for standard R400 SEND/RTR interface handshaking)
SQ_PA_vgt_rtr	1	Ready to receive (see write-up for standard R400 SEND/RTR interface handshaking)

26.1.6 SQ to CP: State report

Name	Direction	Bits	Description
SQ_CP_vrtx_ state	SEQ→CP	3	Oldest vertex state still in the pipe
SQ_CP_pix_state	SEQ→CP	3	Oldest pixel state still in the pipe

26.1.7 SQ to SX: Control bus

Name	Direction	Bits	Description
SQ_SXx_exp_Pixel	SQ→SXx	1	1: Pixel 0: Vertex
SQ_SXx_exp_Clause	SQ→SXx	3	Clause number, which is needed for vertex clauses
SQ_SXx_exp_State	SQ→SXx	3	State ID
SQ_SXx_exp_exportID	SQ→SXx	1	ALU ID

These fields are sent ~~synchronously with SP export data, described in SP0→SX0 interface~~every time the sequencer picks an exporting clause for execution.

26.1.8 SX to SQ : Output file control

Name	Direction	Bits	Description
SXx_SQ_Export_count_rdy	SXx→SQ	1	Raised by SX0 to indicate that the following two fields reflect the result of the most recent export
SXx_SQ_Export_Position	SXx→SQ	1	Specifies whether there is room for another position.
SXx_SQ_Export_Buffer	SXx→SQ	7	Specifies the space available in the output buffers. 0: buffers are full 1: 2K-bits available (32-bits for each of the 64 pixels in a clause) ... 64: 128K-bits available (16 128-bit entries for each of 64 pixels) 65-127: RESERVED

26.1.9 SQ to TP: Control bus

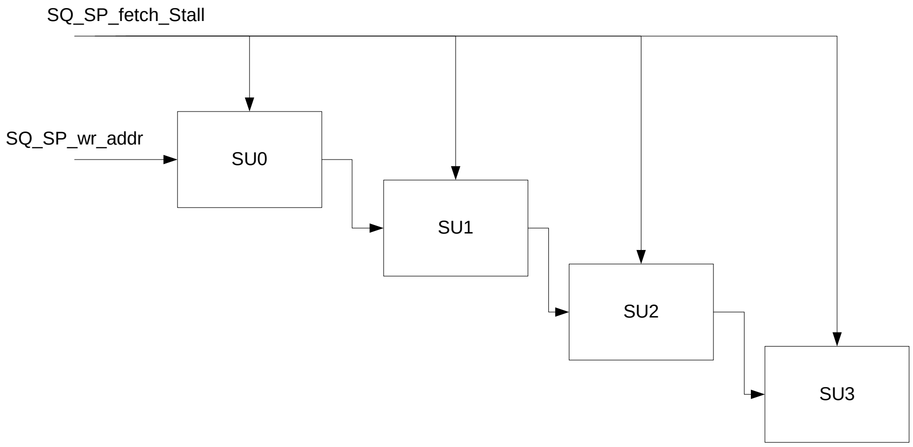
Once every clock, the fetch unit sends to the sequencer on which clause it is now working and if the data in the GPRs is ready or not. This way the sequencer can update the fetch counters for the reservation station fifos. The sequencer also provides the instruction and constants for the fetch to execute and the address in the register file where to write the fetch return data.

Name	Direction	Bits	Description
TPx_SQ_data_rdy	TPx→ SQ	1	Data ready
TPx_SQ_clause_num	TPx→ SQ	3	Clause number
TPx_SQ_Type	TPx→ SQ	1	Type of data sent (0:PIXEL, 1:VERTEX)
SQ_TPx_const	SQ→TPx	48	Fetch state sent over 4 clocks (192 bits total)
SQ_TPx_instuct	SQ→TPx	24	Fetch instruction sent over 4 clocks
SQ_TPx_end_of_clause	SQ→TPx	1	Last instruction of the clause
SQ_TPx_Type	SQ→TPx	1	Type of data sent (0:PIXEL, 1:VERTEX)
SQ_TPx_phase	SQ→TPx	2	Write phase signal
SQ_TP0_lod_correct	SQ→TP0	6	LOD correct 3 bits per comp 2 components per quad
SQ_TP0_pmask	SQ→TP0	4	Pixel mask 1 bit per pixel
SQ_TP1_lod_correct	SQ→TP1	6	LOD correct 3 bits per comp 2 components per quad
SQ_TP1_pmask	SQ→TP1	4	Pixel mask 1 bit per pixel
SQ_TP2_lod_correct	SQ→TP2	6	LOD correct 3 bits per comp 2 components per quad
SQ_TP2_pmask	SQ→TP2	4	Pixel mask 1 bit per pixel
SQ_TP3_lod_correct	SQ→TP3	6	LOD correct 3 bits per comp 2 components per quad
SQ_TP3_pmask	SQ→TP3	4	Pixel mask 1 bit per pixel

SQ_TPx_clause_num	SQ→TPx	3	Clause number
SQ_TPx_write_gpr_index	SQ->TPx	7	Index into Register file for write of returned Fetch Data

26.1.10 *TP to SQ: Texture stall*

The TP sends this signal to the SQ when its input buffer is full. The SQ is going to send it to the SP X clocks after reception (maximum of 3 clocks of pipeline delay).



Name	Direction	Bits	Description
TP_SQ_fetch_stall	TP→ SQ	1	Do not send more texture request if asserted

26.1.11 *SQ to SP: Texture stall*

Name	Direction	Bits	Description
SQ_SPx_fetch_stall	SQ→SPx	1	Do not send more texture request if asserted

26.1.12 *SQ to SP: GPR~~,~~ ~~Parameter cache control~~ and auto counter*

Name	Direction	Bits	Description
SQ_SPx_gpr_wr_addr	SQ→SPx	7	Write address
SQ_SPx_gpr_rd_addr	SQ→SPx	7	Read address
SQ_SPx_gpr_r~~e~~d_~~addr~~en	SQ→SPx	1	Read Enable
SQ_SPx_gpr_~~we~~wr_~~addr~~en	SQ→SPx	1	Write Enable for the GPRs
SQ_SPx_gpr_phase_mux	SQ→SPx	2	The phase mux (arbitrates between inputs, ALU SRC reads and writes)
SQ_SPx_channel_mask	SQ→SPx	4	The channel mask
SQ_SP0_pixel_mask	SQ→SP0	4	The pixel mask
SQ_SP1_pixel_mask	SQ→SP1	4	The pixel mask
SQ_SP2_pixel_mask	SQ→SP2	4	The pixel mask
SQ_SP3_pixel_mask	SQ→SP3	4	The pixel mask
SQ_SPx_gpr_input_mux	SQ→SPx	2	When the phase mux selects the inputs this tells from which source to read from: Interpolated data, VTX0, VTX1, autogen counter.
SQ_SPx_index_count	SQ→SPx	12?	Index count, common for all shader pipes

26.1.13 *SQ to SPx: Instructions*

Name	Direction	Bits	Description
SQ_SPx_instruct_start	SQ→SPx	1	Instruction start
SQ_SP_instruct	SQ→SPx	21	Transferred over 4 cycles 0: SRC A Select 2:0 SRC A Argument Modifier 3:3 SRC A swizzle 11:4 VectorDst 17:12 Unused 20:18 -- - 1: SRC B Select 2:0 SRC B Argument Modifier 3:3 SRC B swizzle 11:4 ScalarDst 17:12 Unused 20:18 -- - 2: SRC C Select 2:0 SRC C Argument Modifier 3:3 SRC C swizzle 11:4 Unused 20:12 -- - 3: Vector Opcode 4:0 Scalar Opcode 10:5 Vector Clamp 11:11 Scalar Clamp 12:12 Vector Write Mask 16:13 Scalar Write Mask 20:17
SQ_SPx_exp_exportID	SQ→SPx	1	ALU ID
SQ_SPx_stall	SQ→SPx	1	Stall signal
SQ_SPx_export_count	SQ→SPx	3	Each set of four pixels or vectors is exported over eight clocks. This field specifies where the SP is in that sequence.
SQ_SPx_export_last	SQ→SPx	1	Asserted on the first shader count of the last export of the clause
SQ_SP0_export_pvalid	SQ→SP0	4	Result of pixel kill in the shader pipe, which must be output for all pixel exports (depth and all color buffers). 4x4 because 16 pixels are computed per clock
SQ_SP0_export_wvalid	SQ→SP0	2	Specifies whether to write low and/or high 32-bit word of the 64-bit export data from each of the 16 pixels or vectors
SQ_SP1_ export_pvalid	SQ→SP1	4	Result of pixel kill in the shader pipe, which must be output for all pixel exports (depth and all color buffers). 4x4 because 16 pixels are computed per clock
SQ_SP1_ export_wvalid	SQ→SP1	2	Specifies whether to write low and/or high 32-bit word of the 64-bit export data from each of the 16 pixels or vectors
SQ_SP2_ export_pvalid	SQ→SP2	4	Result of pixel kill in the shader pipe, which must be output for all pixel exports (depth and all color buffers). 4x4 because 16 pixels are computed per clock
SQ_SP2_ export_wvalid	SQ→SP2	2	Specifies whether to write low and/or high 32-bit word of the 64-bit export data from each of the 16 pixels or vectors
SQ_SP3_ export_pvalid	SQ→SP3	4	Result of pixel kill in the shader pipe, which must be

			output for all pixel exports (depth and all color buffers). 4x4 because 16 pixels are computed per clock
SQ_SP3_ export_wvalid	SQ→SP3	2	Specifies whether to write low and/or high 32-bit word of the 64-bit export data from each of the 16 pixels or vectors

26.1.14 *SP to SQ: Constant address load/ Predicate Set*

Name	Direction	Bits	Description
SP0_SQ_const_addr	SP0→SQ	36	Constant address load / predicate vector load (4 bits only) to the sequencer
SP0_SQ_valid	SP0→SQ	1	Data valid
SP1_SQ_const_addr	SP1→SQ	36	Constant address load / predicate vector load (4 bits only) to the sequencer
SP1_SQ_valid	SP1→SQ	1	Data valid
SP2_SQ_const_addr	SP2→SQ	36	Constant address load / predicate vector load (4 bits only) to the sequencer
SP2_SQ_valid	SP2→SQ	1	Data valid
SP3_SQ_const_addr	SP3→SQ	36	Constant address load / predicate vector load (4 bits only) to the sequencer
SP3_SQ_valid	SP3→SQ	1	Data valid

26.1.15 *SQ to SPx: constant broadcast*

Name	Direction	Bits	Description
SQ_SPx_constant	SQ→SPx	128	Constant broadcast

26.1.16 *SP0 to SQ: Kill vector load*

Name	Direction	Bits	Description
SP0_SQ_kill_vect	SP0→SQ	4	Kill vector load
SP1_SQ_kill_vect	SP1→SQ	4	Kill vector load
SP2_SQ_kill_vect	SP2→SQ	4	Kill vector load
SP3_SQ_kill_vect	SP3→SQ	4	Kill vector load

26.1.17 *SQ to CP: RBBM bus*

Name	Direction	Bits	Description
SQ_RBB_rs	SQ→CP	1	Read Strobe
SQ_RBB_rd	SQ→CP	32	Read Data
SQ_RBBM_nrtrtr	SQ→CP	1	Optional
SQ_RBBM_rtr	SQ→CP	1	Real-Time (Optional)

26.1.18 *CP to SQ: RBBM bus*

Name	Direction	Bits	Description
rbbm_we	CP→SQ	1	Write Enable
rbbm_a	CP→SQ	15	Address -- Upper Extent is TBD (16:2)
rbbm_wd	CP→SQ	32	Data
rbbm_be	CP→SQ	4	Byte Enables
rbbm_re	CP→SQ	1	Read Enable
rbb_rs0	CP→SQ	1	Read Return Strobe 0
rbb_rs1	CP→SQ	1	Read Return Strobe 1
rbb_rd0	CP→SQ	32	Read Data 0
rbb_rd1	CP→SQ	32	Read Data 0
RBBM_SQ_soft_reset	CP→SQ	1	Soft Reset

27. Examples of program executions

27.1.1 *Sequencer Control of a Vector of Vertices*

1. PA sends a vector of 64 vertices (actually vertex indices – 32 bits/index for 2048 bit total) to the RE's Vertex FIFO
   - state pointer as well as tag into position cache is sent along with vertices
   - space was allocated in the position cache for transformed position before the vector was sent
   - **also before the vector is sent to the RE, the CP has loaded the global instruction store with the vertex shader program (using the MH?)**
   - The vertex program is assumed to be loaded when we receive the vertex vector.
     - the SEQ then accesses the IS base for this shader using the local state pointer (provided to all sequencers by the RBBM when the CP is done loading the program)
2. SEQ arbitrates between the Pixel FIFO and the Vertex FIFO – basically the Vertex FIFO always has priority
   - at this point the vector is removed from the Vertex FIFO
   - the arbiter is not going to select a vector to be transformed if the parameter cache is full unless the pipe as nothing else to do (ie no pixels are in the pixel fifo).
3. SEQ allocates space in the SP register file for index data plus GPRs used by the program
   - the number of GPRs required by the program is stored in a local state register, which is accessed using the state pointer that came down with the vertices
   - SEQ will not send vertex data until space in the register file has been allocated
4. SEQ sends the vector to the SP register file over the RE_SP interface (which has a bandwidth of 2048 bits/cycle)
   - the 64 vertex indices are sent to the 64 register files over 4 cycles
     - RF0 of SU0, SU1, SU2, and SU3 is written the first cycle
     - RF1 of SU0, SU1, SU2, and SU3 is written the second cycle
     - RF2 of SU0, SU1, SU2, and SU3 is written the third cycle
     - RF3 of SU0, SU1, SU2, and SU3 is written the fourth cycle
   - the index is written to the least significant 32 bits **(floating point format?) (what about compound indices)** of the 128-bit location within the register file (w); the remaining data bits are set to zero (x, y, z)
5. SEQ constructs a control packet for the vector and sends it to the first reservation station (the FIFO in front of fetch state machine 0, or TSM0 FIFO)
   - the control packet contains the state pointer, the tag to the position cache and a register file base pointer.
6. TSM0 accepts the control packet and fetches the instructions for fetch clause 0 from the global instruction store
   - TSM0 was first selected by the TSM arbiter before it could start
7. all instructions of fetch clause 0 are issued by TSM0
8. the control packet is passed to the next reservation station (the FIFO in front of ALU state machine 0, or ASM0 FIFO)
   - TSM0 does not wait for requests made to the Fetch Unit to complete; it passes the register file write index for the fetch data to the TU, which will write the data to the RF as it is received
   - once the TU has written all the data to the register files, it increments a counter that is associated with ASM0 FIFO; a count greater than zero indicates that the ALU state machine can go ahead start to execute the ALU clause
9. ASM0 accepts the control packet (after being selected by the ASM arbiter) and gets the instructions for ALU clause 0 from the global instruction store
10. all instructions of ALU clause 0 are issued by ASM0, then the control packet is passed to the next reservation station (the FIFO in front of fetch state machine 1, or TSM1 FIFO)
11. the control packet continues to travel down the path of reservation stations until all clauses have been executed
    - position can be exported in ALU clause 3 (or 4?); the data (and the tag) is sent over a position bus (which is shared with all four shader pipes) back to the PA's position cache
    - A parameter cache pointer is also sent along with the position data. This tells to the PA where the data is going to be in the parameter cache.
      - there is a position export FIFO in the SP that buffers position data before it gets sent back to the PA

    - the ASM arbiter will prevent a packet from starting an exporting clause if the position export FIFO is full
- parameter data is exported in clause 7 (as well as position data if it was not exported earlier)
    - parameter data is sent to the Parameter Cache over a dedicated bus
    - the SEQ allocates storage in the Parameter Cache, and the SEQ deallocates that space when there is no longer a need for the parameters (it is told by the PA when using a token).
    - the ASM arbiter will prevent a packet from starting on ASM7 if the parameter cache (or the position buffer if position is being exported) is full

12. after the shader program has completed, the SEQ will free up the GPRs so that they can be used by another shader program

27.1.2 *Sequencer Control of a Vector of Pixels*

1. **As with vertex shader programs, pixel shaders are loaded into the global instruction store by the CP**
    - At this point it is assumed that the pixel program is loaded into the instruction store and thus ready to be read.
2. the RE's Pixel FIFO is loaded with the barycentric coordinates for pixel quads by the detailed walker
    - the state pointer and the LOD correction bits are also placed in the Pixel FIF0
    - the Pixel FIFO is wide enough to source four quad's worth of barycentrics per cycle
3. SEQ arbitrates between Pixel FIFO and Vertex FIFO – when there are no vertices pending OR there is no space left in the register files for vertices, the Pixel FIFO is selected
4. SEQ allocates space in the SP register file for all the GPRs used by the program
    - the number of GPRs required by the program is stored in a local state register, which is accessed using the state pointer
    - SEQ will not allow interpolated data to be sent to the shader until space in the register file has been allocated
5. SEQ controls the transfer of interpolated data to the SP register file over the RE_SP interface (which has a bandwidth of 2048 bits/cycle). See interpolated data bus diagrams for details.
6. SEQ constructs a control packet for the vector and sends it to the first reservation station (the FIFO in front of fetch state machine 0, or TSM0 FIFO)
    - note that there is a separate set of reservation stations/arbiters/state machines for vertices and for pixels
    - the control packet contains the state pointer, the register file base pointer, and the LOD correction bits
    - all other information (such as quad address for example) travels in a separate FIFO
7. TSM0 accepts the control packet and fetches the instructions for fetch clause 0 from the global instruction store
    - TSM0 was first selected by the TSM arbiter before it could start
8. all instructions of fetch clause 0 are issued by TSM0
9. the control packet is passed to the next reservation station (the FIFO in front of ALU state machine 0, or ASM0 FIFO)
    - TSM0 does not wait for fetch requests made to the Fetch Unit to complete; it passes the register file write index for the fetch data to the TU, which will write the data to the RF as it is received
    - once the TU has written all the data for a particular clause to the register files, it increments a counter that is associated with the ASM0 FIFO; a count greater than zero indicates that the ALU state machine can go ahead and pop the FIFO and start to execute the ALU clause
10. ASM0 accepts the control packet (after being selected by the ASM arbiter) and gets the instructions for ALU clause 0 from the global instruction store
11. all instructions of ALU clause 0 are issued by ASM0, then the control packet is passed to the next reservation station (the FIFO in front of fetch state machine 1, or TSM1 FIFO)
12. the control packet continues to travel down the path of reservation stations until all clauses have been executed
    - pixel data is exported in the last ALU clause (clause 7)
        - it is sent to an output FIFO where it will be picked up by the render backend
        - the ASM arbiter will prevent a packet from starting on ASM7 if the output FIFO is full
13. after the shader program has completed, the SEQ will free up the GPRs so that they can be used by another shader program

27.1.3 *Notes*

14. The state machines and arbiters will operate ahead of time so that they will be able to immediately start the real threads or stall.
15. The register file base pointer for a vector needs to travel with the vector through the reservation stations, but the instruction store base pointer does not – this is because the RF pointer is different for all threads, but the IS pointer is only different for each state and thus can be accessed via the state pointer.

28. Open issues

Need to do some testing on the size of the register file as well as on the register file allocation method (dynamic VS static).

Saving power?

Parameter caches in SX?

Using both IJ buffers for center + centroid interpolation?

R400 Sequencer Specification

SQ

Version 1.10~~8~~

Overview: This is an architectural specification for the R400 Sequencer block (SEQ). It provides an overview of the required capabilities and expected uses of the block. It also describes the block interfaces, internal sub-blocks, and provides internal state diagrams.

AUTOMATICALLY UPDATED FIELDS:
Document Location: C:\perforce\r400\doc_lib\design\blocks\sq\R400_Sequencer.doc

~~28. OPEN ISSUES..47~~

Revision Changes:

Rev 0.1 (Laurent Lefebvre) Date: May 7, 2001	First draft.
Rev 0.2 (Laurent Lefebvre) Date : July 9, 2001	Changed the interfaces to reflect the changes in the SP. Added some details in the arbitration section.
Rev 0.3 (Laurent Lefebvre) Date : August 6, 2001	Reviewed the Sequencer spec after the meeting on August 3, 2001.
Rev 0.4 (Laurent Lefebvre) Date : August 24, 2001	Added the dynamic allocation method for register file and an example (written in part by Vic) of the flow of pixels/vertices in the sequencer.
Rev 0.5 (Laurent Lefebvre) Date : September 7, 2001	Added timing diagrams (Vic)
Rev 0.6 (Laurent Lefebvre) Date : September 24, 2001	Changed the spec to reflect the new R400 architecture. Added interfaces.
Rev 0.7 (Laurent Lefebvre) Date : October 5, 2001	Added constant store management, instruction store management, control flow management and data dependant predication.
Rev 0.8 (Laurent Lefebvre) Date : October 8, 2001	Changed the control flow method to be more flexible. Also updated the external interfaces.
Rev 0.9 (Laurent Lefebvre) Date : October 17, 2001	Incorporated changes made in the 10/18/01 control flow meeting. Added a NOP instruction, removed the conditional_execute_or_jump. Added debug registers.
Rev 1.0 (Laurent Lefebvre) Date : October 19, 2001	Refined interfaces to RB. Added state registers.
Rev 1.1 (Laurent Lefebvre) Date : October 26, 2001	Added SEQ→SP0 interfaces. Changed delta precision. Changed VGT→SP0 interface. Debug Methods added.
Rev 1.2 (Laurent Lefebvre) Date : November 16, 2001	Interfaces greatly refined. Cleaned up the spec.
Rev 1.3 (Laurent Lefebvre) Date : November 26, 2001	Added the different interpolation modes.
Rev 1.4 (Laurent Lefebvre) Date : December 6, 2001	Added the auto incrementing counters. Changed the VGT→SQ interface. Added content on constant management. Updated GPRs.
Rev 1.5 (Laurent Lefebvre) Date : December 11, 2001	Removed from the spec all interfaces that weren't directly tied to the SQ. Added explanations on constant management. Added PA→SQ synchronization fields and explanation.
Rev 1.6 (Laurent Lefebvre) Date : January 7, 2002	Added more details on the staging register. Added detail about the parameter caches. Changed the call instruction to a Conditionnal_call instruction. Added details on constant management and updated the diagram.
Rev 1.7 (Laurent Lefebvre) Date : February 4, 2002	Added Real Time parameter control in the SX interface. Updated the control flow section.
Rev 1.8 (Laurent Lefebvre) Date : March 4, 2002	New interfaces to the SX block. Added the end of clause modifier, removed the end of clause instructions.
Rev 1.9 (Laurent Lefebvre) Date : March 18, 2002	Rearangement of the CF instruction bits in order to ensure byte alignment.
Rev 1.10 (Laurent Lefebvre) Date : March 25, 2002	Updated the interfaces and added a section on exporting rules.

1. Overview

The sequencer is based on the R300 design. It chooses two ALU clauses and a fetch clause to execute, and executes all of the instructions in a clause before looking for a new clause of the same type. Two ALU clauses are executed interleaved to hide the ALU latency. Each vector will have eight fetch and eight ALU clauses, but clauses do not need to contain instructions. A vector of pixels or vertices ping-pongs along the sequencer FIFO, bouncing from fetch reservation station to alu reservation station. A FIFO exists between each reservation stage, holding up vectors until the vector currently occupying a reservation station has left. A vector at a reservation station can be chosen to execute. The sequencer looks at all eight alu reservation stations to choose an alu clause to execute and all eight fetch stations to choose a fetch clause to execute. The arbitrator will give priority to clauses/reservation stations closer to the bottom of the pipeline. It will not execute an alu clause until the fetch fetches initiated by the previous fetch clause have completed. There are two separate sets of reservation stations, one for pixel vectors and one for vertices vectors. This way a pixel can pass a vertex and a vertex can pass a pixel.

To support the shader pipe the sequencer also contains the shader instruction cache, constant store, control flow constants and texture state. The four shader pipes also execute the same instruction thus there is only one sequencer for the whole chip.

The sequencer first arbitrates between vectors of 64 vertices that arrive directly from primitive assembly and vectors of 16 quads (64 pixels) that are generated in the scan converter.

The vertex or pixel program specifies how many GPRs it needs to execute. The sequencer will not start the next vector until the needed space is available in the GPRs.

Figure 2: Reservation stations and arbiters

There are two sets of the above figure, one for vertices and one for pixels.

Depending on the arbitration state, the sequencer will either choose a vertex or a pixel packet. The control packet consists of 3 bits of state, 7 bits for the base address of the Shader program and some information on the coverage to determine fetch LOD plus other various small state bits.

On receipt of a packet, the input state machine (not pictured but just before the first FIFO) allocated enough space in the GPRs to store the interpolated values and temporaries. Following this, the barycentric coordinates (and XY screen position if needed) are sent to the interpolator, which will use them to interpolate the parameters and place the results into the GPRs. Then, the input state machine stacks the packet in the first FIFO.

On receipt of a command, the level 0 fetch machine issues a fetch request to the TP and corresponding GPR address for the fetch address (ta). A small command (tcmd) is passed to the fetch system identifying the current level number (0) as well as the GPR write address for the fetch return data. One fetch request is sent every 4 clocks causing the texturing of sixteen 2x2s worth of data (or 64 vertices). Once all the requests are sent the packet is put in FIFO 1.

Upon receipt of the return data, the fetch unit writes the data to the register file using the write address that was provided by the level 0 fetch machine and sends the clause number (0) to the level 0 fetch state machine to signify that the write is done and thus the data is ready. Then, the level 0 fetch machine increments the counter of FIFO 1 to signify to the ALU 0 that the data is ready to be processed.

On receipt of a command, the level 0 ALU machine first decrements the input FIFO 1 counter and then issues a complete set of level 0 shader instructions. For each instruction, the ALU state machine generates 3 source addresses, one destination address and an instruction. Once the last instruction has been issued, the packet is put into FIFO 2.

There will always be two active ALU clauses at any given time (and two arbiters). One arbiter will arbitrate over the odd instructions (4 clocks cycles) and the other one will arbitrate over the even instructions (4 clocks cycles). The only constraints between the two arbiters is that they are not allowed to pick the same clause number as the other one is currently working on if the packet is not of the same type (render state).

If the packet is a vertex packet, upon reaching ALU clause 3, it can export the position if the position is ready. So the arbiter must prevent ALU clause 3 to be selected if the positional buffer is full (or can't be accessed). Along with the positional data, if needed the sprite size and/or edge flags can also be sent.

A special case is for multipass vertex shaders, which can export 12 parameters per last 6 clauses to the output buffer. If the output buffer is full or doesn't have enough space the sequencer will prevent such a vertex group to enter an exporting clause.

Multipass pixel shaders can export 12 parameters to memory from the last clause only (7).

All other clauses process in the same way until the packet finally reaches the last ALU machine (7).

Only one pair of interleaved ALU state machines may have access to the register file address bus or the instruction decode bus at one time. Similarly, only one fetch state machine may have access to the register file address bus at one time. Arbitration is performed by three arbiter blocks (two for the ALU state machines and one for the fetch state machines). The arbiters always favor the higher number state machines, preventing a bunch of half finished jobs from clogging up the register files.

1.2 Data Flow graph (SP)

Figure 6: Interpolation timing diagram

Above is an example of a tile the sequencer might receive from the SC. The write side is how the data get stacked into the XY and IJ buffers, the read side is how the data is passed to the GPRs. The IJ information is packed in the IJ buffer 4 quads at a time or two clocks. The sequencer allows at any given time as many as four quads to interpolate a parameter. They all have to come from the same primitive. Then the sequencer controls the write mask to the GPRs to write the valid data in.

~~{ISSUE : Do we do the center + centroid approach using both IJ buffers?}~~

3. Instruction Store

There is going to be only one instruction store for the whole chip. It will contain 4096 instructions of 96 bits each.

It is likely to be a 1 port memory; we use 1 clock to load the ALU instruction, 1 clocks to load the Fetch instruction, 1 clock to load 2 control flow instructions and 1 clock to write instructions.

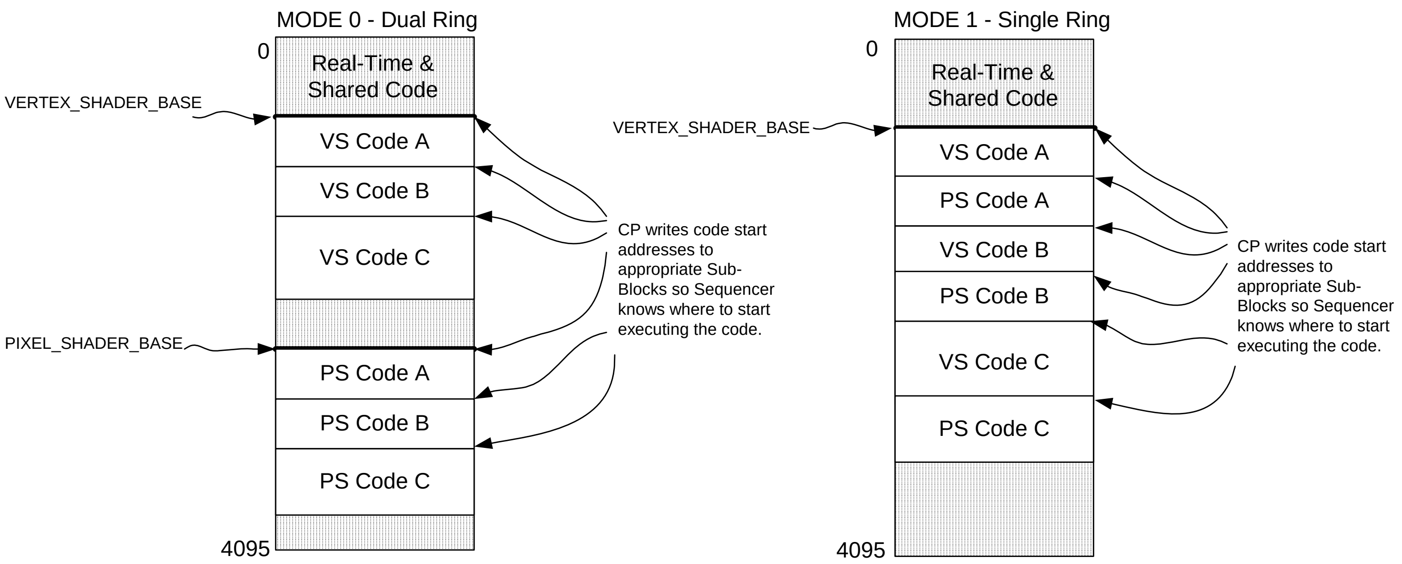
The instruction store is loaded by the CP thru the register mapped registers.

The next picture shows the various modes the CP can load the memory. The Sequencer has to keep track of the loading modes in order to wrap around the correct boundaries. The wrap-around points are arbitrary and they are specified in the VS_BASE and PIX_BASE control registers. The VS_BASE and PS_BASE context registers are used to specify for each context where its shader is in the instruction memory.

For the Real time commands the story is quite the same but for some small differences. There are no wrap-around points for real time so the driver must be careful not to overwrite regular shader data. The shared code (shared subroutines) uses the same path as real time.

R400 CP's Views of Instruction Memory

Updated: 11/14/2001
John A. Carey



CP writes code start addresses to appropriate Sub-Blocks so Sequencer knows where to start executing the code.

CP writes code start addresses to appropriate Sub-Blocks so Sequencer knows where to start executing the code.

Figure 7: The CP's view of the instruction memory

4. Sequencer Instructions

All control flow instructions and move instructions are handled by the sequencer only. The ALUs will perform NOPs during this time (MOV PV,PV, PS,PS) if they have nothing else to do.

5. Constant Stores

5.1 Memory organizations

A likely size for the ALU constant store is 1024x128 bits. The read BW from the ALU constant store is 128 bits/clock and the write bandwidth is 32 bits/clock (directed by the CP bus size not by memory ports).

The maximum logical size of the constant store for a given shader is 256 constants. Or 512 for the pixel/vertex shader pair. The size of the re-mapping table is 128 lines (each line addresses 4 constants). The write granularity is 4 constants or 512 bits. It takes 16 clocks to write the four constants. Real time requires 256 lines in the physical memory (this is physically register mapped).

The texture state is also kept in a similar memory. The size of this memory is ~~128x192~~ 320x96 bits (128 texture states for regular mode, 32 states for RT). The memory thus holds 128 texture states (192 bits per state). The logical size exposes 32 different states total, which are going to be shared between the pixel and the vertex shader. The size of the re-mapping table to for the texture state memory is 32 lines (each line addresses 1 texture state lines in the real memory). The CP write granularity is 1 texture state lines (or 192 bits). The driver sends 512 bits but the CP ignores the top 320 bits. It thus takes 6 clocks to write the texture state. Real time requires 32 lines in the physical memory (this is physically register mapped).

The control flow constant memory doesn't sit behind a renaming table. It is register mapped and thus the driver must reload its content each time there is a change in the control flow constants. Its size is 320*32 because it must hold 8 copies of the 32 dwords of control flow constants and the loop construct constants must be aligned.

The constant re-mapping tables for texture state and ALU constants are logically register mapped for regular mode and physically register mapped for RT operation.

5.2 Management of the Control Flow Constants

The control flow constants are register mapped, thus the CP writes to the according register to set the constant, the SQ decodes the address and writes to the block pointed by its current base pointer (CF_WR_BASE). On the read side, one level of indirection is used. A register (SQ_CONTEXT_MISC.CF_RD_BASE) keeps the current base pointer to the control flow block. This register is copied whenever there is a state change. Should the CP write to CF after the state change, the base register is updated with the (current pointer number +1)% number of states. This way, if the CP doesn't write to CF the state is going to use the previous CF constants.

5.3 Management of the re-mapping tables

5.3.1 *R400 Constant management*

The sequencer is responsible to manage two re-mapping tables (one for the constant store and one for the texture state). On a state change (by the driver), the sequencer will broadside copy the contents of its re-mapping tables to a new one. We have 8 different re-mapping tables we can use concurrently.

The constant memory update will be incremental, the driver only need to update the constants that actually changed between the two state changes.

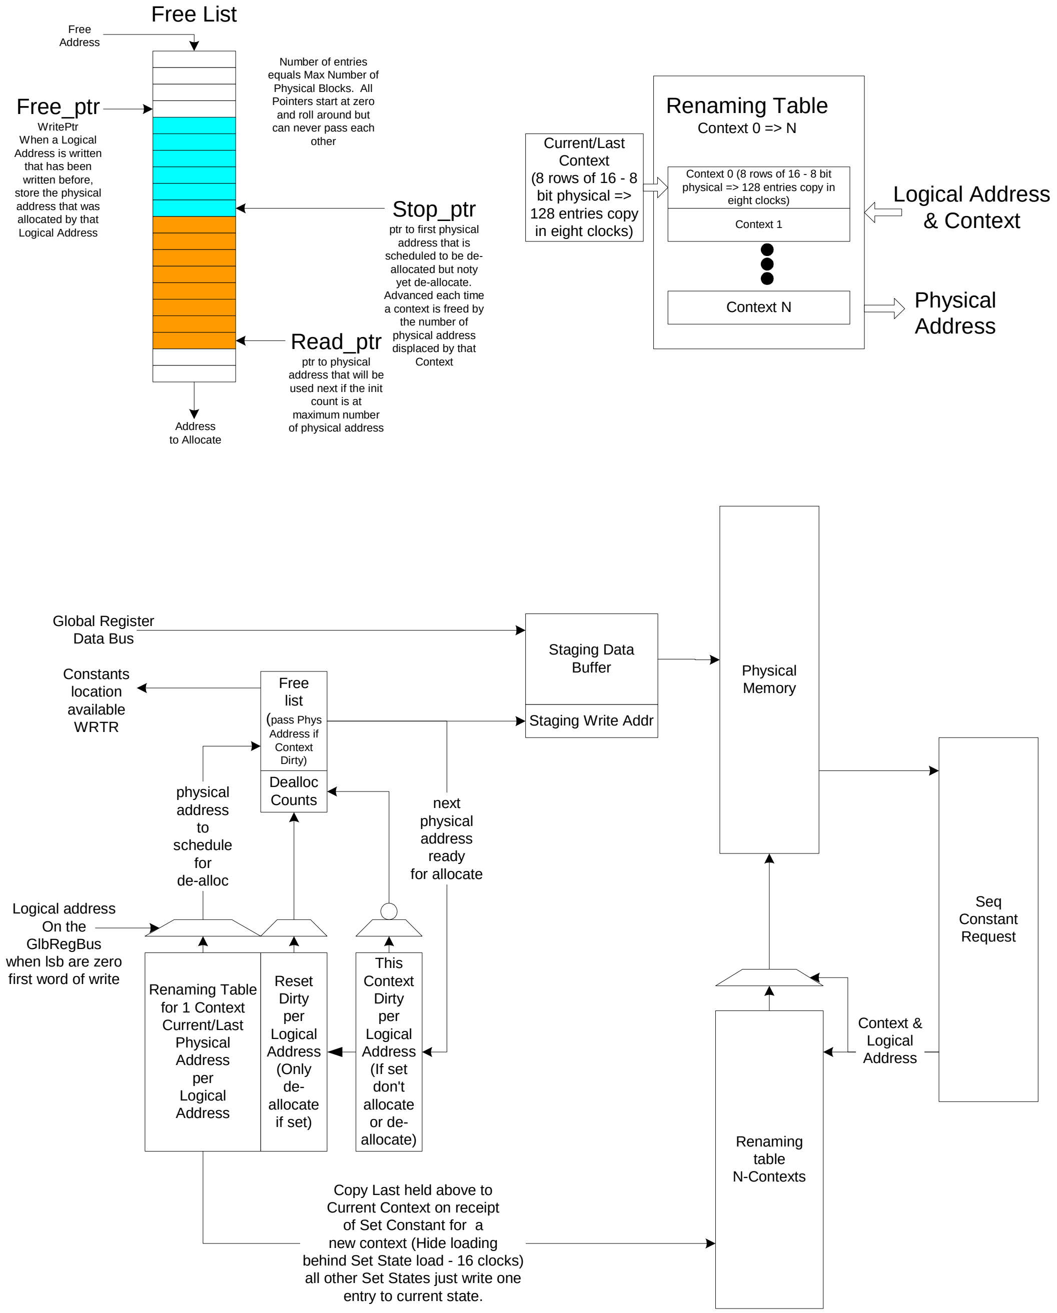
For this model to work in its simplest form, the requirement is that the physical memory MUST be at least twice as large as the logical address space + the space allocated for Real Time. In our case, since the logical address space

is 512 and the reserved RT space can be up to 256 entries, the memory must be of sizes 1280 and above. Similarly the size of the texture store must be of 32*2+32 = 96 entries and above.

5.3.2 *Proposal for R400LE constant management*

To make this scheme work with only 512+256 = 768 entries, upon reception of a CONTROL packet of state + 1, the sequencer would check for SQ_IDLE and PA_IDLE and if both are idle will erase the content of state to replace it with the new state (this is depicted in Figure 9: De-allocation mechanism~~Figure 9: De-allocation mechanism~~~~Figure 9: De-allocation mechanism~~). Note that in the case a state is cleared a value of 0 is written to the corresponding de-allocation counter location so that when the SQ is going to report a state change, nothing will be de-allocated upon the first report.

The second path sets all context dirty bits that were used in the current state to 1 (thus allowing the new state to reuse these physical addresses if needed).



Free List
Free Address
Free_ptr
WritePtr
When a Logical Address is written that has been written before, store the physical address that was allocated by that Logical Address
Number of entries equals Max Number of Physical Blocks. All Pointers start at zero and roll around but can never pass each other
Stop_ptr
ptr to first physical address that is scheduled to be de-allocated but noty yet de-allocate. Advanced each time a context is freed by the number of physical address displaced by that Context
Read_ptr
ptr to physical address that will be used next if the init count is at maximum number of physical address
Address to Allocate
Renaming Table
Context 0 => N
Current/Last Context (8 rows of 16 - 8 bit physical => 128 entries copy in eight clocks)

next physical address ready for allocate
Seq Constant Request
Logical address On the GlbRegBus when lsb are zero first word of write
Renaming Table for 1 Context Current/Last Physical Address per Logical Address
Reset Dirty per Logical Address (Only de-allocate if set)
This Context Dirty per Logical Address (If set don't allocate or de-allocate)
Context & Logical Address
Renaming table N-Contexts
Copy Last held above to Current Context on receipt of Set Constant for a new context (Hide loading behind Set State load - 16 clocks) all other Set States just write one entry to current state.

Figure 8: Constant management

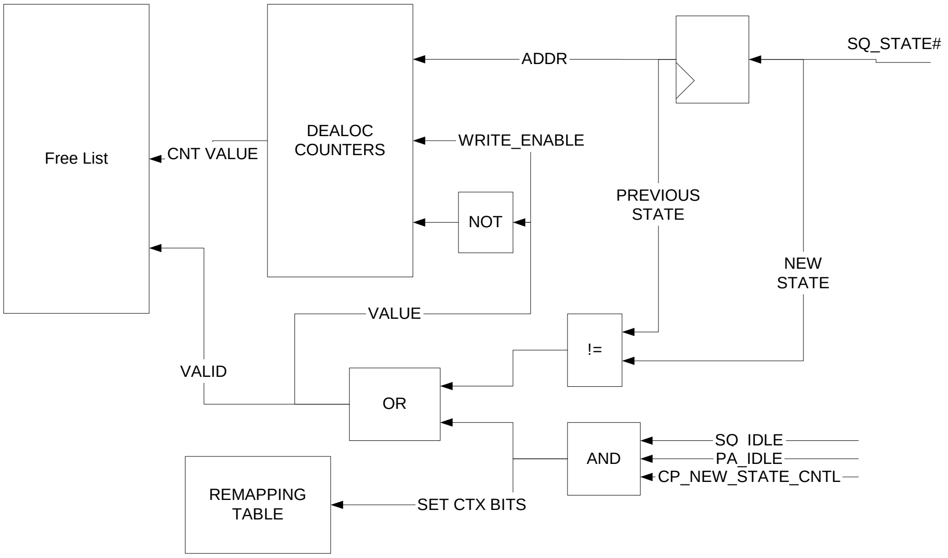

Figure 9: De-allocation mechanism for R400LE

5.3.3 *Dirty bits*

Two sets of dirty bits will be maintained per logical address. The first one will be set to zero on reset and set when the logical address is addressed. The second one will be set to zero whenever a new context is written and set for each address written while in this context. The reset dirty is not set, then writing to that logical address will not require de-allocation of whatever address stored in the renaming table. If it is set and the context dirty is not set, then the physical address store needs to be de-allocated and a new physical address is necessary to store the incoming data. If they are both set, then the data will be written into the physical address held in the renaming for the current logical address. No de-allocation or allocation takes place. This will happen when the driver does a set constant twice to the same logical address between context changes. NOTE: It is important to detect and prevent this, failure to do it will allow multiple writes to allocate all physical memory and thus hang because a context will not fit for rendering to start and thus free up space.

5.3.4 *Free List Block*

A free list block that would consist of a counter (called the IFC or Initial Free Counter) that would reset to zero and incremented every time a chunk of physical memory is used until they have all been used once. This counter would be checked each time a physical block is needed, and if the original ones have not been used up, us a new one, else check the free list for an available physical block address. The count is the physical address for when getting a chunk from the counter.

Storage of a free list big enough to store all physical block addresses.

Maintain three pointers for the free list that are reset to zero. The first one we will call write_ptr. This pointer will identify the next location to write the physical address of a block to be de-allocated. Note: we can never free more physical memory locations than we have. Once recording address the pointer will be incremented to walk the free list like a ring.

The second pointer will be called stop_ptr. The stop_ptr pointer will be advanced by the number of address chunks de-allocates when a context finishes. The address between the stop_ptr and write_ptr cannot be reused because they are still in use. But as soon as the context using then is dismissed the stop_ptr will be advanced.

The third pointer will be called read_ptr. This pointer will point will point to the next address that can be used for allocation as long as the read_ptr does not equal the stop_ptr and the IFC is at its maximum count.

5.3.5 *De-allocate Block*

This block will maintain a free physical address block count for each context. While in current context, a count shall be maintained specifying how many blocks were written into the free list at the write_ptr pointer. This count will be reset upon reset or when this context is active on the back and different than the previous context. It is actually a count of blocks in the previous context that will no longer be used. This count will be used to advance the write_ptr pointer to make available the set of physical blocks freed when the previous context was done. This allows the discard or de-allocation of any number of blocks in one clock.

5.3.6 *Operation of Incremental model*

The basic operation of the model would start with the write_ptr, stop_ptr, read_ptr pointers in the free list set to zero and the free list counter is set to zero. Also all the dirty bits and the previous context will be initialized to zero. When the first set constants happen, the reset dirty bit will not be set, so we will allocate a physical location from the free list counter because its not at the max value. The data will be written into physical address zero. Both the additional copy of the renaming table and the context zeros of the big renaming table will be updated for the logical address that was written by set start with physical address of 0. This process will be repeated for any logical address that are not dirty until the context changes. If a logical address is hit that has its dirty bits set while in the same context, both dirty bits would be set, so the new data will be over-written to the last physical address assigned for this logical address. When the first draw command of the context is detected, the previous context stored in the additional renaming table will be copied to the larger renaming table in the current (new) context location. Then the set constant logical address with be loaded with a new physical address during the copy and if the reset dirty was set, the physical address it replaced in the renaming table would be entered at the write_ptr pointer location on the free list and the write_ptr will be incremented. The de-allocation counter for the previous context (eight) will be incremented. This as set states come in for this context one of the following will happen:

1.) No dirty bits are set for the logical address being updated. A line will be allocated of the free-list counter or the free list at read_ptr pointer if read_ptr != to stop_ptr .
2.) Reset dirty set and Context dirty not set. A new physical address is allocated, the physical address in the renaming table is put on the free list at write_ptr and it is incremented along with the de-allocate counter for the last context.
3.) Context dirty is set then the data will be written into the physical address specified by the logical address.

This process will continue as long as set states arrive. This block will provide backpressure to the CP whenever he has not free list entries available (counter at max and stop_ptr == read_ptr). The command stream will keep a count of contexts of constants in use and prevent more than max constants contexts from being sent.

Whenever a draw packet arrives, the content of the re-mapping table is written to the correct re-mapping table for the context number. Also if the next context uses less constants than the current one all exceeding lines are moved to the free list to be de-allocated later. This happens in parallel with the writing of the re-mapping table to the correct memory.

Now preferable when the constant context leaves the last ALU clause it will be sent to this block and compared with the previous context that left. (Init to zero) If they differ than the older context will no longer be referenced and thus can be de-allocated in the physical memory. This is accomplished by adding the number of blocks freed this context to the stop_ptr pointer. This will make all the physical addresses used by this context available to the read_ptr allocate pointer for future allocation.

This device allows representation of multiple contexts of constants data with N copies of the logical address space. It also allows the second context to be represented as the first set plus some new additional data by just storing the delta's. It allows memory to be efficiently used and when the constants updates are small it can store multiple context. However, if the updates are large, less contexts will be stored and potentially performance will be degraded. Although it will still perform as well as a ring could in this case.

5.4 Constant Store Indexing

In order to do constant store indexing, the sequencer must be loaded first with the indexes (that come from the GPRs). There are 144 wires from the exit of the SP to the sequencer (9 bits pointers x 16 vertexes/clock). Since the data must pass thru the Shader pipe for the float to fixed conversion, there is a latency of 4 clocks (1 instruction)

between the time the sequencer is loaded and the time one can index into the constant store. The assembly will look like this

```
MOVA  R1.X,R2.X       // Loads the sequencer with the content of R2.X, also copies the content of R2.X into R1.X
NOP                   // latency of the float to fixed conversion
ADD   R3,R4,C0[R2.X]// Uses the state from the sequencer to add R4 to C0[R2.X] into R3
```

Note that we don't really care about what is in the brackets because we use the state from the MOVA instruction. R2.X is just written again for the sake of simplicity and coherency.

The storage needed in the sequencer in order to support this feature is 2*64*9 bits = 1152 bits.

5.5 Real Time Commands

The real time commands constants are written by the CP using the register mapped registers allocated for RT. It works is the same way than when dealing with regular constant loads BUT in this case the CP is not sending a logical address but rather a physical address and the reads are not passing thru the re-mapping table but are directly read from the memory. The boundary between the two zones is defined by the CONST_EO_RT control register. Similarly, for the fetch state, the boundary between the two zones is defined by the TSTATE_EO_RT control register.

5.6 Constant Waterfalling

In order to have a reasonable performance in the case of constant store indexing using the address register, we are going to have the possibility of using the physical memory port for read only. This way we can read 1 constant per clock and thus have a worst-case waterfall mode of 1 vertex per clock. There is a small synchronization issue related with this as we need for the SQ to make sure that the constants where actually written to memory (not only sent to the sequencer) before it can allow the first vector of pixels or vertices of the state to go thru the ALUs. To do so, the sequencer keeps 8 bits (one per render state) and sets the bits whenever the last render state is written to memory and clears the bit whenever a state is freed.

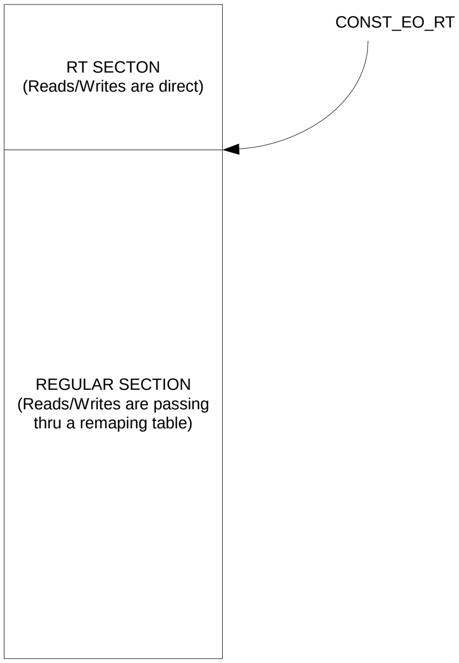

Figure 10: The instruction store

6. Looping and Branches

Loops and branches are planned to be supported and will have to be dealt with at the sequencer level. We plan on supporting constant loops and branches using a control program.

6.1 The controlling state.

The R400 controling state consists of:

Boolean[256:0]
Loop_count[7:0][31:0]
Loop_Start[7:0][31:0]
Loop_Step[7:0][31:0]

That is 256 Booleans and 32 loops.

We have a stack of 4 elements for nested calls of subroutines and 4 loop counters to allow for nested loops.

This state is available on a per shader program basis.

6.2 The Control Flow Program

Examples of control flow programs are located in the R400 programming guide document.

The basic model is as follows:

The render state defined the clause boundaries:
Vertex_shader_fetch[7:0][7:0]   // eight 8 bit pointers to the location where each clauses control program is located
Vertex_shader_alu[7:0][7:0]   // eight 8 bit pointers to the location where each clauses control program is located
Pixel_shader_fetch[7:0][7:0]   // eight 8 bit pointers to the location where each clauses control program is located
Pixel_shader_alu[7:0][7:0]   // eight 8 bit pointers to the location where each clauses control program is located

A pointer value of FF means that the clause doesn't contain any instructions.

The control program for a given clause is executed to completion before moving to another clause, (with the exception of the pick two nature of the alu execution). The control program is the only program aware of the clause boundaries.

The control program has nine basic instructions:

Execute
Conditional_execute
Conditional_Execute_Predicates
Conditional_jump
Conditionnal_Call
Return
Loop_start
Loop_end
NOP

Execute, causes the specified number of instructions in instruction store to be executed.
Conditional_execute checks a condition first, and if true, causes the specified number of instructions in instruction store to be executed.
Loop_start resets the corresponding loop counter to the start value on the first pass after it checks for the end condition and if met jumps over to a specified address.
Loop_end increments (decrements?) the loop counter and jumps back the specified number of instructions.
Conditionnal_Call jumps to an address and pushes the IP counter on the stack if the condition is met. On the return instruction, the IP is popped from the stack.

Conditional_execute_Predicates executes a block of instructions if all bits in the predicate vectors meet the condition.
Conditional_jumps jumps to an address if the condition is met.
NOP is a regular NOP

NOTE THAT ALL JUMPS MUST JUMP TO EVEN CFP ADDRESSES since there are two control flow instructions per memory line. Thus the compiler must insert NOPs where needed to align the jumps on even CFP addresses.

Also if the jump is logically bigger than pshader_cntl_size (or vshader_cntl_size) we break the program (clause) and set the debug registers. If an execute or conditional_execute is lower than cntl_size or bigger than size we also break the program (clause) and set the debug registers.

We have to fit instructions into 48 bits in order to be able to put two control flow instruction per line in the instruction store.

A value of 1 in the Addressing means that the address specified in the Exec Address field (or in the jump address field) is an ABSOLUTE address. If the addressing field is cleared (should be the default) then the address is relative to the base of the current shader program.

Note that whenever a field is marked as RESERVED, it is assumed that all the bits of the field are cleared (0).

Execute					
47	46… 42	41	40 … 24	23 … 12	11 … 0
Addressing	00001	Last	RESERVED	Instruction count	Exec Address

Execute up to 4k instructions at the specified address in the instruction memory. If Last is set, this is the last group of instructions of the clause.

NOP			
47	46 … 42	41	40 … 0
Addressing	00010	Last	RESERVED

This is a regular NOP. If Last is set, this is the last instruction of the clause.

Conditional_Execute								
47	46 … 42	41	40	~~40~~ 39 … ~~33~~32	~~32~~31	~~31~~ 30 … 24	23 … 12	11 … 0
Addressing	00011	Last	RESERVED	Boolean address	Condition	RESERVED	Instruction count	Exec Address

If the specified Boolean (8 bits can address 256 Booleans) meets the specified condition then execute the specified instructions (up to 4k instructions). If Last is set, then if the condition is met, this is the last group of instructions to be executed in the clause. If the condition is not met, we go on to the next control flow instruction.

Conditional_Execute_Predicates								
47	46 … 42	41	~~40~~ 40 … ~~35~~34	~~34~~ 33 … ~~33~~32	~~32~~31	~~31~~ 30 … 24	23 … 12	11 … 0
Addressing	00100	Last	RESERVED	Predicate vector	Condition	RESERVED	Instruction count	Exec Address

Check the AND/OR of all current predicate bits. If AND/OR matches the condition execute the specified number of instructions. We need to AND/OR this with the kill mask in order not to consider the pixels that aren't valid. If Last is set, then if the condition is met, this is the last group of instructions to be executed in the clause. If the condition is not met, we go on to the next control flow instruction.

Loop_Start				
47	46 … 42	41 … 17	16 … 12	11 … 0

Addressing	00101	RESERVED	loop ID	Jump address

Loop Start. Compares the loop iterator with the end value. If loop condition not met jump to the address. Forward jump only. Also computes the index value. The loop id must match between the start to end, and also indicates which control flow constants should be used with the loop.

Loop_End				
47	46 … 42	41 … 17	16 … 12	11 … 0
Addressing	00110	RESERVED	loop ID	start address

Loop end. Increments the counter by one, compares the loop count with the end value. If loop condition met, continue, else, jump BACK to the start of the loop.

The way this is described does not prevent nested loops, and the inclusion of the loop id make this easy to do.

Conditionnal_Call						
47	46 … 42	41 … ~~35~~34	~~34~~ 33 … ~~33~~32	31~~2~~	~~31~~ 30 … 12	11 … 0
Addressing	00111	RESERVED	Predicate vector	Condition	RESERVED	Jump address

If the condition is met, jumps to the specified address and pushes the control flow program counter on the stack.

Return		
47	46 … 42	41 … 0
Addressing	01000	RESERVED

Pops the topmost address from the stack and jumps to that address. If nothing is on the stack, the program will just continue to the next instruction.

Conditionnal_Jump							
47	46 … 42	41 … 40~~1~~	~~40~~ 39 … ~~33~~32	~~32~~31	~~31~~30	~~30~~ 29 … 12	11 … 0
Addressing	01001	RESERVED	Boolean address	Condition	FW only	RESERVED	Jump address

If condition met, jumps to the address. FORWARD jump only allowed if bit 31 set. Bit 31 is only an optimization for the compiler and should NOT be exposed to the API.

To prevent infinite loops, we will keep 9 bits loop iterators instead of 8 (we are only able to loop 256 times). If the counter goes higher than 255 then the loop_end or the loop_start instruction is going to break the loop and set the debug GPRs.

6.3 Data dependant predicate instructions

Data dependant conditionals will be supported in the R400. The only way we plan to support those is by supporting three vector/scalar predicate operations of the form:

PRED_SETE_# - similar to SETE except that the result is 'exported' to the sequencer.
PRED_SETNE_# - similar to SETNE except that the result is 'exported' to the sequencer.
PRED_SETGT_# - similar to SETGT except that the result is 'exported' to the sequencer
PRED_SETGTE_# - similar to SETGTE except that the result is 'exported' to the sequencer

For the scalar operations only we will also support the two following instructions:
PRED_SETE0_# – SETE0

PRED_SETE1_# – SETE1

The export is a single bit - 1 or 0 that is sent using the same data path as the MOVA instruction.   The sequencer will maintain 4 sets of 64 bit predicate vectors (in fact 8 sets because we interleave two programs but only 4 will be exposed) and use it to control the write masking. This predicate is not maintained across clause boundaries. The # sign is used to specify which predicate set you want to use 0 thru 3.

Then we have two conditional execute bits. The first bit is a conditional execute "on" bit and the second bit tells us if we execute on 1 or 0. For example, the instruction:

P0_ADD_# R0,R1,R2

Is only going to write the result of the ADD into those GPRs whose predicate bit is 0. Alternatively, P1_ADD_# would only write the results to the GPRs whose predicate bit is set. The use of the P0 or P1 without precharging the sequencer with a PRED instruction is undefined.

{Issue: do we have to have a NOP between PRED and the first instruction that uses a predicate?}

6.4 HW Detection of PV,PS

Because of the control program, the compiler cannot detect statically dependant instructions. In the case of non-masked writes and subsequent reads the sequencer will insert uses of PV,PS as needed. This will be done by comparing the read address and the write address of consecutive instructions. For masked writes, the sequencer will insert NOPs wherever there is a dependant read/write.

The sequencer will also have to insert NOPs between PRED_SET and MOVA instructions and their uses.

6.5 Register file indexing

Because we can have loops in fetch clause, we need to be able to index into the register file in order to retrieve the data created in a fetch clause loop and use it into an ALU clause. The instruction will include the base address for register indexing and the instruction will contain these controls:

Bit7	Bit 6	
0	0	'absolute register'
0	1	'relative register'
1	0	'previous vector'
1	1	'previous scalar'

In the case of an absolute register we just take the address as is. In the case of a relative register read we take the base address and we add to it the loop_index and this becomes our new address that we give to the shader pipe.

The sequencer is going to keep a loop index computed as such:

Index = Loop_iterator*Loop_step + Loop_start.

We loop until loop_iterator = loop_count. Loop_step is a signed value [-128…127]. The computed index value is a 10 bit counter that is also signed. Its real range is [-256,256]. The tenth bit is only there so that we can provide an out of range value to the "indexing logic" so that it knows when the provided index is out of range and thus can make the necessary arrangements.

6.6 Predicated Instruction support for Texture clauses

For texture clauses, we support the following optimization: we keep 1 bit (thus 4 bits for the four predicate vectors) per predicate vector in the reservation stations. A value of 1 means that one ore more elements in the vector have a value of one (thus we have to do the texture fetches for the whole vector). A value of 0 means that no elements in the vector have his predicate bit set and we can thus skip over the texture fetch. **We have to make sure the invalid pixels aren't considered with this optimization.**

6.7 Debugging the Shaders

In order to be able to debug the pixel/vertex shaders efficiently, we provide 2 methods.

6.7.1 *Method 1: Debugging registers*

Current plans are to expose 2 debugging, or error notification, registers:
1. address register where the first error occurred
2. count of the number of errors

The sequencer will detect the following groups of errors:
- count overflow
- constant indexing overflow
- register indexing overflow

Compiler recognizable errors:
- jump errors
    relative jump address > size of the control flow program
- call stack
    call with stack full
    return with stack empty

A jump error will always cause the program to break. In this case, a break means that a clause will halt execution, but allowing further clauses to be executed.

With all the other errors, program can continue to run, potentially to worst-case limits. The program will only break if the DB_PROB_BREAK register is set.

If indexing outside of the constant or the register range, causing an overflow error, the hardware is specified to return the value with an index of 0. This could be exploited to generate error tokens, by reserving and initializing the 0th register (or constant) for errors.

{ISSUE : Interrupt to the driver or not?}

6.7.2 *Method 2: Exporting the values in the GPRs (12)*

The sequencer will have a count register and an address register for this mode and 3 bits per clause specifying the execution mode for each clause. The modes can be :

1) Normal
2) Debug Kill
3) Debug Addr + Count

Under the normal mode execution follows the normal course. Under the kill mode, all control flow instructions are executed but all normal shader instructions of the clause are replaced by NOPs. Only debug_export instructions of clause 7 will be executed under the debug kill setting. Under the other mode, normal execution is done until we reach an address specified by the address register and instruction count (useful for loops) specified by the count register. After we have hit the instruction n times (n=count) we switch the clause to the kill mode.

Under the debug mode (debug kill OR debug Addr + count), it is assumed that clause 7 is always exporting 12 debug vectors and that all other exports to the SX block (position, color, z, ect) will been turned off (changed into NOPs) by the sequencer (even if they occur before the address stated by the ADDR debug register).

7. Pixel Kill Mask

A vector of 64 bits is kept by the sequencer per group of pixels/vertices. Its purpose is to optimize the texture fetch requests and allow the shader pipe to kill pixels using the following instructions:

MASK_SETE
MASK_SETNE
MASK_SETGT

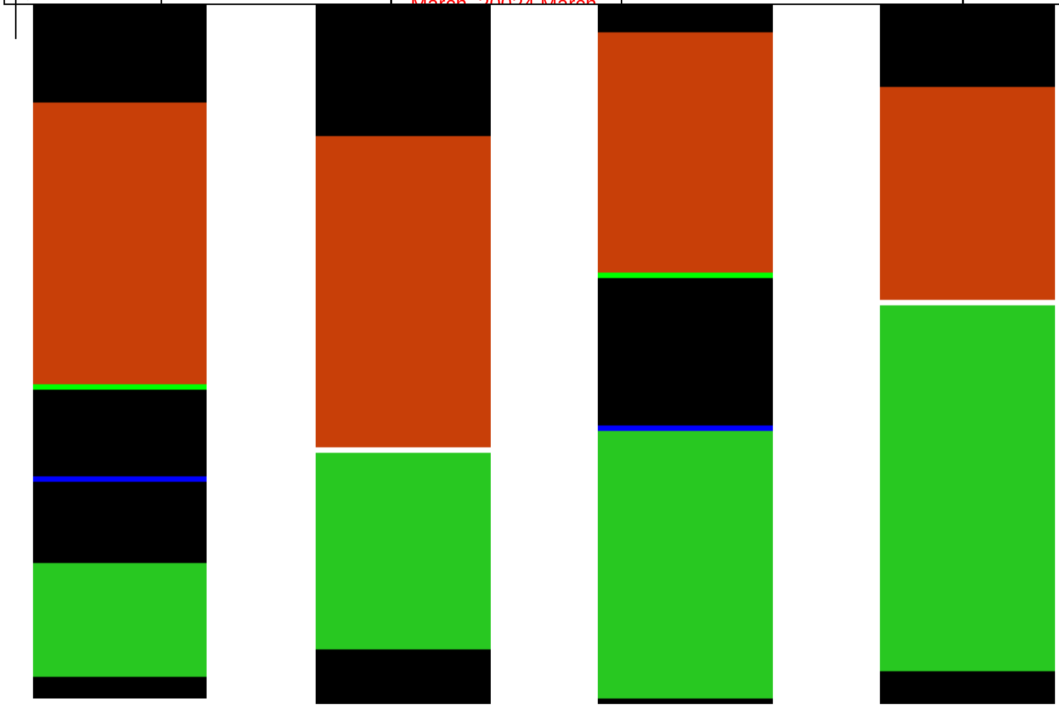
MASK_SETGTE

8. Multipass vertex shaders (HOS)

Multipass vertex shaders are able to export from the 6 last clauses but to memory ONLY.

9. Register file allocation

The register file allocation for vertices and pixels can either be static or dynamic. In both cases, the register file in managed using two round robins (one for pixels and one for vertices). In the dynamic case the boundary between pixels and vertices is allowed to move, in the static case it is fixed to 128-VERTEX_REG_SIZE for vertices and PIXEL_REG_SIZE for pixels.



Above is an example of how the algorithm works. Vertices come in from top to bottom; pixels come in from bottom to top. Vertices are in orange and pixels in green. The blue line is the tail of the vertices and the green line is the tail of the pixels. Thus anything between the two lines is shared. When pixels meets vertices the line turns white and the boundary is static until both vertices and pixels share the same “unallocated bubble”. Then the boundary is allowed to move again. The numbering of the GPRs starts from the bottom of the picture at index 0 and goes up to the top at index 127.

10. Fetch Arbitration

The fetch arbitration logic chooses one of the 8 potentially pending fetch clauses to be executed. The choice is made by looking at the fifos from 7 to 0 and picking the first one ready to execute. Once chosen, the clause state machine will send one 2x2 fetch per clock (or 4 fetches in one clock every 4 clocks) until all the fetch instructions of the clause are sent. This means that there cannot be any dependencies between two fetches of the same clause.

The arbitrator will not wait for the fetches to return prior to selecting another clause for execution. The fetch pipe will be able to handle up to X(?) in flight fetches and thus there can be a fair number of active clauses waiting for their fetch return data.

11. ALU Arbitration

ALU arbitration proceeds in almost the same way than fetch arbitration. The ALU arbitration logic chooses one of the 8 potentially pending ALU clauses to be executed. The choice is made by looking at the fifos from 7 to 0 and picking the first one ready to execute. There are two ALU arbiters, one for the even clocks and one for the odd clocks. For example, here is the sequencing of two interleaved ALU clauses (E and O stands for Even and Odd sets of 4 clocks):

Einst0 Oinst0 Einst1 Oinst1 Einst2 Oinst2 Einst0 Oinst3 Einst1 Oinst4 Einst2 Oinst0…
Proceeding this way hides the latency of 8 clocks of the ALUs. Also note that the interleaving also occurs across clause boundaries.

12. Handling Stalls

When the output file is full, the sequencer prevents the ALU arbitration logic from selecting the last clause (this way nothing can exit the shader pipe until there is place in the output file. If the packet is a vertex packet and the position buffer is full (POS_FULL) then the sequencer also prevents a thread from entering the exporting clause (3?). The sequencer will set the OUT_FILE_FULL signal n clocks before the output file is actually full and thus the ALU arbiter will be able read this signal and act accordingly by not preventing exporting clauses to proceed.

13. Content of the reservation station FIFOs

The reservation FIFOs contain the state of the vector of pixels and vertices. We have two sets of those: one for pixels, and one for vertices. They contain 3 bits of Render State 7 bits for the base address of the GPRs, some bits for LOD correction and coverage mask information in order to fetch fetch for only valid pixels, the quad address.

14. The Output File

The output file is where pixels are put before they go to the RBs. The write BW to this store is 256 bits/clock. Just before this output file are staging registers with write BW 512 bits/clock and read BW 256 bits/clock. The staging registers are 4x128 (and there are 16 of those on the whole chip).

15. IJ Format

The IJ information sent by the PA is of this format on a per quad basis:

We have a vector of IJ's (one IJ per pixel at the centroid of the fragment or at the center of the pixel depending on the mode bit). The interpolation is done at a different precision across the 2x2. The upper left pixel's parameters are always interpolated at full 20x24 mantissa precision. Then the result of the interpolation along with the difference in IJ in reduced precision is used to interpolate the parameter for the other three pixels of the 2x2. Here is how we do it:

Assuming P0 is the interpolated parameter at Pixel 0 having the barycentric coordinates I(0), J(0) and so on for P1,P2 and P3. Also assuming that A is the parameter value at V0 (interpolated with I), B is the parameter value at V1 (interpolated with J) and C is the parameter value at V2 (interpolated with (1-I-J).

$$\Delta 01I = I(1) - I(0)$$
$$\Delta 01J = J(1) - J(0)$$
$$\Delta 02I = I(2) - I(0)$$
$$\Delta 02J = J(2) - J(0)$$
$$\Delta 03I = I(3) - I(0)$$
$$\Delta 03J = J(3) - J(0)$$

P0	P1
P2	P3

$$P0 = C + I(0) * (A - C) + J(0) * (B - C)$$
$$P1 = P0 + \Delta 01I * (A - C) + \Delta 01J * (B - C)$$
$$P2 = P0 + \Delta 02I * (A - C) + \Delta 02J * (B - C)$$
$$P3 = P0 + \Delta 03I * (A - C) + \Delta 03J * (B - C)$$

P0 is computed at 20x24 mantissa precision and P1 to P3 are computed at 8X24 mantissa precision. So far no visual degradation of the image was seen using this scheme.

Multiplies (Full Precision): 2
Multiplies (Reduced precision): 6
Subtracts 19x24 (Parameters): 2

Adds: 8

FORMAT OF P0's IJ : Mantissa 20 Exp 4 for I + Sign
Mantissa 20 Exp 4 for J + Sign

FORMAT of Deltas (x3):Mantissa 8 Exp 4 for I + Sign
Mantissa 8 Exp 4 for J + Sign

Total number of bits : 20*2 + 8*6 + 4*8 + 4*2 = 128

All numbers are kept using the un-normalized floating point convention: if exponent is different than 0 the number is normalized if not, then the number is un-normalized. The maximum range for the IJs (Full precision) is +/- 63 and the range for the Deltas is +/- 127.

15.1 Interpolation of constant attributes

Because of the floating point imprecision, we need to take special provisions if all the interpolated terms are the same or if two of the barycentric coordinates are the same.

We start with the premise that if A = B and B = C and C = A, then P0,1,2,3 = A. Since one or more of the IJ terms may be zero, so we extend this to:

```
if (A=B and B=C and C=A)
   P0,1,2,3 = A;
else if ((I = 0) or (J = 0)) and
          ((J = 0) or (1-I-J = 0)) and
          ((1-J-I = 0) or (I = 0))) {
                if(I != 0) {
                    P0 = A;
                } else if(J != 0) {
                    P0 = B;
                } else {
                    P0 = C;
                }
             //rest of the quad interpolated normally
}
else
{
             normal interpolation
}
```

16. Staging Registers

In order for the reuse of the vertices to be 14, the sequencer will have to re-order the data sent IN ORDER by the VGT for it to be aligned with the parameter cache memory arrangement. Given the following group of vertices sent by the VGT:

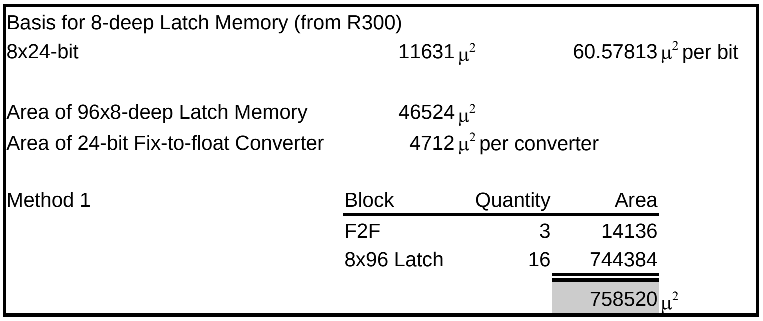
0 1 2 3 4 5 6 7 8 9 10 11 12 13 14 15 || 16 17 18 19 20 21 22 23 24 25 26 27 28 29 30 31 || 32 33 34 35 36 37 38 39 40 41 42 43 44 45 46 47 || 48 49 50 51 52 53 54 55 56 57 58 59 60 61 62 63

The sequencer will re-arrange them in this fashion:

0 1 2 3 16 17 18 19 32 33 34 35 48 49 50 51 || 4 5 6 7 20 21 22 23 36 37 38 39 52 53 54 55 || 8 9 10 11 24 25 26 27 40 41 42 43 56 57 58 59 || 12 13 14 15 28 29 30 31 44 45 46 47 60 61 62 63

The || markers show the SP divisions. In the event a shader pipe is broken, the VGT will send padding to account for the missing pipe. For example, if SP1 is broken, vertices 4 5 6 7 20 21 22 23 36 37 38 39 52 53 54 55 will still be sent by the VGT to the SQ **BUT** will not be processed by the SP and thus should be considered invalid (by the SU and VGT).

The most straightforward, *non-compressed* interface method would be to convert, in the VGT, the data to 32-bit floating point prior to transmission to the VSISRs. In this scenario, the data would be transmitted to (and stored in) the VSISRs in full 32-bit floating point. This method requires three 24-bit fixed-to-float converters in the VGT. Unfortunately, it also requires and additional 3,072 bits of storage across the VSISRs. This interface is illustrated in Figure 12~~Figure 12Figure 12~~. The area of the fixed-to-float converters and the VSISRs for this method is roughly estimated as 0.759sqmm using the R300 process. The gate count estimate is shown in Figure 11~~Figure 11Figure 11~~.



Basis for 8-deep Latch Memory (from R300)				
8x24-bit	11631 μ^2		60.57813 μ^2 per bit	
Area of 96x8-deep Latch Memory	46524 μ^2			
Area of 24-bit Fix-to-float Converter	4712 μ^2 per converter			
Method 1	Block	Quantity	Area	
	F2F	3	14136	
	8x96 Latch	16	744384	
			758520	μ^2

Figure 11:Area Estimate for VGT to Shader Interface

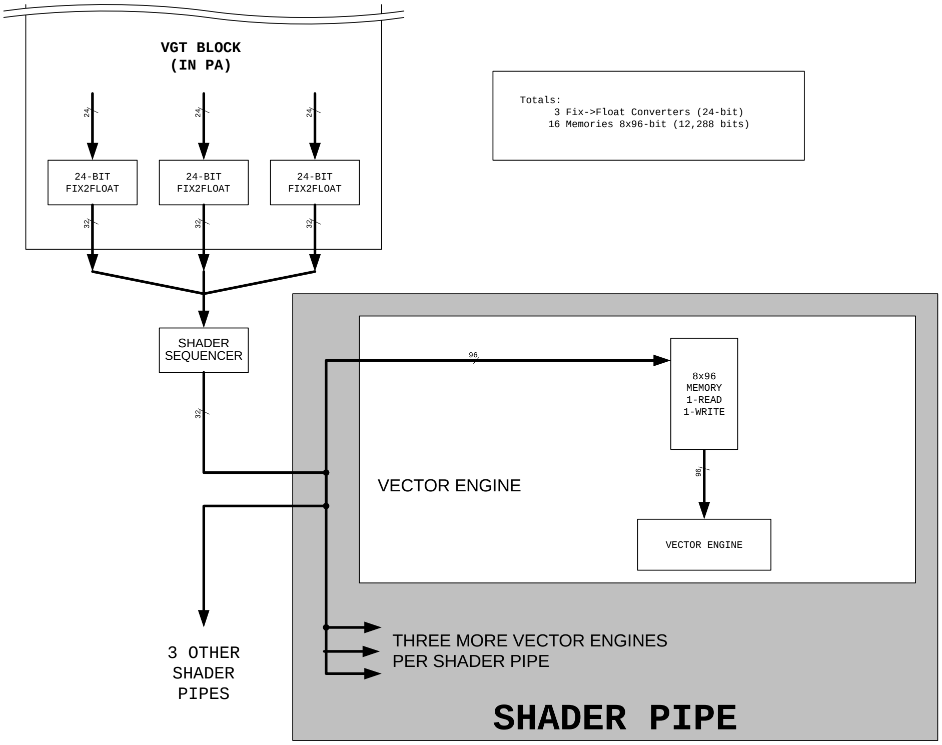


Figure 12:VGT to Shader Interface

17. The parameter cache

The parameter cache is where the vertex shaders export their data. It consists of 16 128x128 memories (1R/1W). The reuse engine will make it so that all vertexes of a given primitive will hit different memories. The allocation method for these memories is a simple round robin. The parameter cache pointers are mapped in the following way: 4MSBs are the memory number and the 7 LSBs are the address within this memory.

MEMORY NUMBER	ADDRESS
4 bits	7 bits

The PA generates the parameter cache addresses as the positions come from the SQ. All it needs to do is keep a Current_Location pointer (7 bits only) and as the positions comes increment the memory number. When the memory number field wraps around, the PA increments the Current_Location by VS_EXPORT_COUNT_7 (a snooped register from the SQ). As an example, say the memories are all empty to begin with and the vertex shader is exporting 8 parameters per vertex (VS_EXPORT_COUNT_7 = 8). The first position received is going to have the PC address 00000000000 the second one 00010000000, third one 00100000000 and so on up to 11110000000. Then the next position received (the 17th) is going to have the address 00000001000, the 18th 00010001000, the 19th 00100001000 and so on. The Current_location is NEVER reset BUT on chip resets. The only thing to be careful about is that if the SX doesn't send you a full group of positions (<64) then you need to fill the address space so that the next group starts correctly aligned (for example if you receive only 33 positions then you need to add 2*VS_EXPORT_COUNT_7to Current_Location and reset the memory count to 0 before the next vector begins).

18. Vertex position exporting

On clause 3 the vertex shader can export to the PA both the vertex position and the point sprite. It can also do so at clause 7 if not done at clause 3. The storage needed to perform the position export is at least 64x128 memories for the position and 64x32 memories for the sprite size. It is going to be taken in the pixel output fifo from the SX blocks. The clause where the position export occurs is specified by the EXPORT_LATE register. If turned on, it means that the export is going to occur at ALU clause 7 if unset position export occurs at clause 3.

19. Exporting Arbitration

Here are the rules for co-issuing exporting ALU clauses.

1) Position exports and position exports cannot be co-issued.

All other types of exports can be co-issued as long as there is place in the receiving buffer.

~~{ISSUE: Do we move the parameter caches to the SX?}~~

Formatted: Bullets and Numbering

20. Exporting Rules

20.1 Parameter caches exports

We support masking and out of order exports to the parameter caches. So one can export multiple times to the same PC line using different masks.

Formatted: Bullets and Numbering

20.2 Memory exports

Memory exports don't support masking. However, you can export out of order to memory locations.

Formatted: Bullets and Numbering

20.3 Position exports

Position exports have to be done IN ORDER and don't support masking.

Formatted: Bullets and Numbering

~~20.~~21. Export Types

The export type (or the location where the data should be put) is specified using the destination address field in the ALU instruction. Here is a list of all possible export modes:

Formatted: Bullets and Numbering

~~20.1~~21.1 Vertex Shading

0:15	- 16 parameter cache
16:31	- Empty (Reserved?)
32:43	- 12 vertex exports to the frame buffer and index
44:47	- Empty
48:59	- 12 debug export (interpret as normal vertex export)
60	- export addressing mode
61	- Empty
62	- position
63	- sprite size export that goes with position export (point_h,point_w,edgeflag,misc)

Formatted: Bullets and Numbering

~~20.2~~21.2 Pixel Shading

0	- Color for buffer 0 (primary)
1	- Color for buffer 1

2	- Color for buffer 2
3	- Color for buffer 3
4:7	- Empty
8	- Buffer 0 Color/Fog (primary)
9	- Buffer 1 Color/Fog
10	- Buffer 2 Color/Fog
11	- Buffer 3 Color/Fog
12:15	- Empty
16:31	- Empty (Reserved?)
32:43	- 12 exports for multipass pixel shaders.
44:47	- Empty
48:59	- 12 debug exports (interpret as normal pixel export)
60	- export addressing mode
61:62	- Empty
63	- Z for primary buffer (Z exported to 'alpha' component)

Formatted: Bullets and Numbering

~~21.~~22. Special Interpolation modes

~~21.1~~22.1 Real time commands

We are unable to use the parameter memory since there is no way for a command stream to write into it. Instead we need to add three 16x128 memories (one for each of three vertices x 16 interpolants). These will be mapped onto the register bus and written by type 0 packets, and output to the the parameter busses (the sequencer and/or PA need to be able to address the realtime parameter memory as well as the regular parameter store. For higher performance we should be able able to view them as two banks of 16 and do double buffering allowing one to be loaded, while the other is rasterized with. Most overlay shaders will need 2 or 4 scalar coordinates, one option might be to restrict the memory to 16x64 or 32x64 allowing only two interpolated scalars per cycle, the only problem I see with this is, if we view support for 16 vector-4 interpolants important (true only if we map Microsoft's high priority stream to the realtime stream), then the PA/sequencer need to support a realtime-specific mode where we need to address 32 vectors of parameters instead of 16. This mode is triggered by the primitive type: REAL TIME. The actual memories are in the in the SX blocks. The parameter data memories are hooked on the RBBM bus and are loaded by the CP using register mapped memory.

Formatted: Bullets and Numbering

~~21.2~~22.2 Sprites/ XY screen coordinates/ FB information

When working with sprites, one may want to overwrite the parameter 0 with SC generated data. Also, XY screen coordinates may be needed in the shader program. This functionality is controlled by the gen_I0 register (in SQ) in conjunction with the SND_XY register (in SC). Also it is possible to send the faceness information (for OGL front/back special operations) to the shader using the same control register. Here is a list of all the modes and how they interact together:

Gen_st is a bit taken from the interface between the SC and the SQ. This is the MSB of the primitive type. If the bit is set, it means we are dealing with Point AA, Line AA or sprite and in this case the vertex values are going to generated between 0 and 1.

Param_Gen_I0 disable, snd_xy disable, no gen_st – I0 = No modification
Param_Gen_I0 disable, snd_xy disable, gen_st – I0 = No modification
Param_Gen_I0 disable, snd_xy enable, no gen_st – I0 = No modification
Param_Gen_I0 disable, snd_xy enable, gen_st – I0 = No modification
Param_Gen_I0 enable, snd_xy disable, no gen_st – I0 = garbage, garbage, garbage, faceness
Param_Gen_I0 enable, snd_xy disable, gen_st – I0 = garbage, garbage, s, t
Param_Gen_I0 enable, snd_xy enable, no gen_st – I0 = screen x, screen y, garbage, faceness
Param_Gen_I0 enable, snd_xy enable, gen_st – I0 = screen x, screen y, s, t

Formatted: Bullets and Numbering

~~21.3~~22.3 Auto generated counters

In the cases we are dealing with multipass shaders, the sequencer is going to generate a vector count to be able to both use this count to write the 1st pass data to memory and then use the count to retrieve the data on the 2nd pass. The count is always generated in the same way but it is passed to the shader in a slightly different way depending on the shader type (pixel or vertex). This is toggled on and off using the GEN_INDEX register. The sequencer is going to keep two counters, one for pixels and one for vertices. Every time a full vector of vertices or pixels is written to the GPRs the counter is incremented. Every time a state change is detected, the corresponding counter is reset. While there is only one count broadcast to the GPRs, the LSB are hardwired to specific values making the index different for all elements in the vector.

~~21.3.1~~22.3.1 *Vertex shaders*

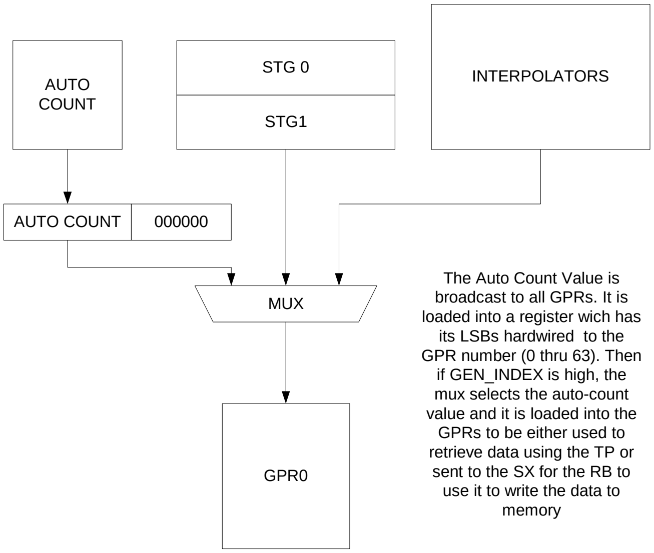
Formatted: Bullets and Numbering

In the case of vertex shaders, if GEN_INDEX is set, the data will be put into the x field of the third register (it means that the compiler must allocate 3 GPRs in all multipass vertex shader modes).

~~21.3.2~~22.3.2 *Pixel shaders*

Formatted: Bullets and Numbering

In the case of pixel shaders, if GEN_INDEX is set and Param_Gen_I0 is enabled, the data will be put in the x field of the 2nd register (R1.x), else if GEN_INDEX is set the data will be put into the x field of the 1st register (R0.x).



The Auto Count Value is broadcast to all GPRs. It is loaded into a register wich has its LSBs hardwired to the GPR number (0 thru 63). Then if GEN_INDEX is high, the mux selects the auto-count value and it is loaded into the GPRs to be either used to retrieve data using the TP or sent to the SX for the RB to use it to write the data to memory

Figure 13: GPR input mux Control

~~22.~~23. State management

Formatted: Bullets and Numbering

Every clock, the sequencer will report to the CP the oldest states still in the pipe. These are the states of the programs as they enter the last ALU clause.

~~22.1~~23.1 Parameter cache synchronization

Formatted: Bullets and Numbering

In order for the sequencer not to begin a group of pixels before the associated group of vertices has finished, the sequencer will keep a 6 bit count per state (for a total of 8 counters). These counters are initialized to 0 and every time a vertex shader exports its data TO THE PARAMETER CACHE, the corresponding pointer is incremented. When the SC sends a new vector of pixels with the SC_SQ_new_vector bit asserted, the sequencer will first check if the count is greater than 0 before accepting the transmission (it will in fact accept the transmission but then lower its ready to receive). Then the sequencer waits for the count to go to one and decrements it. The sequencer can then issue the group of pixels to the interpolators. Every time the state changes, the new state counter is initialized to 0.

~~23.~~24. XY Address imports

Formatted: Bullets and Numbering

The SC will be able to send the XY addresses to the GPRs. It does so by interleaving the writes of the IJs (to the IJ buffer) with XY writes (to the XY buffer). Then when writing the data to the GPRs, the sequencer is going to interpolate the IJ data or pass the XY data thru a Fix→float converter and expander and write the converted values to the GPRs. The Xys are currently SCREEN SPACE COORDINATES. The values in the XY buffers will wrap. See section 22.2~~21.2~~ for details on how to control the interpolation in this mode.

~~23.1~~24.1 Vertex indexes imports

Formatted: Bullets and Numbering

In order to import vertex indexes, we have 16 8x96 staging registers. These are loaded one line at a time by the VGT block (96 bits). They are loaded in floating point format and can be transferred in 4 or 8 clocks to the GPRs.

~~24.~~25. Registers

Formatted: Bullets and Numbering

~~24.1~~25.1 Control

REG_DYNAMIC	Dynamic allocation (pixel/vertex) of the register file on or off.
REG_SIZE_PIX	Size of the register file's pixel portion (minimal size when dynamic allocation turned on)
REG_SIZE_VTX	Size of the register file's vertex portion (minimal size when dynamic allocation turned on)
ARBITRATION_POLICY	policy of the arbitration between vertexes and pixels
INST_STORE_ALLOC	interleaved, separate
INST_BASE_VTX	start point for the vertex instruction store (RT always ends at vertex_base and Begins at 0)
INST_BASE_PIX	start point for the pixel shader instruction store
ONE_THREAD	debug state register. Only allows one program at a time into the GPRs
ONE_ALU	debug state register. Only allows one ALU program at a time to be executed (instead of 2)
INSTRUCTION	This is where the CP puts the base address of the instruction writes and type (auto-incremented on reads/writes) Register mapped
CONSTANTS	512*4 ALU constants + 32*6 Texture state 32 bits registers (logically mapped)
CONSTANTS_RT	256*4 ALU constants + 32*6 texture states? (physically mapped)
CONSTANT_EO_RT	This is the size of the space reserved for real time in the constant store (from 0 to CONSTANT_EO_RT). The re-mapping table operates on the rest of the memory
TSTATE_EO_RT	This is the size of the space reserved for real time in the fetch state store (from 0 to TSTATE_EO_RT). The re-mapping table operates on the rest of the memory
EXPORT_LATE	Controls whether or not we are exporting position from clause 3. If set, position exports occur at clause 7.

~~24.2~~25.2 Context

Formatted: Bullets and Numbering

VS_FETCH_{0…7}	eight 8 bit pointers to the location where each clauses control program is located
VS_ALU_{0…7}	eight 8 bit pointers to the location where each clauses control program is located
PS_FETCH_{0…7}	eight 8 bit pointers to the location where each clauses control program is located
PS_ALU_{0…7}	eight 8 bit pointers to the location where each clauses control program is located
PS_BASE	base pointer for the pixel shader in the instruction store
VS_BASE	base pointer for the vertex shader in the instruction store
VS_CF_SIZE	size of the vertex shader (# of instructions in control program/2)
PS_CF_SIZE	size of the pixel shader (# of instructions in control program/2)
PS_SIZE	size of the pixel shader (cntl+instructions)
VS_SIZE	size of the vertex shader (cntl+instructions)
PS_NUM_REG	number of GPRs to allocate for pixel shader programs
VS_NUM_REG	number of GPRs to allocate for vertex shader programs
PARAM_SHADE	One 16 bit register specifying which parameters are to be gouraud shaded (0 = flat, 1 = gouraud)
PROVO_VERT	0 : vertex 0, 1: vertex 1, 2: vertex 2, 3: Last vertex of the primitive

PARAM_WRAP	64 bits: for which parameters (and channels (xyzw)) do we do the cyl wrapping (0=linear, 1=cylindrical).
PS_EXPORT_MODE	0xxxx : Normal mode 1xxxx : Multipass mode If normal, bbbz where bbb is how many colors (0-4) and z is export z or not If multipass 1-12 exports for color.
~~VS_EXPORT_MASK~~	~~which of the last 6 ALU clauses is exporting (multipass only)~~
VS_EXPORT_MODE	0: position (1 vector), 1: position (2 vectors), 3:multipass
VS_EXPORT _COUNT_{0…6}	Six 4 bit counters representing the # of interpolated parameters exported in clause 7 (located in VS_EXPORT_COUNT_6) OR # of exported vectors to memory per clause in multipass mode (per clause)
PARAM_GEN_I0	Do we overwrite or not the parameter 0 with XY data and generated T and S values
GEN_INDEX	Auto generates an address from 0 to XX. Puts the results into R0-1 for pixel shaders and R2 for vertex shaders
CONST_BASE_VTX (9 bits)	Logical Base address for the constants of the Vertex shader
CONST_BASE_PIX (9 bits)	Logical Base address for the constants of the Pixel shader
CONST_SIZE_PIX (8 bits)	Size of the logical constant store for pixel shaders
CONST_SIZE_VTX (8 bits)	Size of the logical constant store for vertex shaders
INST_PRED_OPTIMIZE	Turns on the predicate bit optimization (if of, conditional_execute_predicates is always executed).
CF_BOOLEANS	256 boolean bits
CF_LOOP_COUNT	32x8 bit counters (number of times we traverse the loop)
CF_LOOP_START	32x8 bit counters (init value used in index computation)
CF_LOOP_STEP	32x8 bit counters (step value used in index computation)

Formatted: Bullets and Numbering

~~25.~~26. DEBUG Registers

~~25.1~~26.1 Context

DB_PROB_ADDR	instruction address where the first problem occurred
DB_PROB_COUNT	number of problems encountered during the execution of the program
DB_PROB_BREAK	break the clause if an error is found.
DB_INST_COUNT	instruction counter for debug method 2
DB_BREAK_ADDR	break address for method number 2
DB_CLAUSE _MODE_ALU_{0…7}	clause mode for debug method 2 (0: normal, 1: addr, 2: kill)
DB_CLAUSE _MODE_FETCH_{0…7}	clause mode for debug method 2 (0: normal, 1: addr, 2: kill)

Formatted: Bullets and Numbering

~~25.2~~26.2 Control

DB_ALUCST_MEMSIZE	Size of the physical ALU constant memory
DB_TSTATE_MEMSIZE	Size of the physical texture state memory

Formatted: Bullets and Numbering

~~26.~~27. Interfaces

~~26.1~~27.1 External Interfaces

Whenever an x is used, it means that the bus is broadcast to all units of the same name. For example, if a bus is named SQ→SPx it means that SQ is going to broadcast the same information to all SP instances.

Formatted: Bullets and Numbering

27.2 SC to SP Interfaces

27.2.1 SC_SP#

Formatted: Bullets and Numbering

There is one of these interfaces at front of each of the SP (buffer to stage pixel interpolators). This interface transmits the I,J data for pixel interpolation. For the entire system, two quads per clock are transferred to the 4 SPs, so each of these 4 interfaces transmits one half of a quad per clock. The interface below describes a half of a quad worth of data.

The actual data which is transferred per quad is
Ref Pix I => S4.20 Floating Point I value
Ref Pix J => S4.20 Floating Point J value
Delta Pix I (x3) => S4.8 Floating Point Delta I value
Delta Pix J (x3) => S4.8 Floating Point Delta J value
This equates to a total of 128 bits which transferred over 2 clocks
and therefor needs an interface 64 bits wide

Additionally, X,Y data (12-bit unsigned fixed) is conditionally sent across this data bus over the same wires in an additional clock. The X,Y data is sent on the lower 24 bits of the data bus with faceness in the msb.
Transfers across these interfaces are synchronized with the SC_SQ IJ Control Bus transfers.

The data transfer across each of these busses is controlled by a IJ_BUF_INUSE_COUNT in the SC. Each time the SC has sent a pixel vector's worth of data to the SPs, he will increment the IJ_BUF_INUSE_COUNT count. Prior to sending the next pixel vectors data, he will check to make sure the count is less than MAX_BUFER_MINUS_2, if not the SC will stall until the SQ returns a pipelined pulse to decrement the count when he has scheduled a buffer free. Note: We could/may optimize for the case of only sending only IJ to use all the buffers to pre-load more. Currently it is planned for the SP to hold 2 double buffers of I,J data and two buffers of X,Y data, so if either X,Y or Centers and Centroids are on, then the SC can send two Buffers.

In at least the initial version, the SC shall send 16 quads per pixel vector even if the vector is not full. This will increment buffer write address pointers correctly all the time. (We may revisit this for both the SX,SP,SQ and add a EndOfVector signal on all interfaces to quit early. We opted for the simple mode first with a belief that only the end of packet and multiple new vector signals should cause a partial vector and that this would not really be significant performance hit.)

Name	**Bits**	**Description**
SC_SP#_data	64	IJ information sent over 2 clocks (or X,Y in 24 LSBs with faceness in upper bit) **Type 0 or 1**, First clock I, second clk J Field ULC URC LLC LRC Bits [63:39] [38:26] [25:13] [12:0] Format SE4M20 SE4M8 SE4M8 SE4M8 **Type 2** Field Face X Y Bits [63] [23:12] [11:0] Format Bit Unsigned Unsigned
SC_SP#_valid	1	Valid
SC_SP#_last_quad	1	This bit will be set on the last transfer of data per quad.
SC_SP#_type	2	0 -> Indicates centroids 1 -> Indicates centers 2 -> Indicates X,Y Data and faceness on data bus The SC shall look at state data to determine how many types to send for the interpolation process.

The # is included for clarity in the spec and will be replaced with a prefix of u#_ in the verilog module statement for the SC and the SP block will have neither because the instantiation will insert the prefix.

27.2.2 SC_SQ

Formatted: Bullets and Numbering

This is the control information sent to the sequencer in order to synchronize and control the interpolation and/or loading data into the GPRs needed to execute a shader program on the sent pixels. This data will be sent over two clocks per transfer with 1 to 16 transfers. Therefore the bus (approx 92 bits) could be folded in half to approx 46 bits.

Name	**Bits**	**Description**
SC_SQ_data	46	Control Data sent to the SQ 1 clk transfers Event – valid data consist of event_id and state_id. Instruct SQ to post an event vector to send state id and event_id through request fifo and onto the reservation stations making sure state id and/or event_id gets back to the CP. Events only follow end of packets so no pixel vectors will be in progress. Empty Quad Mask – Transfer Control data consisting of pc_dealloc or new_vector. Receipt of this is to transfer pc_dealloc or new_vector without any valid quad data. New vector will always be posted to request fifo and pc_dealloc will be attached to any pixel vector outstanding or posted in request fifo if no valid quad outstanding. 2 clk transfers Quad Data Valid – Sending quad data with or without new_vector or pc_dealloc. New vector will be posted to request fifo with or without a pixel vector and pc_dealloc will be posted with a pixel vector unless none is in progress. In this case the pc_dealloc will be posted in the request queue. Filler quads will be transferred with The Quad mask set but the pixel corresponding pixel mask set to zero.
SC_SQ_valid	1	SC sending valid data, 2nd clk could be all zeroes

SC_SQ_data – first clock and second clock transfers are shown in the table below.

Name	**BitField**	**Bits**	**Description**
1st Clock Transfer			
SC_SQ_event	0	1	This transfer is a 1 clock event vector Force quad_mask = new_vector=pc_dealloc=0
SC_SQ_event_id	[2:1]	2	This field identifies the event 0 => denotes an End Of State Event 1 => TBD
SC_SQ_pc_dealloc	3	1	Deallocation token for the Parameter Cache
SC_SQ_new_vector	4	1	The SQ must wait for Vertex shader done count > 0 and after dispatching the Pixel Vector the SQ will decrement the count.
SC_SQ_quad_mask	[8:5]	4	Quad Write mask left to right SP0 => SP3
SC_SQ_end_of_prim	9	1	End Of the primitive
SC_SQ_state_id	[12:10]	3	State/constant pointer (6*3+3)
SC_SQ_pix_mask	[28:13]	16	Valid bits for all pixels SP0=>SP3 (UL,UR,LL,LR)
SC_SQ_prim_type	[31:29]	3	Stippled line and Real time command need to load tex cords from

			alternate buffer 000: Normal 100: Realtime 101: Line AA 110: Point AA (Sprite)
SC_SQ_pc_ptr0	[42:32]	11	Parameter Cache pointer for vertex 0
2nd Clock Transfer			
SC_SQ_pc_ptr1	[10:0]	11	Parameter Cache pointer for vertex 1
SC_SQ_pc_ptr2	[21:11]	11	Parameter Cache pointer for vertex 2
SC_SQ_lod_correct	[45:22]	24	LOD correction per quad (6 bits per quad)

Name	**Bits**	**Description**
SQ_SC_free_buff	1	Pipelined bit that instructs SC to decrement count of buffers in use.
SQ_SC_dec_cntr_cnt	1	Pipelined bit that instructs SC to decrement count of new vector and/or event sent to prevent SC from overflowing SQ interpolator/Reservation request fifo.

The scan converter will submit a partial vector whenever:

1.) He gets a primitive marked with an end of packet signal.

2.) A current pixel vector is being assembled with at least one or more valid quads and the vector has been marked for deallocate when a primitive marked new_vector arrives. The Scan Converter will submit a partial vector (up to 16quads with zero pixel mask to fill out the vector) prior to submitting the new_vector marker\primitive.

(This will prevent a hang which can be demonstrated when all primitives in a packet three vectors are culled except for a one quad primitive that gets marked pc_dealloc (vertices maximum size). In this case two new_vectors are submitted and processed, but then one valid quad with the pc_dealloc creates a vector and then the new would wait for another vertex vector to be processed, but the one being waited for could never export until the pc_dealloc signal made it through and thus the hang.)

Formatted: Bullets and Numbering

~~26.1.1 SC to SQ : IJ Control bus~~

Formatted: Bullets and Numbering

~~This is the control information sent to the sequencer in order to control the IJ fifos and all other information needed to execute a shader program on the sent pixels. This information is sent over 2 clocks, if SENDXY is asserted the next control packet is going to be ignored and XY information is going to be sent on the IJ bus (for the quads that where just sent). All pixels from the group of quads are from the same primitive, all quads of a vector are from the same render state.~~

~~26.1.2 SQ to SP: Interpolator bus~~

Formatted: Bullets and Numbering

~~26.1.3~~27.2.3 SQ to SX: Interpolator bus

Name	**Direction**	**Bits**	**Description**
SQ_~~SPx~~SXx_interp_flat_vtx	SQ→SPx	2	Provoking vertex for flat shading
SQ_S~~P~~Xx_interp_flat_gouraud	SQ→SPx	1	Flat or gouraud shading
SQ_S~~P~~Xx_interp_cyl_wrap	SQ→SPx	4	Wich channel needs to be cylindrical wrapped
SQ_S~~X~~Xx_ptr1~~mux0~~	SQ→SXx	11	Parameter Cache Pointer
SQ_SXx_ptr2~~mux1~~	SQ→SXx	11	Parameter Cache Pointer
SQ_SXx_ptr3~~mux2~~	SQ→SXx	11	Parameter Cache Pointer
SQ_SXx_~~RT_switch~~rt_sel	SQ→SXx	1	Selects between RT and Normal data
SQ_SXx_pc_wr_en	SQ→SXx	1	Write enable for the PC memories
SQ_SXx_pc_wr_addr	SQ→SXx	7	Write address for the PCs
SQ_SXx_pc_cmask	SQ→SXx	4	Channel mask

~~26.1.4~~27.2.4 SQ to SP: Staging Register Data

Formatted: Bullets and Numbering

This is a broadcast bus that sends the VSISR information to the staging registers of the shader pipes.

Name	**Direction**	**Bits**	**Description**

SQ_SPx_~~vgt_vsisr~~vsr_data	SQ→SPx	96	Pointers of indexes or HOS surface information
SQ_SPx_~~vgt_vsisr~~vsr_double	SQ→SPx	1	0: Normal 96 bits per vert 1: double 192 bits per vert
SQ_SP0__~~data_~~valid	SQ→SP0	1	Data is valid
SQ_SP1__~~data_~~valid	SQ→SP1	1	Data is valid
SQ_SP2__~~data_~~valid	SQ→SP2	1	Data is valid
SQ_SP3__~~data_~~valid	SQ→SP3	1	Data is valid

~~26.1.5~~27.2.5 *~~PA~~ VGT to SQ : Vertex interface*

Formatted: Bullets and Numbering

~~26.1.5.1~~27.2.5.1 Interface Signal Table

The area difference between the two methods is not sufficient to warrant complicating the interface or the state requirements of the VSISRs. **Therefore, the POR for this interface is that the VGT will transmit the data to the VSISRs (via the Shader Sequencer) in full, 32-bit floating-point format.** The VGT can transmit up to six 32-bit floating-point values to each VSISR where four or more values require two transmission clocks. The data bus is 96 bits wide.

Name	Bits	Description
~~PA~~VGT_SQ__~~vgt_~~vsisr_data	96	Pointers of indexes or HOS surface information
VGT~~PA~~_SQ__~~vgt_~~vsisr_double	1	0: Normal 96 bits per vert 1: double 192 bits per vert
VGT~~PA_~~_SQ__~~vgt_~~end_of_vector	1	Indicates the last VSISR data set for the current process vector (for double vector data, "end_of_vector" is set on the second vector)
VGT~~PA~~_SQ__~~vgt_vsisr~~indx_valid	1	Vsisr data is valid
VGT~~PA~~_SQ__~~vgt_~~state	3	Render State (6*3+3 for constants). This signal is guaranteed to be correct when "~~PA~~VGT_SQ_vgt_end_of_vector" is high.
VGT~~PA~~_SQ__~~vgt_~~send	1	Data on the VGT_SQ is valid receive (see write-up for standard R400 SEND/RTR interface handshaking)
SQ_VGT_~~PA_vgt_~~rtr	1	Ready to receive (see write-up for standard R400 SEND/RTR interface handshaking)

~~26.1.6~~27.2.6 SQ to CP: State report

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
SQ_CP_vrtx_ state	SEQ→CP	3	Oldest vertex state still in the pipe
SQ_CP_pix_state	SEQ→CP	3	Oldest pixel state still in the pipe

~~26.1.7~~27.2.7 SQ to SX: Control bus

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
SQ_SXx_exp_~~Pixel~~pix	SQ→SXx	1	1: Pixel 0: Vertex
SQ_SXx_exp_c~~C~~lause	SQ→SXx	3	Clause number, which is needed for vertex clauses
SQ_SXx_exp_s~~S~~tate	SQ→SXx	3	State ID
SQ_SXx_exp_~~exportID~~alu_id	SQ→SXx	1	ALU ID

These fields are sent ~~synchronously with SP export data, described in SP0 →SX0 interface~~every time the sequencer picks an exporting clause for execution.

~~26.1.8~~27.2.8 SX to SQ : Output file control

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
SXx_SQ_~~Export~~exp_count_rdy	SXx→SQ	1	Raised by SX0 to indicate that the following two fields reflect the result of the most recent export
SXx_SQ_~~Export~~exp_~~P~~position_space	SXx→SQ	1	Specifies whether there is room for another position.
SXx_SQ_exp~~Export~~_b~~B~~uffer_space	SXx→SQ	7	Specifies the space available in the output buffers. 0: buffers are full 1: 2K-bits available (32-bits for each of the 64 pixels in a clause) ... 64: 128K-bits available (16 128-bit entries for each of 64 pixels) 65-127: RESERVED

~~26.1.9~~27.2.9 SQ to TP: Control bus

Formatted: Bullets and Numbering

Once every clock, the fetch unit sends to the sequencer on which clause it is now working and if the data in the GPRs is ready or not. This way the sequencer can update the fetch counters for the reservation station fifos. The sequencer also provides the instruction and constants for the fetch to execute and the address in the register file where to write the fetch return data.

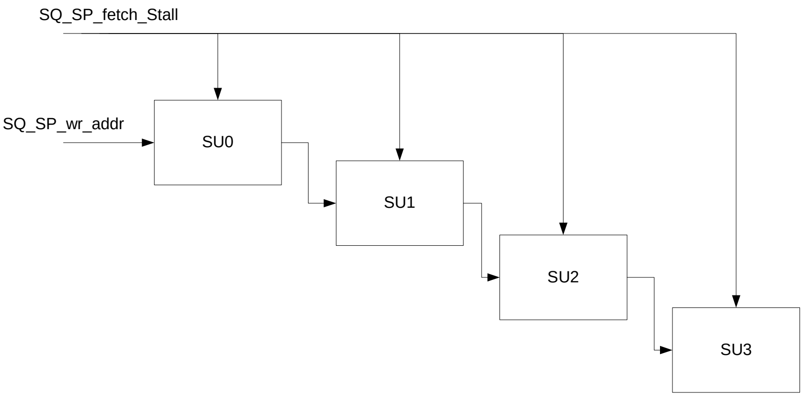
Name	Direction	Bits	Description
TPx_SQ_data_rdy	TPx→ SQ	1	Data ready
TPx_SQ_clause_num	TPx→ SQ	3	Clause number
TPx_SQ_t~~T~~ype	TPx→ SQ	1	Type of data sent (0:PIXEL, 1:VERTEX)
SQ_TPx_send	SQ→TPx	1	Sending valid data
SQ_TPx_const	SQ→TPx	48	Fetch state sent over 4 clocks (192 bits total)
SQ_TPx_~~instuct~~instr	SQ→TPx	24	Fetch instruction sent over 4 clocks
SQ_TPx_end_of_clause	SQ→TPx	1	Last instruction of the clause
SQ_TPx_Type	SQ→TPx	1	Type of data sent (0:PIXEL, 1:VERTEX)
SQ_TPx_phase	SQ→TPx	2	Write phase signal
SQ_TP0_lod_correct	SQ→TP0	6	LOD correct 3 bits per comp 2 components per quad
SQ_TP0_pmask	SQ→TP0	4	Pixel mask 1 bit per pixel
SQ_TP1_lod_correct	SQ→TP1	6	LOD correct 3 bits per comp 2 components per quad
SQ_TP1_pmask	SQ→TP1	4	Pixel mask 1 bit per pixel
SQ_TP2_lod_correct	SQ→TP2	6	LOD correct 3 bits per comp 2 components per quad

SQ_TP2_pmask	SQ→TP2	4	Pixel mask 1 bit per pixel
SQ_TP3_lod_correct	SQ→TP3	6	LOD correct 3 bits per comp 2 components per quad
SQ_TP3_pmask	SQ→TP3	4	Pixel mask 1 bit per pixel
SQ_TPx_clause_num	SQ→TPx	3	Clause number
SQ_TPx_write_gpr_index	SQ->TPx	7	Index into Register file for write of returned Fetch Data

~~26.1.10~~27.2.10 *TP to SQ: Texture stall*

Formatted: Bullets and Numbering

The TP sends this signal to the SQ when its input buffer is full. The SQ is going to send it to the SP X clocks after reception (maximum of 3 clocks of pipeline delay).



Name	Direction	Bits	Description
TP_SQ_fetch_stall	TP→ SQ	1	Do not send more texture request if asserted

~~26.1.11~~27.2.11 *SQ to SP: Texture stall*

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
SQ_SPx_fetch_stall	SQ→SPx	1	Do not send more texture request if asserted

~~26.1.12~~27.2.12 *SQ to SP: GPR~~, Parameter cache control~~ and auto counter*

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
SQ_SPx_gpr_wr_addr	SQ→SPx	7	Write address
SQ_SPx_gpr_rd_addr	SQ→SPx	7	Read address
SQ_SPx_gpr_r~~e~~d_~~addr~~en	SQ→SPx	1	Read Enable
SQ_SPx_gpr_~~we~~wr_~~addr~~en	SQ→SPx	1	Write Enable for the GPRs
SQ_SPx_gpr_phase_mux	SQ→SPx	2	The phase mux (arbitrates between inputs, ALU SRC reads and writes)
SQ_SPx_channel_mask	SQ→SPx	4	The channel mask
SQ_SP0_pixel_mask	SQ→SP0	4	The pixel mask
SQ_SP1_pixel_mask	SQ→SP1	4	The pixel mask
SQ_SP2_pixel_mask	SQ→SP2	4	The pixel mask
SQ_SP3_pixel_mask	SQ→SP3	4	The pixel mask
SQ_SPx_gpr_input_mux	SQ→SPx	2	When the phase mux selects the inputs this tells from which source to read from: Interpolated data, VTX0, VTX1, autogen counter.
SQ_SPx_~~index~~auto_count	SQ→SPx	12?	~~Index~~ Auto count generated by the SQ, common for all shader pipes

~~26.1.13~~27.2.13 SQ to SPx: Instructions

Formatted: Bullets and Numbering

Name	Direction	Bits	Description

SQ_SPx_stall	SQ→SPx	1	Stall signal
SQ_SP0_exp~~ort~~_pvalid	SQ→SP0	4	Result of pixel kill in the shader pipe, which must be output for all pixel exports (depth and all color buffers). 4x4 because 16 pixels are computed per clock
SQ_SP1_ exp~~ort~~_pvalid	SQ→SP1	4	Result of pixel kill in the shader pipe, which must be output for all pixel exports (depth and all color buffers). 4x4 because 16 pixels are computed per clock
SQ_SP2_ exp~~ort~~_pvalid	SQ→SP2	4	Result of pixel kill in the shader pipe, which must be output for all pixel exports (depth and all color buffers). 4x4 because 16 pixels are computed per clock
SQ_SP3_ exp~~ort~~_pvalid	SQ→SP3	4	Result of pixel kill in the shader pipe, which must be output for all pixel exports (depth and all color buffers). 4x4 because 16 pixels are computed per clock

~~26.1.14~~27.2.14 SP to SQ: Constant address load/ Predicate Set

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
SP0_SQ_const_addr	SP0→SQ	36	Constant address load / predicate vector load (4 bits only) to the sequencer
SP0_SQ_valid	SP0→SQ	1	Data valid
SP1_SQ_const_addr	SP1→SQ	36	Constant address load / predicate vector load (4 bits only) to the sequencer

SP1_SQ_valid	SP1→SQ	1	Data valid
SP2_SQ_const_addr	SP2→SQ	36	Constant address load / predicate vector load (4 bits only) to the sequencer
SP2_SQ_valid	SP2→SQ	1	Data valid
SP3_SQ_const_addr	SP3→SQ	36	Constant address load / predicate vector load (4 bits only) to the sequencer
SP3_SQ_valid	SP3→SQ	1	Data valid

~~26.1.15~~27.2.15 *SQ to SPx: constant broadcast*

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
SQ_SPx_constt~~tant~~	SQ→SPx	128	Constant broadcast

~~26.1.16~~27.2.16 *SP0 to SQ: Kill vector load*

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
SP0_SQ_kill_vect	SP0→SQ	4	Kill vector load
SP1_SQ_kill_vect	SP1→SQ	4	Kill vector load
SP2_SQ_kill_vect	SP2→SQ	4	Kill vector load
SP3_SQ_kill_vect	SP3→SQ	4	Kill vector load

~~26.1.17~~27.2.17 *SQ to CP: RBBM bus*

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
SQ_RBB_rs	SQ→CP	1	Read Strobe
SQ_RBB_rd	SQ→CP	32	Read Data
SQ_RBBM_nrtrtr	SQ→CP	1	Optional
SQ_RBBM_rtr	SQ→CP	1	Real-Time (Optional)

~~26.1.18~~27.2.18 *CP to SQ: RBBM bus*

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
rbbm_we	CP→SQ	1	Write Enable
rbbm_a	CP→SQ	15	Address -- Upper Extent is TBD (16:2)
rbbm_wd	CP→SQ	32	Data
rbbm_be	CP→SQ	4	Byte Enables
rbbm_re	CP→SQ	1	Read Enable
rbb_rs0	CP→SQ	1	Read Return Strobe 0
rbb_rs1	CP→SQ	1	Read Return Strobe 1
rbb_rd0	CP→SQ	32	Read Data 0
rbb_rd1	CP→SQ	32	Read Data 0
RBBM_SQ_soft_reset	CP→SQ	1	Soft Reset

~~27.~~28. Examples of program executions

Formatted: Bullets and Numbering

~~27.1.1~~28.1.1 *Sequencer Control of a Vector of Vertices*

1. PA sends a vector of 64 vertices (actually vertex indices – 32 bits/index for 2048 bit total) to the RE's Vertex FIFO
   - state pointer as well as tag into position cache is sent along with vertices
   - space was allocated in the position cache for transformed position before the vector was sent
   - **also before the vector is sent to the RE, the CP has loaded the global instruction store with the vertex shader program (using the MH?)**
   - The vertex program is assumed to be loaded when we receive the vertex vector.
     - the SEQ then accesses the IS base for this shader using the local state pointer (provided to all sequencers by the RBBM when the CP is done loading the program)
2. SEQ arbitrates between the Pixel FIFO and the Vertex FIFO – basically the Vertex FIFO always has priority
   - at this point the vector is removed from the Vertex FIFO

- the arbiter is not going to select a vector to be transformed if the parameter cache is full unless the pipe as nothing else to do (ie no pixels are in the pixel fifo).

3. SEQ allocates space in the SP register file for index data plus GPRs used by the program
   - the number of GPRs required by the program is stored in a local state register, which is accessed using the state pointer that came down with the vertices
   - SEQ will not send vertex data until space in the register file has been allocated

4. SEQ sends the vector to the SP register file over the RE_SP interface (which has a bandwidth of 2048 bits/cycle)
   - the 64 vertex indices are sent to the 64 register files over 4 cycles
     - RF0 of SU0, SU1, SU2, and SU3 is written the first cycle
     - RF1 of SU0, SU1, SU2, and SU3 is written the second cycle
     - RF2 of SU0, SU1, SU2, and SU3 is written the third cycle
     - RF3 of SU0, SU1, SU2, and SU3 is written the fourth cycle
   - the index is written to the least significant 32 bits **(floating point format?) (what about compound indices)** of the 128-bit location within the register file (w); the remaining data bits are set to zero (x, y, z)

5. SEQ constructs a control packet for the vector and sends it to the first reservation station (the FIFO in front of fetch state machine 0, or TSM0 FIFO)
   - the control packet contains the state pointer, the tag to the position cache and a register file base pointer.

6. TSM0 accepts the control packet and fetches the instructions for fetch clause 0 from the global instruction store
   - TSM0 was first selected by the TSM arbiter before it could start

7. all instructions of fetch clause 0 are issued by TSM0

8. the control packet is passed to the next reservation station (the FIFO in front of ALU state machine 0, or ASM0 FIFO)
   - TSM0 does not wait for requests made to the Fetch Unit to complete; it passes the register file write index for the fetch data to the TU, which will write the data to the RF as it is received
   - once the TU has written all the data to the register files, it increments a counter that is associated with ASM0 FIFO; a count greater than zero indicates that the ALU state machine can go ahead start to execute the ALU clause

9. ASM0 accepts the control packet (after being selected by the ASM arbiter) and gets the instructions for ALU clause 0 from the global instruction store

10. all instructions of ALU clause 0 are issued by ASM0, then the control packet is passed to the next reservation station (the FIFO in front of fetch state machine 1, or TSM1 FIFO)

11. the control packet continues to travel down the path of reservation stations until all clauses have been executed
    - position can be exported in ALU clause 3 (or 4?); the data (and the tag) is sent over a position bus (which is shared with all four shader pipes) back to the PA's position cache
    - A parameter cache pointer is also sent along with the position data. This tells to the PA where the data is going to be in the parameter cache.
      - there is a position export FIFO in the SP that buffers position data before it gets sent back to the PA
      - the ASM arbiter will prevent a packet from starting an exporting clause if the position export FIFO is full
    - parameter data is exported in clause 7 (as well as position data if it was not exported earlier)
      - parameter data is sent to the Parameter Cache over a dedicated bus
      - the SEQ allocates storage in the Parameter Cache, and the SEQ deallocates that space when there is no longer a need for the parameters (it is told by the PA when using a token).
      - the ASM arbiter will prevent a packet from starting on ASM7 if the parameter cache (or the position buffer if position is being exported) is full

12. after the shader program has completed, the SEQ will free up the GPRs so that they can be used by another shader program

~~27.1.2~~28.1.2 *Sequencer Control of a Vector of Pixels*

Formatted: Bullets and Numbering

1. **As with vertex shader programs, pixel shaders are loaded into the global instruction store by the CP**
   - At this point it is assumed that the pixel program is loaded into the instruction store and thus ready to be read.

2. the RE’s Pixel FIFO is loaded with the barycentric coordinates for pixel quads by the detailed walker
   - the state pointer and the LOD correction bits are also placed in the Pixel FIF0
   - the Pixel FIFO is wide enough to source four quad’s worth of barycentrics per cycle
3. SEQ arbitrates between Pixel FIFO and Vertex FIFO – when there are no vertices pending OR there is no space left in the register files for vertices, the Pixel FIFO is selected
4. SEQ allocates space in the SP register file for all the GPRs used by the program
   - the number of GPRs required by the program is stored in a local state register, which is accessed using the state pointer
   - SEQ will not allow interpolated data to be sent to the shader until space in the register file has been allocated
5. SEQ controls the transfer of interpolated data to the SP register file over the RE_SP interface (which has a bandwidth of 2048 bits/cycle). See interpolated data bus diagrams for details.
6. SEQ constructs a control packet for the vector and sends it to the first reservation station (the FIFO in front of fetch state machine 0, or TSM0 FIFO)
   - note that there is a separate set of reservation stations/arbiters/state machines for vertices and for pixels
   - the control packet contains the state pointer, the register file base pointer, and the LOD correction bits
   - all other information (such as quad address for example) travels in a separate FIFO
7. TSM0 accepts the control packet and fetches the instructions for fetch clause 0 from the global instruction store
   - TSM0 was first selected by the TSM arbiter before it could start
8. all instructions of fetch clause 0 are issued by TSM0
9. the control packet is passed to the next reservation station (the FIFO in front of ALU state machine 0, or ASM0 FIFO)
   - TSM0 does not wait for fetch requests made to the Fetch Unit to complete; it passes the register file write index for the fetch data to the TU, which will write the data to the RF as it is received
   - once the TU has written all the data for a particular clause to the register files, it increments a counter that is associated with the ASM0 FIFO; a count greater than zero indicates that the ALU state machine can go ahead and pop the FIFO and start to execute the ALU clause
10. ASM0 accepts the control packet (after being selected by the ASM arbiter) and gets the instructions for ALU clause 0 from the global instruction store
11. all instructions of ALU clause 0 are issued by ASM0, then the control packet is passed to the next reservation station (the FIFO in front of fetch state machine 1, or TSM1 FIFO)
12. the control packet continues to travel down the path of reservation stations until all clauses have been executed
    - pixel data is exported in the last ALU clause (clause 7)
      - it is sent to an output FIFO where it will be picked up by the render backend
      - the ASM arbiter will prevent a packet from starting on ASM7 if the output FIFO is full
13. after the shader program has completed, the SEQ will free up the GPRs so that they can be used by another shader program

~~27.1.3~~28.1.3 *Notes*

Formatted: Bullets and Numbering

14. The state machines and arbiters will operate ahead of time so that they will be able to immediately start the real threads or stall.
15. The register file base pointer for a vector needs to travel with the vector through the reservation stations, but the instruction store base pointer does not – this is because the RF pointer is different for all threads, but the IS pointer is only different for each state and thus can be accessed via the state pointer.

~~28.~~29. Open issues

Formatted: Bullets and Numbering

Need to do some testing on the size of the register file as well as on the register file allocation method (dynamic VS static).

Saving power?

Parameter caches in SX?

Using both IJ buffers for center + centroid interpolation?

R400 Sequencer Specification

SQ

Version 1.11~~0~~

Overview: This is an architectural specification for the R400 Sequencer block (SEQ). It provides an overview of the required capabilities and expected uses of the block. It also describes the block interfaces, internal sub-blocks, and provides internal state diagrams.

Revision Changes:

Rev 0.1 (Laurent Lefebvre) Date: May 7, 2001	First draft.
Rev 0.2 (Laurent Lefebvre) Date : July 9, 2001	Changed the interfaces to reflect the changes in the SP. Added some details in the arbitration section.
Rev 0.3 (Laurent Lefebvre) Date : August 6, 2001	Reviewed the Sequencer spec after the meeting on August 3, 2001.
Rev 0.4 (Laurent Lefebvre) Date : August 24, 2001	Added the dynamic allocation method for register file and an example (written in part by Vic) of the flow of pixels/vertices in the sequencer.
Rev 0.5 (Laurent Lefebvre) Date : September 7, 2001	Added timing diagrams (Vic)
Rev 0.6 (Laurent Lefebvre) Date : September 24, 2001	Changed the spec to reflect the new R400 architecture. Added interfaces.
Rev 0.7 (Laurent Lefebvre) Date : October 5, 2001	Added constant store management, instruction store management, control flow management and data dependant predication.
Rev 0.8 (Laurent Lefebvre) Date : October 8, 2001	Changed the control flow method to be more flexible. Also updated the external interfaces.
Rev 0.9 (Laurent Lefebvre) Date : October 17, 2001	Incorporated changes made in the 10/18/01 control flow meeting. Added a NOP instruction, removed the conditional_execute_or_jump. Added debug registers.
Rev 1.0 (Laurent Lefebvre) Date : October 19, 2001	Refined interfaces to RB. Added state registers.
Rev 1.1 (Laurent Lefebvre) Date : October 26, 2001	Added SEQ→SP0 interfaces. Changed delta precision. Changed VGT→SP0 interface. Debug Methods added.
Rev 1.2 (Laurent Lefebvre) Date : November 16, 2001	Interfaces greatly refined. Cleaned up the spec.
Rev 1.3 (Laurent Lefebvre) Date : November 26, 2001	Added the different interpolation modes.
Rev 1.4 (Laurent Lefebvre) Date : December 6, 2001	Added the auto incrementing counters. Changed the VGT→SQ interface. Added content on constant management. Updated GPRs.
Rev 1.5 (Laurent Lefebvre) Date : December 11, 2001	Removed from the spec all interfaces that weren't directly tied to the SQ. Added explanations on constant management. Added PA→SQ synchronization fields and explanation.
Rev 1.6 (Laurent Lefebvre) Date : January 7, 2002	Added more details on the staging register. Added detail about the parameter caches. Changed the call instruction to a Conditionnal_call instruction. Added details on constant management and updated the diagram.
Rev 1.7 (Laurent Lefebvre) Date : February 4, 2002	Added Real Time parameter control in the SX interface. Updated the control flow section.
Rev 1.8 (Laurent Lefebvre) Date : March 4, 2002	New interfaces to the SX block. Added the end of clause modifier, removed the end of clause instructions.
Rev 1.9 (Laurent Lefebvre) Date : March 18, 2002	Rearangement of the CF instruction bits in order to ensure byte alignement.
Rev 1.10 (Laurent Lefebvre) Date : March 25, 2002	Updated the interfaces and added a section on exporting rules.
Rev 1.11 (Laurent Lefebvre) Date :	Added CP state report interface. Last version of the spec with the old control flow scheme

1. Overview

The sequencer is based on the R300 design. It chooses two ALU clauses and a fetch clause to execute, and executes all of the instructions in a clause before looking for a new clause of the same type. Two ALU clauses are executed interleaved to hide the ALU latency. Each vector will have eight fetch and eight ALU clauses, but clauses do not need to contain instructions. A vector of pixels or vertices ping-pongs along the sequencer FIFO, bouncing from fetch reservation station to alu reservation station. A FIFO exists between each reservation stage, holding up vectors until the vector currently occupying a reservation station has left. A vector at a reservation station can be chosen to execute. The sequencer looks at all eight alu reservation stations to choose an alu clause to execute and all eight fetch stations to choose a fetch clause to execute. The arbitrator will give priority to clauses/reservation stations closer to the bottom of the pipeline. It will not execute an alu clause until the fetch fetches initiated by the previous fetch clause have completed. There are two separate sets of reservation stations, one for pixel vectors and one for vertices vectors. This way a pixel can pass a vertex and a vertex can pass a pixel.

To support the shader pipe the sequencer also contains the shader instruction cache, constant store, control flow constants and texture state. The four shader pipes also execute the same instruction thus there is only one sequencer for the whole chip.

The sequencer first arbitrates between vectors of 64 vertices that arrive directly from primitive assembly and vectors of 16 quads (64 pixels) that are generated in the scan converter.

The vertex or pixel program specifies how many GPRs it needs to execute. The sequencer will not start the next vector until the needed space is available in the GPRs.

Figure 2: Reservation stations and arbiters

There are two sets of the above figure, one for vertices and one for pixels.

Depending on the arbitration state, the sequencer will either choose a vertex or a pixel packet. The control packet consists of 3 bits of state, 7 bits for the base address of the Shader program and some information on the coverage to determine fetch LOD plus other various small state bits.

On receipt of a packet, the input state machine (not pictured but just before the first FIFO) allocated enough space in the GPRs to store the interpolated values and temporaries. Following this, the barycentric coordinates (and XY screen position if needed) are sent to the interpolator, which will use them to interpolate the parameters and place the results into the GPRs. Then, the input state machine stacks the packet in the first FIFO.

On receipt of a command, the level 0 fetch machine issues a fetch request to the TP and corresponding GPR address for the fetch address (ta). A small command (tcmd) is passed to the fetch system identifying the current level number (0) as well as the GPR write address for the fetch return data. One fetch request is sent every 4 clocks causing the texturing of sixteen 2x2s worth of data (or 64 vertices). Once all the requests are sent the packet is put in FIFO 1.

Upon receipt of the return data, the fetch unit writes the data to the register file using the write address that was provided by the level 0 fetch machine and sends the clause number (0) to the level 0 fetch state machine to signify that the write is done and thus the data is ready. Then, the level 0 fetch machine increments the counter of FIFO 1 to signify to the ALU 0 that the data is ready to be processed.

On receipt of a command, the level 0 ALU machine first decrements the input FIFO 1 counter and then issues a complete set of level 0 shader instructions. For each instruction, the ALU state machine generates 3 source addresses, one destination address and an instruction. Once the last instruction has been issued, the packet is put into FIFO 2.

There will always be two active ALU clauses at any given time (and two arbiters). One arbiter will arbitrate over the odd instructions (4 clocks cycles) and the other one will arbitrate over the even instructions (4 clocks cycles). The only constraints between the two arbiters is that they are not allowed to pick the same clause number as the other one is currently working on if the packet is not of the same type (render state).

If the packet is a vertex packet, upon reaching ALU clause 3, it can export the position if the position is ready. So the arbiter must prevent ALU clause 3 to be selected if the positional buffer is full (or can't be accessed). Along with the positional data, if needed the sprite size and/or edge flags can also be sent.

A special case is for multipass vertex shaders, which can export 12 parameters per last 6 clauses to the output buffer. If the output buffer is full or doesn't have enough space the sequencer will prevent such a vertex group to enter an exporting clause.

Multipass pixel shaders can export 12 parameters to memory from the last clause only (7).

All other clauses process in the same way until the packet finally reaches the last ALU machine (7).

Only one pair of interleaved ALU state machines may have access to the register file address bus or the instruction decode bus at one time. Similarly, only one fetch state machine may have access to the register file address bus at one time. Arbitration is performed by three arbiter blocks (two for the ALU state machines and one for the fetch state machines). The arbiters always favor the higher number state machines, preventing a bunch of half finished jobs from clogging up the register files.

1.2 Data Flow graph (SP)

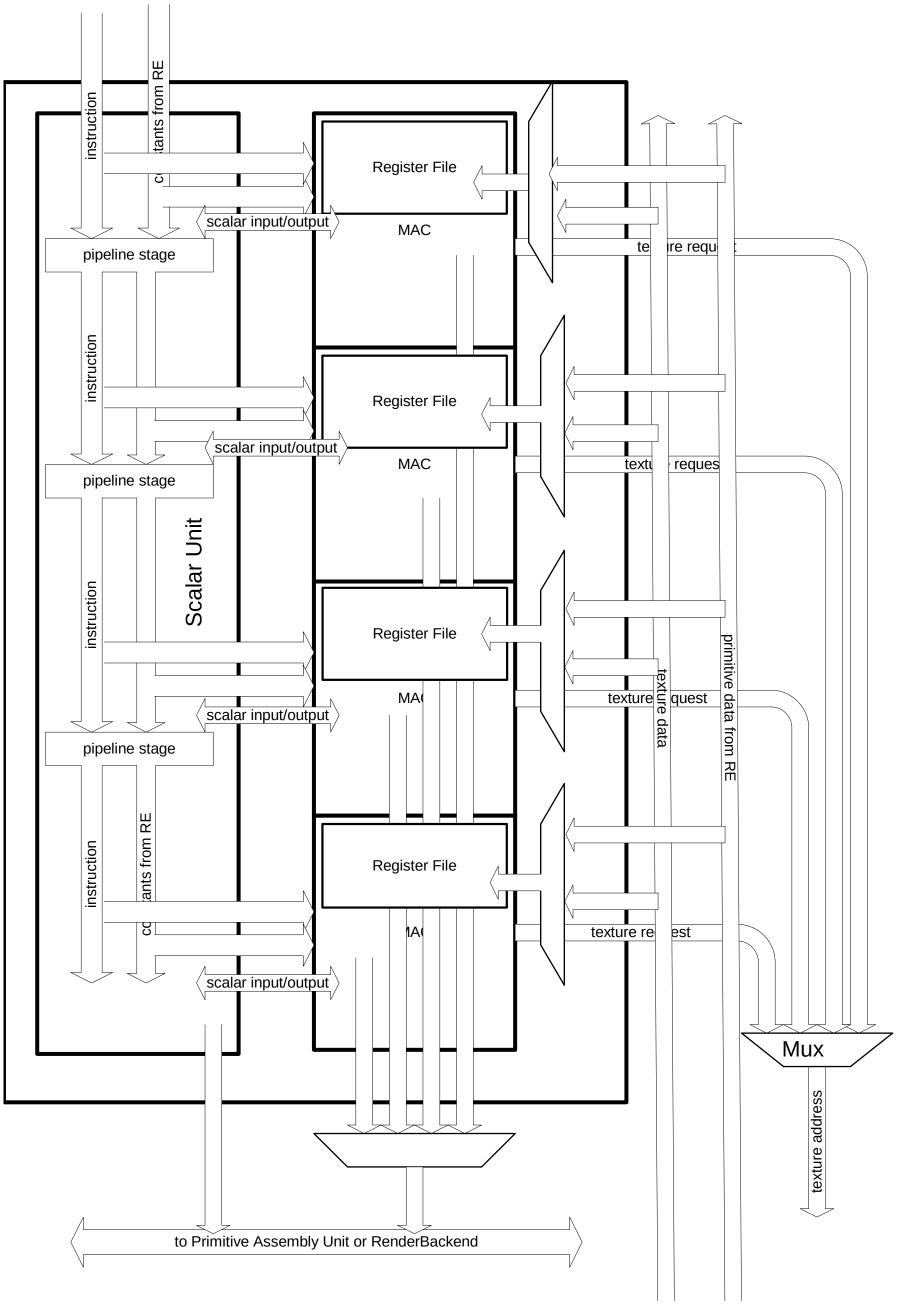

Figure 3: The shader Pipe

The gray area represents blocks that are replicated 4 times per shader pipe (16 times on the overall chip).

Figure 6: Interpolation timing diagram

Above is an example of a tile the sequencer might receive from the SC. The write side is how the data get stacked into the XY and IJ buffers, the read side is how the data is passed to the GPRs. The IJ information is packed in the IJ buffer 4 quads at a time or two clocks. The sequencer allows at any given time as many as four quads to interpolate a parameter. They all have to come from the same primitive. Then the sequencer controls the write mask to the GPRs to write the valid data in.

3. Instruction Store

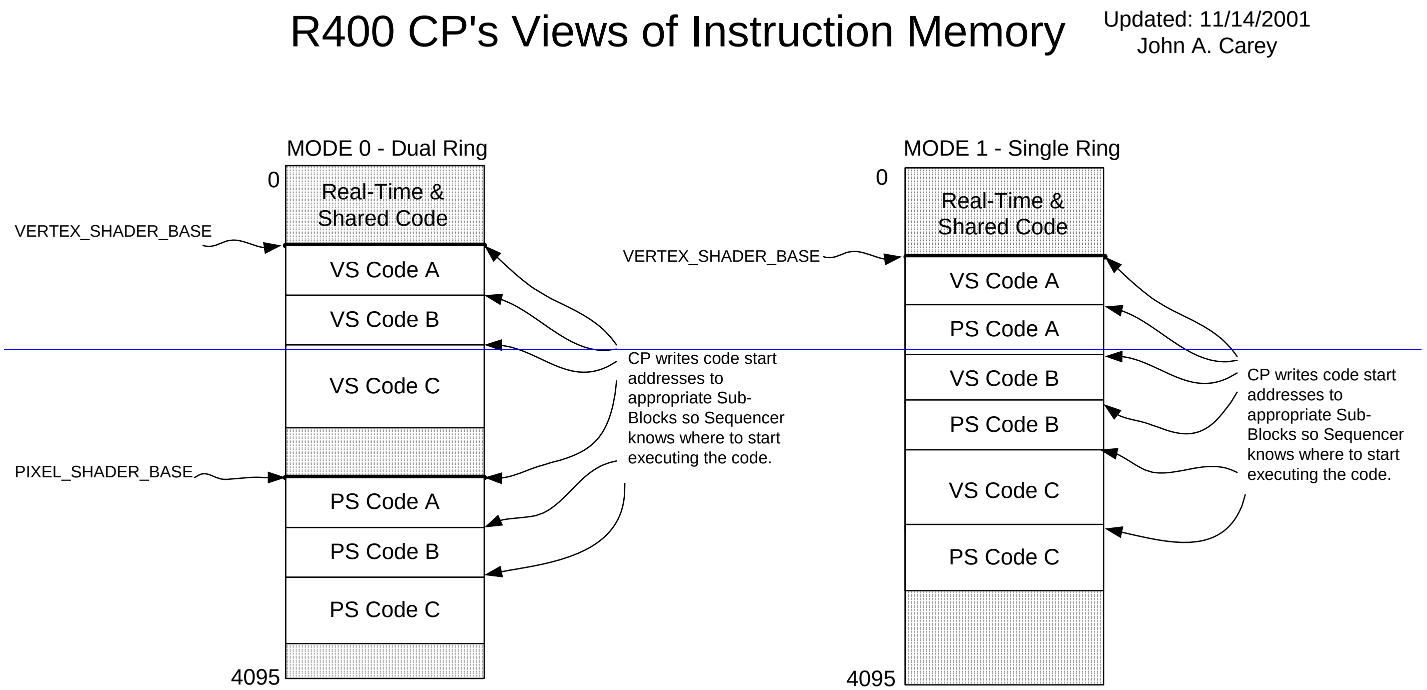
There is going to be only one instruction store for the whole chip. It will contain 4096 instructions of 96 bits each.

It is likely to be a 1 port memory; we use 1 clock to load the ALU instruction, 1 clocks to load the Fetch instruction, 1 clock to load 2 control flow instructions and 1 clock to write instructions.

The instruction store is loaded by the CP thru the register mapped registers.

~~The next picture shows the various modes the CP can load the memory. The Sequencer has to keep track of the loading modes in order to wrap around the correct boundaries. The wrap-around points are arbitrary and they are specified in the VS_BASE and PIX_BASE control registers.~~ The VS_BASE and PS_BASE context registers are used to specify for each context where its shader is in the instruction memory.

For the Real time commands the story is quite the same but for some small differences. There are no wrap-around points for real time so the driver must be careful not to overwrite regular shader data. The shared code (shared subroutines) uses the same path as real time.



4. Figure 7: The CP's view of the instruction memory

Formatted: Bullets and Numbering

~~5.~~4. Sequencer Instructions

All control flow instructions and move instructions are handled by the sequencer only. The ALUs will perform NOPs during this time (MOV PV,PV, PS,PS) if they have nothing else to do.

~~6.~~5. Constant Stores

~~6.1~~5.1 Memory organizations

A likely size for the ALU constant store is 1024x128 bits. The read BW from the ALU constant store is 128 bits/clock and the write bandwidth is 32 bits/clock (directed by the CP bus size not by memory ports).

The maximum logical size of the constant store for a given shader is 256 constants. Or 512 for the pixel/vertex shader pair. The size of the re-mapping table is 128 lines (each line addresses 4 constants). The write granularity is 4 constants or 512 bits. It takes 16 clocks to write the four constants. Real time requires 256 lines in the physical memory (this is physically register mapped).

The texture state is also kept in a similar memory. The size of this memory is 320x96 bits (128 texture states for regular mode, 32 states for RT). The memory thus holds 128 texture states (192 bits per state). The logical size exposes 32 different states total, which are going to be shared between the pixel and the vertex shader. The size of the re-mapping table to for the texture state memory is 32 lines (each line addresses 1 texture state lines in the real memory). The CP write granularity is 1 texture state lines (or 192 bits). The driver sends 512 bits but the CP ignores the top 320 bits. It thus takes 6 clocks to write the texture state. Real time requires 32 lines in the physical memory (this is physically register mapped).

The control flow constant memory doesn't sit behind a renaming table. It is register mapped and thus the driver must reload its content each time there is a change in the control flow constants. Its size is 320*32 because it must hold 8 copies of the 32 dwords of control flow constants and the loop construct constants must be aligned.

The constant re-mapping tables for texture state and ALU constants are logically register mapped for regular mode and physically register mapped for RT operation.

~~6.2~~5.2 Management of the Control Flow Constants

The control flow constants are register mapped, thus the CP writes to the according register to set the constant, the SQ decodes the address and writes to the block pointed by its current base pointer (CF_WR_BASE). On the read side, one level of indirection is used. A register (SQ_CONTEXT_MISC.CF_RD_BASE) keeps the current base pointer to the control flow block. This register is copied whenever there is a state change. Should the CP write to CF after the state change, the base register is updated with the (current pointer number +1)% number of states. This way, if the CP doesn't write to CF the state is going to use the previous CF constants.

~~6.3~~5.3 Management of the re-mapping tables

~~6.3.1~~5.3.1 *R400 Constant management*

The sequencer is responsible to manage two re-mapping tables (one for the constant store and one for the texture state). On a state change (by the driver), the sequencer will broadside copy the contents of its re-mapping tables to a new one. We have 8 different re-mapping tables we can use concurrently.

The constant memory update will be incremental, the driver only need to update the constants that actually changed between the two state changes.

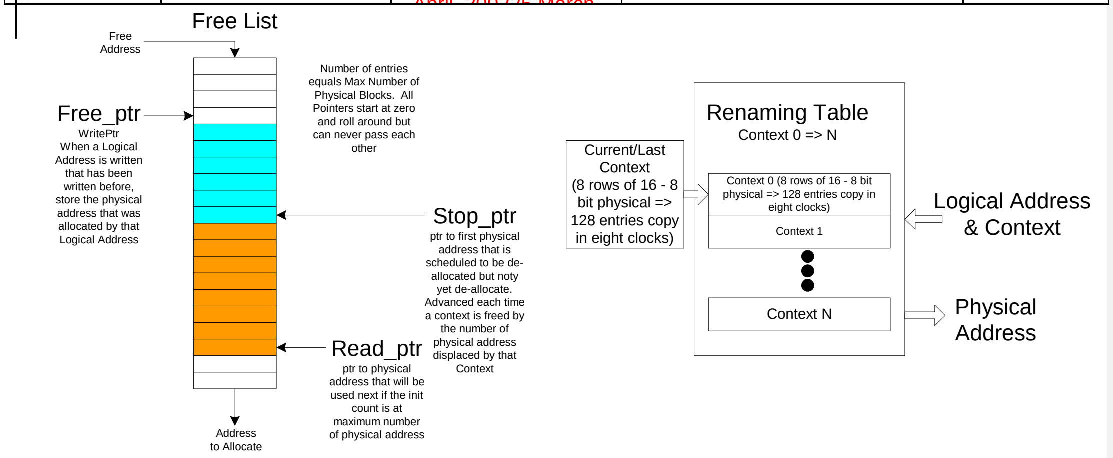
For this model to work in its simplest form, the requirement is that the physical memory MUST be at least twice as large as the logical address space + the space allocated for Real Time. In our case, since the logical address space

is 512 and the reserved RT space can be up to 256 entries, the memory must be of sizes 1280 and above. Similarly the size of the texture store must be of 32*2+32 = 96 entries and above.

~~6.3.2~~5.3.2 Proposal for R400LE constant management

To make this scheme work with only 512+256 = 768 entries, upon reception of a CONTROL packet of state + 1, the sequencer would check for SQ_IDLE and PA_IDLE and if both are idle will erase the content of state to replace it with the new state (this is depicted in Figure 8: De-allocation mechanism~~Figure 9: De-allocation mechanism~~~~Figure 9: De-allocation mechanism~~). Note that in the case a state is cleared a value of 0 is written to the corresponding de-allocation counter location so that when the SQ is going to report a state change, nothing will be de-allocated upon the first report.

The second path sets all context dirty bits that were used in the current state to 1 (thus allowing the new state to reuse these physical addresses if needed).



Free List
Free Address
Free_ptr
WritePtr
When a Logical Address is written that has been written before, store the physical address that was allocated by that Logical Address
Number of entries equals Max Number of Physical Blocks. All Pointers start at zero and roll around but can never pass each other
Stop_ptr
ptr to first physical address that is scheduled to be de-allocated but noty yet de-allocate. Advanced each time a context is freed by the number of physical address displaced by that Context
Read_ptr
ptr to physical address that will be used next if the init count is at maximum number of physical address

Figure 7~~8~~: Constant management

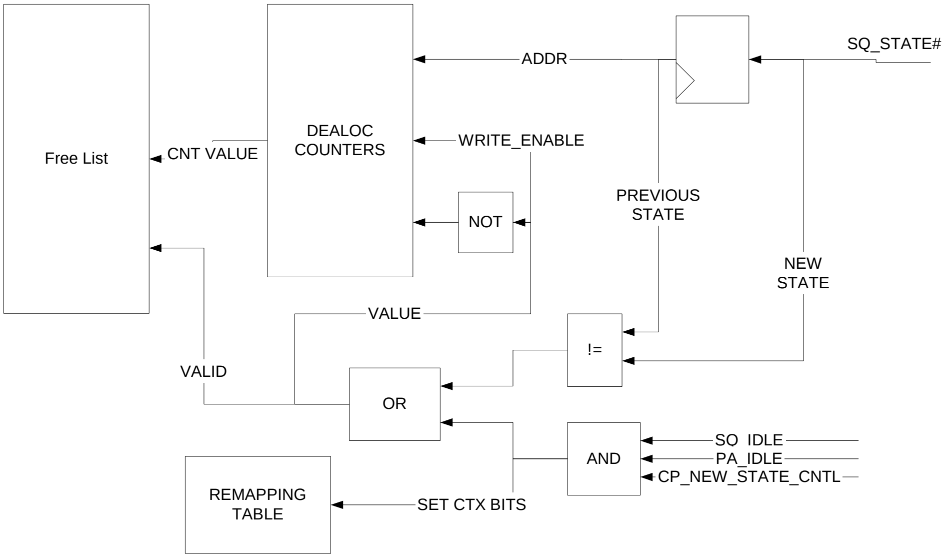

Figure ~~9~~8: De-allocation mechanism for R400LE

~~6.3.3~~5.3.3 *Dirty bits*

Two sets of dirty bits will be maintained per logical address. The first one will be set to zero on reset and set when the logical address is addressed. The second one will be set to zero whenever a new context is written and set for each address written while in this context. The reset dirty is not set, then writing to that logical address will not require de-allocation of whatever address stored in the renaming table. If it is set and the context dirty is not set, then the physical address store needs to be de-allocated and a new physical address is necessary to store the incoming data. If they are both set, then the data will be written into the physical address held in the renaming for the current logical address. No de-allocation or allocation takes place. This will happen when the driver does a set constant twice to the same logical address between context changes. NOTE: It is important to detect and prevent this, failure to do it will allow multiple writes to allocate all physical memory and thus hang because a context will not fit for rendering to start and thus free up space.

~~6.3.4~~5.3.4 *Free List Block*

A free list block that would consist of a counter (called the IFC or Initial Free Counter) that would reset to zero and incremented every time a chunk of physical memory is used until they have all been used once. This counter would be checked each time a physical block is needed, and if the original ones have not been used up, us a new one, else check the free list for an available physical block address. The count is the physical address for when getting a chunk from the counter.

Storage of a free list big enough to store all physical block addresses.

Maintain three pointers for the free list that are reset to zero. The first one we will call write_ptr. This pointer will identify the next location to write the physical address of a block to be de-allocated. Note: we can never free more physical memory locations than we have. Once recording address the pointer will be incremented to walk the free list like a ring.

The second pointer will be called stop_ptr. The stop_ptr pointer will be advanced by the number of address chunks de-allocates when a context finishes. The address between the stop_ptr and write_ptr cannot be reused because they are still in use. But as soon as the context using then is dismissed the stop_ptr will be advanced.

The third pointer will be called read_ptr. This pointer will point will point to the next address that can be used for allocation as long as the read_ptr does not equal the stop_ptr and the IFC is at its maximum count.

~~6.3.5~~5.3.5 *De-allocate Block*

This block will maintain a free physical address block count for each context. While in current context, a count shall be maintained specifying how many blocks were written into the free list at the write_ptr pointer. This count will be reset upon reset or when this context is active on the back and different than the previous context. It is actually a count of blocks in the previous context that will no longer be used. This count will be used to advance the write_ptr pointer to make available the set of physical blocks freed when the previous context was done. This allows the discard or de-allocation of any number of blocks in one clock.

~~6.3.6~~5.3.6 *Operation of Incremental model*

The basic operation of the model would start with the write_ptr, stop_ptr, read_ptr pointers in the free list set to zero and the free list counter is set to zero. Also all the dirty bits and the previous context will be initialized to zero. When the first set constants happen, the reset dirty bit will not be set, so we will allocate a physical location from the free list counter because its not at the max value. The data will be written into physical address zero. Both the additional copy of the renaming table and the context zeros of the big renaming table will be updated for the logical address that was written by set start with physical address of 0. This process will be repeated for any logical address that are not dirty until the context changes. If a logical address is hit that has its dirty bits set while in the same context, both dirty bits would be set, so the new data will be over-written to the last physical address assigned for this logical address. When the first draw command of the context is detected, the previous context stored in the additional renaming table will be copied to the larger renaming table in the current (new) context location. Then the set constant logical address with be loaded with a new physical address during the copy and if the reset dirty was set, the physical address it replaced in the renaming table would be entered at the write_ptr pointer location on the free list and the write_ptr will be incremented. The de-allocation counter for the previous context (eight) will be incremented. This as set states come in for this context one of the following will happen:

1.) No dirty bits are set for the logical address being updated. A line will be allocated of the free-list counter or the free list at read_ptr pointer if read_ptr != to stop_ptr .
2.) Reset dirty set and Context dirty not set. A new physical address is allocated, the physical address in the renaming table is put on the free list at write_ptr and it is incremented along with the de-allocate counter for the last context.
3.) Context dirty is set then the data will be written into the physical address specified by the logical address.

This process will continue as long as set states arrive. This block will provide backpressure to the CP whenever he has not free list entries available (counter at max and stop_ptr == read_ptr). The command stream will keep a count of contexts of constants in use and prevent more than max constants contexts from being sent.

Whenever a draw packet arrives, the content of the re-mapping table is written to the correct re-mapping table for the context number. Also if the next context uses less constants than the current one all exceeding lines are moved to the free list to be de-allocated later. This happens in parallel with the writing of the re-mapping table to the correct memory.

Now preferable when the constant context leaves the last ALU clause it will be sent to this block and compared with the previous context that left. (Init to zero) If they differ than the older context will no longer be referenced and thus can be de-allocated in the physical memory. This is accomplished by adding the number of blocks freed this context to the stop_ptr pointer. This will make all the physical addresses used by this context available to the read_ptr allocate pointer for future allocation.

This device allows representation of multiple contexts of constants data with N copies of the logical address space. It also allows the second context to be represented as the first set plus some new additional data by just storing the delta's. It allows memory to be efficiently used and when the constants updates are small it can store multiple context. However, if the updates are large, less contexts will be stored and potentially performance will be degraded. Although it will still perform as well as a ring could in this case.

~~6.4~~5.4 Constant Store Indexing

In order to do constant store indexing, the sequencer must be loaded first with the indexes (that come from the GPRs). There are 144 wires from the exit of the SP to the sequencer (9 bits pointers x 16 vertexes/clock). Since the data must pass thru the Shader pipe for the float to fixed conversion, there is a latency of 4 clocks (1 instruction)

between the time the sequencer is loaded and the time one can index into the constant store. The assembly will look like this

```
MOVA  R1.X,R2.X        // Loads the sequencer with the content of R2.X, also copies the content of R2.X into R1.X
NOP                    // latency of the float to fixed conversion
ADD   R3,R4,C0[R2.X]// Uses the state from the sequencer to add R4 to C0[R2.X] into R3
```

Note that we don't really care about what is in the brackets because we use the state from the MOVA instruction. R2.X is just written again for the sake of simplicity and coherency.

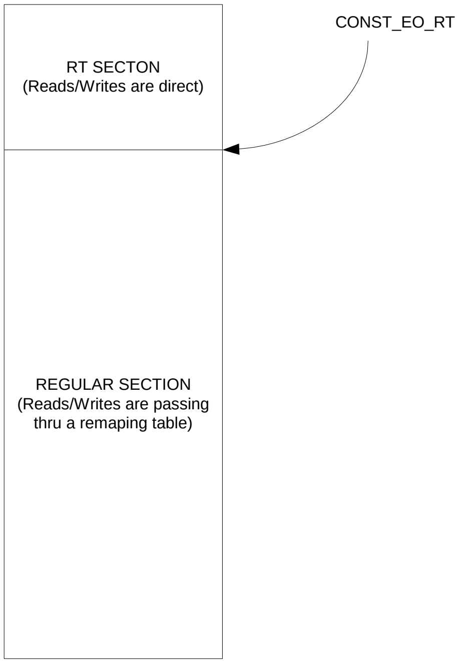
The storage needed in the sequencer in order to support this feature is 2*64*9 bits = 1152 bits.

~~6.5~~5.5 Real Time Commands

The real time commands constants are written by the CP using the register mapped registers allocated for RT. It works is the same way than when dealing with regular constant loads BUT in this case the CP is not sending a logical address but rather a physical address and the reads are not passing thru the re-mapping table but are directly read from the memory. The boundary between the two zones is defined by the CONST_EO_RT control register. Similarly, for the fetch state, the boundary between the two zones is defined by the TSTATE_EO_RT control register.

~~6.6~~5.6 Constant Waterfalling

In order to have a reasonable performance in the case of constant store indexing using the address register, we are going to have the possibility of using the physical memory port for read only. This way we can read 1 constant per clock and thus have a worst-case waterfall mode of 1 vertex per clock. There is a small synchronization issue related with this as we need for the SQ to make sure that the constants where actually written to memory (not only sent to the sequencer) before it can allow the first vector of pixels or vertices of the state to go thru the ALUs. To do so, the sequencer keeps 8 bits (one per render state) and sets the bits whenever the last render state is written to memory and clears the bit whenever a state is freed.



CONST_EO_RT

REGULAR SECTION
(Reads/Writes are passing thru a remaping table)

Figure 9~~10~~: The instruction store

~~7.~~6. Looping and Branches

Loops and branches are planned to be supported and will have to be dealt with at the sequencer level. We plan on supporting constant loops and branches using a control program.

~~7.1~~6.1 The controlling state.

The R400 controling state consists of:

Boolean[256:0]
Loop_count[7:0][31:0]
Loop_Start[7:0][31:0]
Loop_Step[7:0][31:0]

That is 256 Booleans and 32 loops.

We have a stack of 4 elements for nested calls of subroutines and 4 loop counters to allow for nested loops.

This state is available on a per shader program basis.

~~7.2~~6.2 The Control Flow Program

Examples of control flow programs are located in the R400 programming guide document.

The basic model is as follows:

The render state defined the clause boundaries:
Vertex_shader_fetch[7:0][7:0]   // eight 8 bit pointers to the location where each clauses control program is located
Vertex_shader_alu[7:0][7:0]   // eight 8 bit pointers to the location where each clauses control program is located
Pixel_shader_fetch[7:0][7:0]   // eight 8 bit pointers to the location where each clauses control program is located
Pixel_shader_alu[7:0][7:0]   // eight 8 bit pointers to the location where each clauses control program is located

A pointer value of FF means that the clause doesn't contain any instructions.

The control program for a given clause is executed to completion before moving to another clause, (with the exception of the pick two nature of the alu execution). The control program is the only program aware of the clause boundaries.

The control program has nine basic instructions:

Execute
Conditional_execute
Conditional_Execute_Predicates
Conditional_jump
Conditionnal_Call
Return
Loop_start
Loop_end
NOP

Execute, causes the specified number of instructions in instruction store to be executed.
Conditional_execute checks a condition first, and if true, causes the specified number of instructions in instruction store to be executed.
Loop_start resets the corresponding loop counter to the start value on the first pass after it checks for the end condition and if met jumps over to a specified address.
Loop_end increments (decrements?) the loop counter and jumps back the specified number of instructions.
Conditionnal_Call jumps to an address and pushes the IP counter on the stack if the condition is met. On the return instruction, the IP is popped from the stack.

Conditional_execute_Predicates executes a block of instructions if all bits in the predicate vectors meet the condition.
Conditional_jumps jumps to an address if the condition is met.
NOP is a regular NOP

NOTE THAT ALL JUMPS MUST JUMP TO EVEN CFP ADDRESSES since there are two control flow instructions per memory line. Thus the compiler must insert NOPs where needed to align the jumps on even CFP addresses.

Also if the jump is logically bigger than pshader_cntl_size (or vshader_cntl_size) we break the program (clause) and set the debug registers. If an execute or conditional_execute is lower than cntl_size or bigger than size we also break the program (clause) and set the debug registers.

We have to fit instructions into 48 bits in order to be able to put two control flow instruction per line in the instruction store.

A value of 1 in the Addressing means that the address specified in the Exec Address field (or in the jump address field) is an ABSOLUTE address. If the addressing field is cleared (should be the default) then the address is relative to the base of the current shader program.

Note that whenever a field is marked as RESERVED, it is assumed that all the bits of the field are cleared (0).

Execute					
47	46… 42	41	40 … 24	23 … 12	11 … 0
Addressing	00001	Last	RESERVED	Instruction count	Exec Address

Execute up to 4k instructions at the specified address in the instruction memory. If Last is set, this is the last group of instructions of the clause.

NOP			
47	46 … 42	41	40 … 0
Addressing	00010	Last	RESERVED

This is a regular NOP. If Last is set, this is the last instruction of the clause.

Conditional_Execute								
47	46 … 42	41	40	39 … 32	31	30 … 24	23 … 12	11 … 0
Addressing	00011	Last	RESERVED	Boolean address	Condition	RESERVED	Instruction count	Exec Address

If the specified Boolean (8 bits can address 256 Booleans) meets the specified condition then execute the specified instructions (up to 4k instructions). If Last is set, then if the condition is met, this is the last group of instructions to be executed in the clause. If the condition is not met, we go on to the next control flow instruction.

Conditional_Execute_Predicates								
47	46 … 42	41	40 … 34	33 … 32	31	30 … 24	23 … 12	11 … 0
Addressing	00100	Last	RESERVED	Predicate vector	Condition	RESERVED	Instruction count	Exec Address

Check the AND/OR of all current predicate bits. If AND/OR matches the condition execute the specified number of instructions. We need to AND/OR this with the kill mask in order not to consider the pixels that aren't valid. If Last is set, then if the condition is met, this is the last group of instructions to be executed in the clause. If the condition is not met, we go on to the next control flow instruction.

Loop_Start				
47	46 … 42	41 … 17	16 … 12	11 … 0
Addressing	00101	RESERVED	loop ID	Jump address

Loop Start. Compares the loop iterator with the end value. If loop condition not met jump to the address. Forward jump only. Also computes the index value. The loop id must match between the start to end, and also indicates which control flow constants should be used with the loop.

Loop_End				
47	46 … 42	41 … 17	16 … 12	11 … 0
Addressing	00110	RESERVED	loop ID	start address

Loop end. Increments the counter by one, compares the loop count with the end value. If loop condition met, continue, else, jump BACK to the start of the loop.

The way this is described does not prevent nested loops, and the inclusion of the loop id make this easy to do.

Conditionnal_Call						
47	46 … 42	41 … 34	33 … 32	31	30 … 12	11 … 0
Addressing	00111	RESERVED	Predicate vector	Condition	RESERVED	Jump address

If the condition is met, jumps to the specified address and pushes the control flow program counter on the stack.

Return		
47	46 … 42	41 … 0
Addressing	01000	RESERVED

Pops the topmost address from the stack and jumps to that address. If nothing is on the stack, the program will just continue to the next instruction.

Conditionnal_Jump							
47	46 … 42	41 … 40	39 … 32	31	30	29 … 12	11 … 0
Addressing	01001	RESERVED	Boolean address	Condition	FW only	RESERVED	Jump address

If condition met, jumps to the address. FORWARD jump only allowed if bit 31 set. Bit 31 is only an optimization for the compiler and should NOT be exposed to the API.

To prevent infinite loops, we will keep 9 bits loop iterators instead of 8 (we are only able to loop 256 times). If the counter goes higher than 255 then the loop_end or the loop_start instruction is going to break the loop and set the debug GPRs.

~~7.3~~6.3 Data dependant predicate instructions

Data dependant conditionals will be supported in the R400. The only way we plan to support those is by supporting three vector/scalar predicate operations of the form:

PRED_SETE_# - similar to SETE except that the result is 'exported' to the sequencer.
PRED_SETNE_# - similar to SETNE except that the result is 'exported' to the sequencer.
PRED_SETGT_# - similar to SETGT except that the result is 'exported' to the sequencer
PRED_SETGTE_# - similar to SETGTE except that the result is 'exported' to the sequencer

For the scalar operations only we will also support the two following instructions:
PRED_SETE0_# – SETE0
PRED_SETE1_# – SETE1

The export is a single bit - 1 or 0 that is sent using the same data path as the MOVA instruction. The sequencer will maintain 4 sets of 64 bit predicate vectors (in fact 8 sets because we interleave two programs but only 4 will be exposed) and use it to control the write masking. This predicate is not maintained across clause boundaries. The # sign is used to specify which predicate set you want to use 0 thru 3.

Then we have two conditional execute bits. The first bit is a conditional execute "on" bit and the second bit tells us if we execute on 1 or 0. For example, the instruction:

P0_ADD_# R0,R1,R2

Is only going to write the result of the ADD into those GPRs whose predicate bit is 0. Alternatively, P1_ADD_# would only write the results to the GPRs whose predicate bit is set. The use of the P0 or P1 without precharging the sequencer with a PRED instruction is undefined.

{Issue: do we have to have a NOP between PRED and the first instruction that uses a predicate?}

~~7.4~~6.4 HW Detection of PV,PS

Because of the control program, the compiler cannot detect statically dependant instructions. In the case of non-masked writes and subsequent reads the sequencer will insert uses of PV,PS as needed. This will be done by comparing the read address and the write address of consecutive instructions. For masked writes, the sequencer will insert NOPs wherever there is a dependant read/write.

The sequencer will also have to insert NOPs between PRED_SET and MOVA instructions and their uses.

~~7.5~~6.5 Register file indexing

Because we can have loops in fetch clause, we need to be able to index into the register file in order to retrieve the data created in a fetch clause loop and use it into an ALU clause. The instruction will include the base address for register indexing and the instruction will contain these controls:

Bit7	Bit 6	
0	0	'absolute register'
0	1	'relative register'
1	0	'previous vector'
1	1	'previous scalar'

In the case of an absolute register we just take the address as is. In the case of a relative register read we take the base address and we add to it the loop_index and this becomes our new address that we give to the shader pipe.

The sequencer is going to keep a loop index computed as such:

Index = Loop_iterator*Loop_step + Loop_start.

We loop until loop_iterator = loop_count. Loop_step is a signed value [-128…127]. The computed index value is a 10 bit counter that is also signed. Its real range is [-256,256]. The tenth bit is only there so that we can provide an out of range value to the "indexing logic" so that it knows when the provided index is out of range and thus can make the necessary arrangements.

~~7.6~~6.6 Predicated Instruction support for Texture clauses

For texture clauses, we support the following optimization: we keep 1 bit (thus 4 bits for the four predicate vectors) per predicate vector in the reservation stations. A value of 1 means that one ore more elements in the vector have a value of one (thus we have to do the texture fetches for the whole vector). A value of 0 means that no elements in the vector have his predicate bit set and we can thus skip over the texture fetch. **We have to make sure the invalid pixels aren't considered with this optimization.**

~~7.7~~6.7 Debugging the Shaders

In order to be able to debug the pixel/vertex shaders efficiently, we provide 2 methods.

~~7.7.1~~6.7.1 *Method 1: Debugging registers*

Current plans are to expose 2 debugging, or error notification, registers:
1. address register where the first error occurred
2. count of the number of errors

The sequencer will detect the following groups of errors:
- count overflow
- constant indexing overflow
- register indexing overflow

Compiler recognizable errors:
- jump errors
  relative jump address > size of the control flow program
- call stack
  call with stack full
  return with stack empty

A jump error will always cause the program to break. In this case, a break means that a clause will halt execution, but allowing further clauses to be executed.

With all the other errors, program can continue to run, potentially to worst-case limits. The program will only break if the DB_PROB_BREAK register is set.

If indexing outside of the constant or the register range, causing an overflow error, the hardware is specified to return the value with an index of 0. This could be exploited to generate error tokens, by reserving and initializing the 0th register (or constant) for errors.

{ISSUE : Interrupt to the driver or not?}

~~7.7.2~~6.7.2 *Method 2: Exporting the values in the GPRs (12)*

The sequencer will have a count register and an address register for this mode and 3 bits per clause specifying the execution mode for each clause. The modes can be :

1) Normal
2) Debug Kill
3) Debug Addr + Count

Under the normal mode execution follows the normal course. Under the kill mode, all control flow instructions are executed but all normal shader instructions of the clause are replaced by NOPs. Only debug_export instructions of clause 7 will be executed under the debug kill setting. Under the other mode, normal execution is done until we reach an address specified by the address register and instruction count (useful for loops) specified by the count register. After we have hit the instruction n times (n=count) we switch the clause to the kill mode.

Under the debug mode (debug kill OR debug Addr + count), it is assumed that clause 7 is always exporting 12 debug vectors and that all other exports to the SX block (position, color, z, ect) will been turned off (changed into NOPs) by the sequencer (even if they occur before the address stated by the ADDR debug register).

~~8.~~7. Pixel Kill Mask

A vector of 64 bits is kept by the sequencer per group of pixels/vertices. Its purpose is to optimize the texture fetch requests and allow the shader pipe to kill pixels using the following instructions:

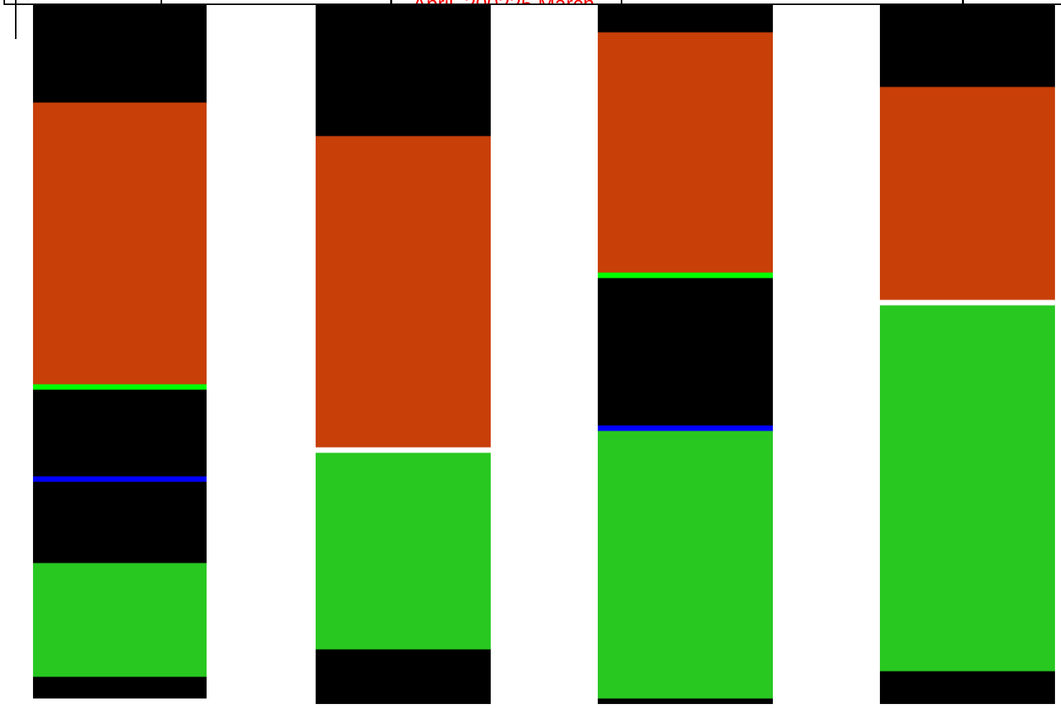
MASK_SETE
MASK_SETNE
MASK_SETGT
MASK_SETGTE

~~9.~~8. Multipass vertex shaders (HOS)

Multipass vertex shaders are able to export from the 6 last clauses but to memory ONLY.

~~10.~~9. Register file allocation

The register file allocation for vertices and pixels can either be static or dynamic. In both cases, the register file in managed using two round robins (one for pixels and one for vertices). In the dynamic case the boundary between pixels and vertices is allowed to move, in the static case it is fixed to 128-VERTEX_REG_SIZE for vertices and PIXEL_REG_SIZE for pixels.



Above is an example of how the algorithm works. Vertices come in from top to bottom; pixels come in from bottom to top. Vertices are in orange and pixels in green. The blue line is the tail of the vertices and the green line is the tail of the pixels. Thus anything between the two lines is shared. When pixels meets vertices the line turns white and the boundary is static until both vertices and pixels share the same "unallocated bubble". Then the boundary is allowed to move again. The numbering of the GPRs starts from the bottom of the picture at index 0 and goes up to the top at index 127.

~~11.~~10. Fetch Arbitration

The fetch arbitration logic chooses one of the 8 potentially pending fetch clauses to be executed. The choice is made by looking at the fifos from 7 to 0 and picking the first one ready to execute. Once chosen, the clause state machine will send one 2x2 fetch per clock (or 4 fetches in one clock every 4 clocks) until all the fetch instructions of the clause are sent. This means that there cannot be any dependencies between two fetches of the same clause.

The arbitrator will not wait for the fetches to return prior to selecting another clause for execution. The fetch pipe will be able to handle up to X(?) in flight fetches and thus there can be a fair number of active clauses waiting for their fetch return data.

~~12.~~11. ALU Arbitration

ALU arbitration proceeds in almost the same way than fetch arbitration. The ALU arbitration logic chooses one of the 8 potentially pending ALU clauses to be executed. The choice is made by looking at the fifos from 7 to 0 and picking the first one ready to execute. There are two ALU arbiters, one for the even clocks and one for the odd clocks. For example, here is the sequencing of two interleaved ALU clauses (E and O stands for Even and Odd sets of 4 clocks):

Einst0 Oinst0 Einst1 Oinst1 Einst2 Oinst2 Einst0 Oinst3 Einst1 Oinst4 Einst2 Oinst0…
Proceeding this way hides the latency of 8 clocks of the ALUs. Also note that the interleaving also occurs across clause boundaries.

~~13.~~12. Handling Stalls

When the output file is full, the sequencer prevents the ALU arbitration logic from selecting the last clause (this way nothing can exit the shader pipe until there is place in the output file. If the packet is a vertex packet and the position buffer is full (POS_FULL) then the sequencer also prevents a thread from entering the exporting clause (3?). The sequencer will set the OUT_FILE_FULL signal n clocks before the output file is actually full and thus the ALU arbiter will be able read this signal and act accordingly by not preventing exporting clauses to proceed.

~~14.~~13. Content of the reservation station FIFOs

The reservation FIFOs contain the state of the vector of pixels and vertices. We have two sets of those: one for pixels, and one for vertices. They contain 3 bits of Render State 7 bits for the base address of the GPRs, some bits for LOD correction and coverage mask information in order to fetch fetch for only valid pixels, the quad address.

~~15.~~14. The Output File

The output file is where pixels are put before they go to the RBs. The write BW to this store is 256 bits/clock. Just before this output file are staging registers with write BW 512 bits/clock and read BW 256 bits/clock. The staging registers are 4x128 (and there are 16 of those on the whole chip).

~~16.~~15. IJ Format

The IJ information sent by the PA is of this format on a per quad basis:

We have a vector of IJ's (one IJ per pixel at the centroid of the fragment or at the center of the pixel depending on the mode bit). The interpolation is done at a different precision across the 2x2. The upper left pixel's parameters are always interpolated at full 20x24 mantissa precision. Then the result of the interpolation along with the difference in IJ in reduced precision is used to interpolate the parameter for the other three pixels of the 2x2. Here is how we do it:

Assuming P0 is the interpolated parameter at Pixel 0 having the barycentric coordinates I(0), J(0) and so on for P1,P2 and P3. Also assuming that A is the parameter value at V0 (interpolated with I), B is the parameter value at V1 (interpolated with J) and C is the parameter value at V2 (interpolated with (1-I-J).

$$\begin{aligned}
\Delta 01I &= I(1) - I(0)\\
\Delta 01J &= J(1) - J(0)\\
\Delta 02I &= I(2) - I(0)\\
\Delta 02J &= J(2) - J(0)\\
\Delta 03I &= I(3) - I(0)\\
\Delta 03J &= J(3) - J(0)
\end{aligned}$$

P0	P1
P2	P3

$$\begin{aligned}
P0 &= C + I(0) * (A - C) + J(0) * (B - C)\\
P1 &= P0 + \Delta 01I * (A - C) + \Delta 01J * (B - C)\\
P2 &= P0 + \Delta 02I * (A - C) + \Delta 02J * (B - C)\\
P3 &= P0 + \Delta 03I * (A - C) + \Delta 03J * (B - C)
\end{aligned}$$

P0 is computed at 20x24 mantissa precision and P1 to P3 are computed at 8X24 mantissa precision. So far no visual degradation of the image was seen using this scheme.

Multiplies (Full Precision): 2
Multiplies (Reduced precision): 6
Subtracts 19x24 (Parameters): 2

Adds: 8

FORMAT OF P0's IJ : Mantissa 20 Exp 4 for I + Sign
Mantissa 20 Exp 4 for J + Sign

FORMAT of Deltas (x3):Mantissa 8 Exp 4 for I + Sign
Mantissa 8 Exp 4 for J + Sign

Total number of bits : 20*2 + 8*6 + 4*8 + 4*2 = 128

All numbers are kept using the un-normalized floating point convention: if exponent is different than 0 the number is normalized if not, then the number is un-normalized. The maximum range for the IJs (Full precision) is +/- 63 and the range for the Deltas is +/- 127.

~~16.1~~15.1 Interpolation of constant attributes

Because of the floating point imprecision, we need to take special provisions if all the interpolated terms are the same or if two of the barycentric coordinates are the same.

We start with the premise that if A = B and B = C and C = A, then P0,1,2,3 = A. Since one or more of the IJ terms may be zero, so we extend this to:

```
if (A=B and B=C and C=A)
   P0,1,2,3 = A;
else if ((I = 0) or (J = 0)) and
          ((J = 0) or (1-I-J = 0)) and
          ((1-J-I = 0) or (I = 0))) {
                if(I != 0) {
                    P0 = A;
                } else if(J != 0) {
                    P0 = B;
                } else {
                    P0 = C;
               }
            //rest of the quad interpolated normally
}
else
{
            normal interpolation
}
```

~~17.~~16. Staging Registers

In order for the reuse of the vertices to be 14, the sequencer will have to re-order the data sent IN ORDER by the VGT for it to be aligned with the parameter cache memory arrangement. Given the following group of vertices sent by the VGT:

0 1 2 3 4 5 6 7 8 9 10 11 12 13 14 15 || 16 17 18 19 20 21 22 23 24 25 26 27 28 29 30 31 || 32 33 34 35 36 37 38 39 40 41 42 43 44 45 46 47 || 48 49 50 51 52 53 54 55 56 57 58 59 60 61 62 63

The sequencer will re-arrange them in this fashion:

0 1 2 3 16 17 18 19 32 33 34 35 48 49 50 51 || 4 5 6 7 20 21 22 23 36 37 38 39 52 53 54 55 || 8 9 10 11 24 25 26 27 40 41 42 43 56 57 58 59 || 12 13 14 15 28 29 30 31 44 45 46 47 60 61 62 63

The || markers show the SP divisions. In the event a shader pipe is broken, the VGT will send padding to account for the missing pipe. For example, if SP1 is broken, vertices 4 5 6 7 20 21 22 23 36 37 38 39 52 53 54 55 will still be sent by the VGT to the SQ **BUT** will not be processed by the SP and thus should be considered invalid (by the SU and VGT).

The most straightforward, *non-compressed* interface method would be to convert, in the VGT, the data to 32-bit floating point prior to transmission to the VSISRs. In this scenario, the data would be transmitted to (and stored in) the VSISRs in full 32-bit floating point. This method requires three 24-bit fixed-to-float converters in the VGT. Unfortunately, it also requires and additional 3,072 bits of storage across the VSISRs. This interface is illustrated in Figure 11~~Figure 12Figure 12~~. The area of the fixed-to-float converters and the VSISRs for this method is roughly estimated as 0.759sqmm using the R300 process. The gate count estimate is shown in Figure 10~~Figure 11Figure 11~~.

Basis for 8-deep Latch Memory (from R300)			
8x24-bit	11631 μ^2	60.57813 μ^2 per bit	
Area of 96x8-deep Latch Memory	46524 μ^2		
Area of 24-bit Fix-to-float Converter	4712 μ^2 per converter		

Method 1	Block	Quantity	Area
	F2F	3	14136
	8x96 Latch	16	744384
			758520 μ^2

Figure 10~~11~~:Area Estimate for VGT to Shader Interface

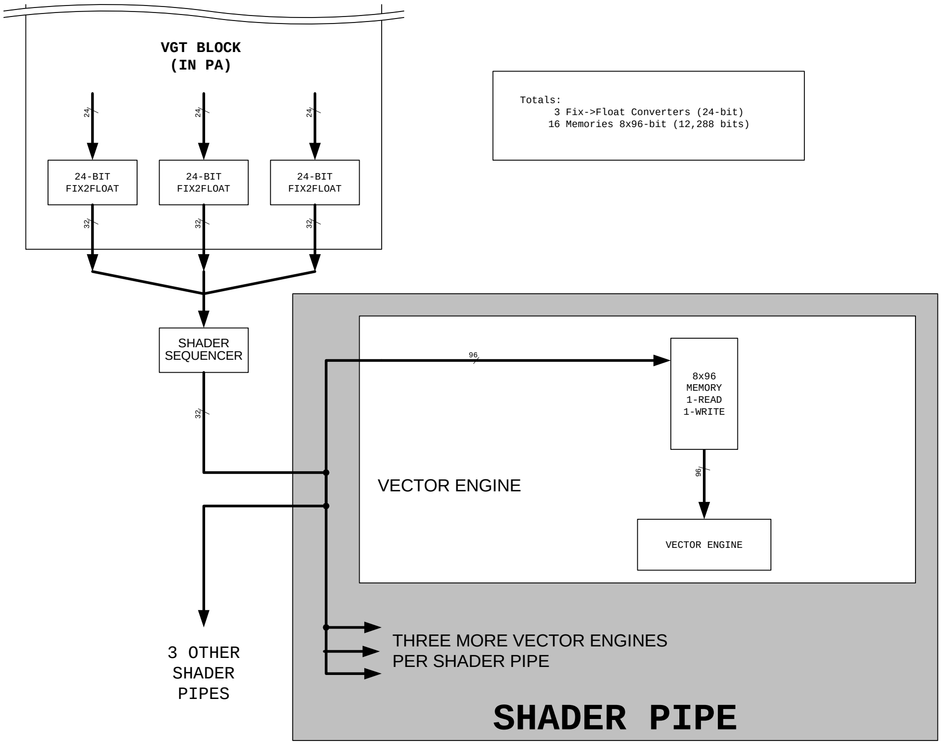


Figure 11~~12~~:VGT to Shader Interface

~~18.~~17. The parameter cache

The parameter cache is where the vertex shaders export their data. It consists of 16 128x128 memories (1R/1W). The reuse engine will make it so that all vertexes of a given primitive will hit different memories. The allocation method for these memories is a simple round robin. The parameter cache pointers are mapped in the following way: 4MSBs are the memory number and the 7 LSBs are the address within this memory.

MEMORY NUMBER 4 bits	ADDRESS 7 bits

The PA generates the parameter cache addresses as the positions come from the SQ. All it needs to do is keep a Current_Location pointer (7 bits only) and as the positions comes increment the memory number. When the memory number field wraps around, the PA increments the Current_Location by VS_EXPORT_COUNT_7 (a snooped register from the SQ). As an example, say the memories are all empty to begin with and the vertex shader is exporting 8 parameters per vertex (VS_EXPORT_COUNT_7 = 8). The first position received is going to have the PC address 00000000000 the second one 00010000000, third one 00100000000 and so on up to 11110000000. Then the next position received (the 17th) is going to have the address 00000001000, the 18th 00010001000, the 19th 00100001000 and so on. The Current_location is NEVER reset BUT on chip resets. The only thing to be careful about is that if the SX doesn't send you a full group of positions (<64) then you need to fill the address space so that the next group starts correctly aligned (for example if you receive only 33 positions then you need to add 2*VS_EXPORT_COUNT_7to Current_Location and reset the memory count to 0 before the next vector begins).

~~19.~~18. Vertex position exporting

On clause 3 the vertex shader can export to the PA both the vertex position and the point sprite. It can also do so at clause 7 if not done at clause 3. The storage needed to perform the position export is at least 64x128 memories for the position and 64x32 memories for the sprite size. It is going to be taken in the pixel output fifo from the SX blocks. The clause where the position export occurs is specified by the EXPORT_LATE register. If turned on, it means that the export is going to occur at ALU clause 7 if unset position export occurs at clause 3.

~~20.~~19. Exporting Arbitration

Here are the rules for co-issuing exporting ALU clauses.

1) Position exports and position exports cannot be co-issued.

All other types of exports can be co-issued as long as there is place in the receiving buffer.

~~21.~~20. Exporting Rules

~~21.1~~20.1 Parameter caches exports

We support masking and out of order exports to the parameter caches. So one can export multiple times to the same PC line using different masks.

~~21.2~~20.2 Memory exports

Memory exports don't support masking. However, you can export out of order to memory locations.

~~21.3~~20.3 Position exports

Position exports have to be done IN ORDER and don't support masking.

~~22.~~21. Export Types

The export type (or the location where the data should be put) is specified using the destination address field in the ALU instruction. Here is a list of all possible export modes:

~~22.1~~21.1 Vertex Shading

0:15	- 16 parameter cache
16:~~31~~31	- Empty (Reserved?)
32	- Export Address
~~32~~33:~~43~~ 40	- ~~12~~ 8 vertex exports to the frame buffer and index
~~44~~41:47	- Empty
48:~~59~~55	- ~~12~~ 8 debug export (interpret as normal vertex export)
60	- export addressing mode
61	- Empty
62	- position
63	- sprite size export that goes with position export (point_h,point_w,edgeflag,misc)

~~22.2~~21.2 Pixel Shading

0	- Color for buffer 0 (primary)
1	- Color for buffer 1
2	- Color for buffer 2
3	- Color for buffer 3
4:7	- Empty

8	- Buffer 0 Color/Fog (primary)
9	- Buffer 1 Color/Fog
10	- Buffer 2 Color/Fog
11	- Buffer 3 Color/Fog
12:15	- Empty
16:~~31~~31	- Empty (Reserved?)
32	- Export Address
~~32~~33:~~43~~40	- ~~12~~ 8 exports for multipass pixel shaders.
~~44~~41:47	- Empty
48:~~59~~55	- ~~12~~ 8 debug exports (interpret as normal pixel export)
60	- export addressing mode
61:62	- Empty
63	- Z for primary buffer (Z exported to 'alpha' component)

~~23.~~22. Special Interpolation modes

~~23.1~~22.1 Real time commands

We are unable to use the parameter memory since there is no way for a command stream to write into it. Instead we need to add three 16x128 memories (one for each of three vertices x 16 interpolants). These will be mapped onto the register bus and written by type 0 packets, and output to the the parameter busses (the sequencer and/or PA need to be able to address the realtime parameter memory as well as the regular parameter store. For higher performance we should be able able to view them as two banks of 16 and do double buffering allowing one to be loaded, while the other is rasterized with. Most overlay shaders will need 2 or 4 scalar coordinates, one option might be to restrict the memory to 16x64 or 32x64 allowing only two interpolated scalars per cycle, the only problem I see with this is, if we view support for 16 vector-4 interpolants important (true only if we map Microsoft's high priority stream to the realtime stream), then the PA/sequencer need to support a realtime-specific mode where we need to address 32 vectors of parameters instead of 16. This mode is triggered by the primitive type: REAL TIME. The actual memories are in the in the SX blocks. The parameter data memories are hooked on the RBBM bus and are loaded by the CP using register mapped memory.

~~23.2~~22.2 Sprites/ XY screen coordinates/ FB information

When working with sprites, one may want to overwrite the parameter 0 with SC generated data. Also, XY screen coordinates may be needed in the shader program. This functionality is controlled by the gen_I0 register (in SQ) in conjunction with the SND_XY register (in SC). Also it is possible to send the faceness information (for OGL front/back special operations) to the shader using the same control register. Here is a list of all the modes and how they interact together:

Gen_st is a bit taken from the interface between the SC and the SQ. This is the MSB of the primitive type. If the bit is set, it means we are dealing with Point AA, Line AA or sprite and in this case the vertex values are going to generated between 0 and 1.

Param_Gen_I0 disable, snd_xy disable, no gen_st – I0 = No modification
Param_Gen_I0 disable, snd_xy disable, gen_st – I0 = No modification
Param_Gen_I0 disable, snd_xy enable, no gen_st – I0 = No modification
Param_Gen_I0 disable, snd_xy enable, gen_st – I0 = No modification
Param_Gen_I0 enable, snd_xy disable, no gen_st – I0 = garbage, garbage, garbage, faceness
Param_Gen_I0 enable, snd_xy disable, gen_st – I0 = garbage, garbage, s, t
Param_Gen_I0 enable, snd_xy enable, no gen_st – I0 = screen x, screen y, garbage, faceness
Param_Gen_I0 enable, snd_xy enable, gen_st – I0 = screen x, screen y, s, t

~~23.3~~22.3 Auto generated counters

In the cases we are dealing with multipass shaders, the sequencer is going to generate a vector count to be able to both use this count to write the 1st pass data to memory and then use the count to retrieve the data on the 2nd pass. The count is always generated in the same way but it is passed to the shader in a slightly different way depending on the shader type (pixel or vertex). This is toggled on and off using the GEN_INDEX register. The sequencer is going to keep two counters, one for pixels and one for vertices. Every time a full vector of vertices or pixels is written to the

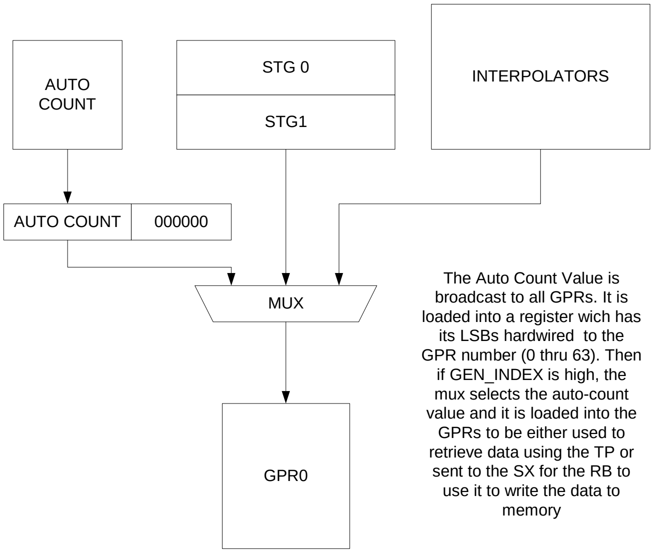
GPRs the counter is incremented. Every time a state change is detected, the corresponding counter is reset. While there is only one count broadcast to the GPRs, the LSB are hardwired to specific values making the index different for all elements in the vector.

~~23.3.1~~22.3.1 *Vertex shaders*

In the case of vertex shaders, if GEN_INDEX is set, the data will be put into the x field of the third register (it means that the compiler must allocate 3 GPRs in all multipass vertex shader modes).

~~23.3.2~~22.3.2 *Pixel shaders*

In the case of pixel shaders, if GEN_INDEX is set and Param_Gen_I0 is enabled, the data will be put in the x field of the 2nd register (R1.x), else if GEN_INDEX is set the data will be put into the x field of the 1st register (R0.x).



The Auto Count Value is broadcast to all GPRs. It is loaded into a register wich has its LSBs hardwired to the GPR number (0 thru 63). Then if GEN_INDEX is high, the mux selects the auto-count value and it is loaded into the GPRs to be either used to retrieve data using the TP or sent to the SX for the RB to use it to write the data to memory

Figure 12~~13~~: GPR input mux Control

~~24.~~23. State management

Every clock, the sequencer will report to the CP the oldest states still in the pipe. These are the states of the programs as they enter the last ALU clause.

~~24.1~~23.1 Parameter cache synchronization

In order for the sequencer not to begin a group of pixels before the associated group of vertices has finished, the sequencer will keep a 6 bit count per state (for a total of 8 counters). These counters are initialized to 0 and every time a vertex shader exports its data TO THE PARAMETER CACHE, the corresponding pointer is incremented. When the SC sends a new vector of pixels with the SC_SQ_new_vector bit asserted, the sequencer will first check if the count is greater than 0 before accepting the transmission (it will in fact accept the transmission but then lower its ready to receive). Then the sequencer waits for the count to go to one and decrements it. The sequencer can then issue the group of pixels to the interpolators. Every time the state changes, the new state counter is initialized to 0.

~~25.~~24. XY Address imports

The SC will be able to send the XY addresses to the GPRs. It does so by interleaving the writes of the IJs (to the IJ buffer) with XY writes (to the XY buffer). Then when writing the data to the GPRs, the sequencer is going to interpolate the IJ data or pass the XY data thru a Fix→float converter and expander and write the converted values to the GPRs. The Xys are currently SCREEN SPACE COORDINATES. The values in the XY buffers will wrap. See section 22.2 for details on how to control the interpolation in this mode.

~~25.1~~24.1 Vertex indexes imports

In order to import vertex indexes, we have 16 8x96 staging registers. These are loaded one line at a time by the VGT block (96 bits). They are loaded in floating point format and can be transferred in 4 or 8 clocks to the GPRs.

~~26.~~25. Registers

~~26.1~~25.1 Control

REG_DYNAMIC	Dynamic allocation (pixel/vertex) of the register file on or off.
REG_SIZE_PIX	Size of the register file's pixel portion (minimal size when dynamic allocation turned on)
REG_SIZE_VTX	Size of the register file's vertex portion (minimal size when dynamic allocation turned on)
ARBITRATION_POLICY	policy of the arbitration between vertexes and pixels
~~INST_STORE_ALLOC~~	~~interleaved, separate~~
INST_BASE_VTX	start point for the vertex instruction store (RT always ends at vertex_base and Begins at 0)
INST_BASE_PIX	start point for the pixel shader instruction store
ONE_THREAD	debug state register. Only allows one program at a time into the GPRs
ONE_ALU	debug state register. Only allows one ALU program at a time to be executed (instead of 2)
INSTRUCTION	This is where the CP puts the base address of the instruction writes and type (auto-incremented on reads/writes) Register mapped
CONSTANTS	512*4 ALU constants + 32*6 Texture state 32 bits registers (logically mapped)
CONSTANTS_RT	256*4 ALU constants + 32*6 texture states? (physically mapped)
CONSTANT_EO_RT	This is the size of the space reserved for real time in the constant store (from 0 to CONSTANT_EO_RT). The re-mapping table operates on the rest of the memory
TSTATE_EO_RT	This is the size of the space reserved for real time in the fetch state store (from 0 to TSTATE_EO_RT). The re-mapping table operates on the rest of the memory
EXPORT_LATE	Controls whether or not we are exporting position from clause 3. If set, position exports occur at clause 7.

~~26.2~~25.2 Context

VS_FETCH_{0…7}	eight 8 bit pointers to the location where each clauses control program is located
VS_ALU_{0…7}	eight 8 bit pointers to the location where each clauses control program is located
PS_FETCH_{0…7}	eight 8 bit pointers to the location where each clauses control program is located
PS_ALU_{0…7}	eight 8 bit pointers to the location where each clauses control program is located
PS_BASE	base pointer for the pixel shader in the instruction store
VS_BASE	base pointer for the vertex shader in the instruction store
VS_CF_SIZE	size of the vertex shader (# of instructions in control program/2)
PS_CF_SIZE	size of the pixel shader (# of instructions in control program/2)
PS_SIZE	size of the pixel shader (cntl+instructions)
VS_SIZE	size of the vertex shader (cntl+instructions)
PS_NUM_REG	number of GPRs to allocate for pixel shader programs
VS_NUM_REG	number of GPRs to allocate for vertex shader programs
PARAM_SHADE	One 16 bit register specifying which parameters are to be gouraud shaded (0 = flat, 1 = gouraud)
PROVO_VERT	0 : vertex 0, 1: vertex 1, 2: vertex 2, 3: Last vertex of the primitive
PARAM_WRAP	64 bits: for which parameters (and channels (xyzw)) do we do the cyl wrapping (0=linear, 1=cylindrical).
PS_EXPORT_MODE	0xxxx : Normal mode 1xxxx : Multipass mode

	If normal, bbbz where bbb is how many colors (0-4) and z is export z or not
	If multipass 1-12 exports for color.
VS_EXPORT_MODE	0: position (1 vector), 1: position (2 vectors), 3:multipass
VS_EXPORT _COUNT_{0…6}	Six 4 bit counters representing the # of interpolated parameters exported in clause 7 (located in VS_EXPORT_COUNT_6) OR # of exported vectors to memory per clause in multipass mode (per clause)
PARAM_GEN_I0	Do we overwrite or not the parameter 0 with XY data and generated T and S values
GEN_INDEX	Auto generates an address from 0 to XX. Puts the results into R0-1 for pixel shaders and R2 for vertex shaders
CONST_BASE_VTX (9 bits)	Logical Base address for the constants of the Vertex shader
CONST_BASE_PIX (9 bits)	Logical Base address for the constants of the Pixel shader
CONST_SIZE_PIX (8 bits)	Size of the logical constant store for pixel shaders
CONST_SIZE_VTX (8 bits)	Size of the logical constant store for vertex shaders
INST_PRED_OPTIMIZE	Turns on the predicate bit optimization (if of, conditional_execute_predicates is always executed).
CF_BOOLEANS	256 boolean bits
CF_LOOP_COUNT	32x8 bit counters (number of times we traverse the loop)
CF_LOOP_START	32x8 bit counters (init value used in index computation)
CF_LOOP_STEP	32x8 bit counters (step value used in index computation)

~~27.~~26. DEBUG Registers

~~27.1~~26.1 Context

DB_PROB_ADDR	instruction address where the first problem occurred
DB_PROB_COUNT	number of problems encountered during the execution of the program
DB_PROB_BREAK	break the clause if an error is found.
DB_INST_COUNT	instruction counter for debug method 2
DB_BREAK_ADDR	break address for method number 2
DB_CLAUSE _MODE_ALU_{0…7}	clause mode for debug method 2 (0: normal, 1: addr, 2: kill)
DB_CLAUSE _MODE_FETCH_{0…7}	clause mode for debug method 2 (0: normal, 1: addr, 2: kill)

~~27.2~~26.2 Control

DB_ALUCST_MEMSIZE	Size of the physical ALU constant memory
DB_TSTATE_MEMSIZE	Size of the physical texture state memory

~~28.~~27. Interfaces

~~28.1~~27.1 External Interfaces

Whenever an x is used, it means that the bus is broadcast to all units of the same name. For example, if a bus is named SQ→SPx it means that SQ is going to broadcast the same information to all SP instances.

~~28.2~~27.2 SC to SP Interfaces

~~28.2.1~~27.2.1 *SC_SP#*

There is one of these interfaces at front of each of the SP (buffer to stage pixel interpolators). This interface transmits the I,J data for pixel interpolation. For the entire system, two quads per clock are transferred to the 4 SPs, so each of these 4 interfaces transmits one half of a quad per clock. The interface below describes a half of a quad worth of data.

The actual data which is transferred per quad is
Ref Pix I => S4.20 Floating Point I value
Ref Pix J => S4.20 Floating Point J value
Delta Pix I (x3) => S4.8 Floating Point Delta I value
Delta Pix J (x3) => S4.8 Floating Point Delta J value
This equates to a total of 128 bits which transferred over 2 clocks
and therefor needs an interface 64 bits wide

Additionally, X,Y data (12-bit unsigned fixed) is conditionally sent across this data bus over the same wires in an additional clock. The X,Y data is sent on the lower 24 bits of the data bus with faceness in the msb.
Transfers across these interfaces are synchronized with the SC_SQ IJ Control Bus transfers.

The data transfer across each of these busses is controlled by a IJ_BUF_INUSE_COUNT in the SC. Each time the SC has sent a pixel vector's worth of data to the SPs, he will increment the IJ_BUF_INUSE_COUNT count. Prior to sending the next pixel vectors data, he will check to make sure the count is less than MAX_BUFER_MINUS_2, if not the SC will stall until the SQ returns a pipelined pulse to decrement the count when he has scheduled a buffer free. Note: We could/may optimize for the case of only sending only IJ to use all the buffers to pre-load more. Currently it is planned for the SP to hold 2 double buffers of I,J data and two buffers of X,Y data, so if either X,Y or Centers and Centroids are on, then the SC can send two Buffers.

In at least the initial version, the SC shall send 16 quads per pixel vector even if the vector is not full. This will increment buffer write address pointers correctly all the time. (We may revisit this for both the SX,SP,SQ and add a EndOfVector signal on all interfaces to quit early. We opted for the simple mode first with a belief that only the end of packet and multiple new vector signals should cause a partial vector and that this would not really be significant performance hit.)

Name	Bits	Description
SC_SP#_data	64	IJ information sent over 2 clocks (or X,Y in 24 LSBs with faceness in upper bit) **Type 0 or 1**, First clock I, second clk J Field ULC URC LLC LRC Bits [63:39] [38:26] [25:13] [12:0] Format SE4M20 SE4M8 SE4M8 SE4M8 **Type 2** Field Face X Y Bits [63] [23:12] [11:0] Format Bit Unsigned Unsigned
SC_SP#_valid	1	Valid
SC_SP#_last_quad_data	1	This bit will be set on the last transfer of data per quad.
SC_SP#_type	2	0 -> Indicates centroids 1 -> Indicates centers 2 -> Indicates X,Y Data and faceness on data bus The SC shall look at state data to determine how many types to send for the interpolation process.

The # is included for clarity in the spec and will be replaced with a prefix of u#_ in the verilog module statement for the SC and the SP block will have neither because the instantiation will insert the prefix.

~~28.2.2~~27.2.2 *SC_SQ*

This is the control information sent to the sequencer in order to synchronize and control the interpolation and/or loading data into the GPRs needed to execute a shader program on the sent pixels. This data will be sent over two clocks per transfer with 1 to 16 transfers. Therefore the bus (approx 92 bits) could be folded in half to approx ~~46~~ 47 bits.

Name	Bits	Description
SC_SQ_data	46	Control Data sent to the SQ 1 clk transfers Event – valid data consist of event_id and

		state_id. Instruct SQ to post an event vector to send state id and event_id through request fifo and onto the reservation stations making sure state id and/or event_id gets back to the CP. Events only follow end of packets so no pixel vectors will be in progress. Empty Quad Mask – Transfer Control data consisting of pc_dealloc or new_vector. Receipt of this is to transfer pc_dealloc or new_vector without any valid quad data. New vector will always be posted to request fifo and pc_dealloc will be attached to any pixel vector outstanding or posted in request fifo if no valid quad outstanding. 2 clk transfers Quad Data Valid – Sending quad data with or without new_vector or pc_dealloc. New vector will be posted to request fifo with or without a pixel vector and pc_dealloc will be posted with a pixel vector unless none is in progress. In this case the pc_dealloc will be posted in the request queue. Filler quads will be transferred with The Quad mask set but the pixel corresponding pixel mask set to zero.
SC_SQ_valid	1	SC sending valid data, 2nd clk could be all zeroes

SC_SQ_data – first clock and second clock transfers are shown in the table below.

Name	**BitField**	**Bits**	**Description**
1st Clock Transfer			
SC_SQ_event	0	1	This transfer is a 1 clock event vector Force quad_mask = new_vector=pc_dealloc=0
SC_SQ_event_id	[2:1]	2	This field identifies the event 0 => denotes an End Of State Event 1 => TBD
SC_SQ_pc_dealloc	[5:3]~~3~~	3~~1~~	Deallocation token for the Parameter Cache
SC_SQ_new_vector	6~~4~~	1	The SQ must wait for Vertex shader done count > 0 and after dispatching the Pixel Vector the SQ will decrement the count.
SC_SQ_quad_mask	[10~~8~~:7~~5~~]	4	Quad Write mask left to right SP0 => SP3
SC_SQ_end_of_prim	11~~9~~	1	End Of the primitive
SC_SQ_state_id	[14~~2~~:12~~0~~]	3	State/constant pointer (6*3+3)
SC_SQ_pix_mask	[30~~28~~:15~~3~~]	16	Valid bits for all pixels SP0=>SP3 (UL,UR,LL,LR)
SC_SQ_prim_type	[33~~1~~:31~~29~~]	3	Stippled line and Real time command need to load tex cords from alternate buffer 000: Normal ~~100~~010: Realtime 101: Line AA

			110: Point AA (Sprite)
SC_SQ_provok_vtx~~SC_SQ_pc_ptr0~~	[35:34]~~[42:32]~~	2~~11~~	Provoking vertex for flat shading~~Parameter Cache pointer for vertex 0~~
SC_SQ_pc_ptr0	[46:36]	11	Parameter Cache pointer for vertex 0
2nd Clock Transfer			
SC_SQ_pc_ptr1	[10:0]	11	Parameter Cache pointer for vertex 1
SC_SQ_pc_ptr2	[21:11]	11	Parameter Cache pointer for vertex 2
SC_SQ_lod_correct	[45:22]	24	LOD correction per quad (6 bits per quad)

Name	Bits	Description
SQ_SC_free_buff	1	Pipelined bit that instructs SC to decrement count of buffers in use.
SQ_SC_dec_cntr_cnt	1	Pipelined bit that instructs SC to decrement count of new vector and/or event sent to prevent SC from overflowing SQ interpolator/Reservation request fifo.

The scan converter will submit a partial vector whenever:

1.) He gets a primitive marked with an end of packet signal.
2.) A current pixel vector is being assembled with at least one or more valid quads and the vector has been marked for deallocate when a primitive marked new_vector arrives. The Scan Converter will submit a partial vector (up to 16quads with zero pixel mask to fill out the vector) prior to submitting the new_vector marker\primitive.

(This will prevent a hang which can be demonstrated when all primitives in a packet three vectors are culled except for a one quad primitive that gets marked pc_dealloc (vertices maximum size). In this case two new_vectors are submitted and processed, but then one valid quad with the pc_dealloc creates a vector and then the new would wait for another vertex vector to be processed, but the one being waited for could never export until the pc_dealloc signal made it through and thus the hang.)

~~28.2.3~~27.2.3 *SQ to SX: Interpolator bus*

Name	Direction	Bits	Description
SQ_SXx_interp_flat_vtx	SQ→SPx	2	Provoking vertex for flat shading
SQ_SXx_interp_flat_gouraud	SQ→SPx	1	Flat or gouraud shading
SQ_SXx_interp_cyl_wrap	SQ→SPx	4	Wich channel needs to be cylindrical wrapped
SQ_SXx_pc_ptr0~~1~~	SQ→SXx	11	Parameter Cache Pointer
SQ_SXx_pc_ptr1~~2~~	SQ→SXx	11	Parameter Cache Pointer
SQ_SXx_pc_ptr2~~3~~	SQ→SXx	11	Parameter Cache Pointer
SQ_SXx_rt_sel	SQ→SXx	1	Selects between RT and Normal data
SQ_SXx_pc_wr_en	SQ→SXx	1	Write enable for the PC memories
SQ_SXx_pc_wr_addr	SQ→SXx	7	Write address for the PCs
SQ_SXx_pc_channel_mask	SQ→SXx	4	Channel mask

~~28.2.4~~27.2.4 *SQ to SP: Staging Register Data*

This is a broadcast bus that sends the VSISR information to the staging registers of the shader pipes.

Name	Direction	Bits	Description
SQ_SPx_vsr_data	SQ→SPx	96	Pointers of indexes or HOS surface information
SQ_SPx_vsr_double	SQ→SPx	1	0: Normal 96 bits per vert 1: double 192 bits per vert
SQ_SP0_vsr_valid	SQ→SP0	1	Data is valid
SQ_SP1_vsr_valid	SQ→SP1	1	Data is valid
SQ_SP2_vsr_valid	SQ→SP2	1	Data is valid
SQ_SP3_vsr_valid	SQ→SP3	1	Data is valid
SQ_SPx_vsr_read	SQ→SPx	1	Increment the read pointers

~~28.2.5~~27.2.5 *VGT to SQ : Vertex interface*

~~28.2.5.1~~27.2.5.1 Interface Signal Table

The area difference between the two methods is not sufficient to warrant complicating the interface or the state requirements of the VSISRs. **Therefore, the POR for this interface is that the VGT will transmit the data to the VSISRs (via the Shader Sequencer) in full, 32-bit floating-point format.** The VGT can transmit up to six 32-bit floating-point values to each VSISR where four or more values require two transmission clocks. The data bus is 96 bits wide.

Name	Bits	Description
VGT_SQ_vsisr_data	96	Pointers of indexes or HOS surface information
VGT_SQ_vsisr_double	1	0: Normal 96 bits per vert 1: double 192 bits per vert
VGT_SQ_end_of_vector	1	Indicates the last VSISR data set for the current process vector (for double vector data, "end_of_vector" is set on the ~~second~~ first vector)
VGT_SQ_indx_valid	1	Vsisr data is valid
VGT_SQ_state	3	Render State (6*3+3 for constants). This signal is guaranteed to be correct when "VGT_SQ_vgt_end_of_vector" is high.
VGT_SQ_send	1	Data on the VGT_SQ is valid receive (see write-up for standard R400 SEND/RTR interface handshaking)
SQ_VGT_rtr	1	Ready to receive (see write-up for standard R400 SEND/RTR interface handshaking)

~~27.2.6 SQ to CP: State report~~

Formatted: Bullets and Numbering

~~27.2.7~~27.2.6 SQ to SX: Control bus

Name	Direction	Bits	Description
SQ_SXx_exp_pix	SQ→SXx	1	1: Pixel 0: Vertex
SQ_SXx_exp_clause	SQ→SXx	3	Clause number, which is needed for vertex clauses
SQ_SXx_exp_state	SQ→SXx	3	State ID
SQ_SXx_exp_alu_id	SQ→SXx	1	ALU ID
SQ_SXx_exp_valid	SQ→SXx	1	Valid bit

These fields are sent every time the sequencer picks an exporting clause for execution.

~~27.2.8~~27.2.7 SX to SQ : Output file control

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
SXx_SQ_exp_count_rdy	SXx→SQ	1	Raised by SX0 to indicate that the following two fields reflect the result of the most recent export
SXx_SQ_exp_pos~~ition~~_avail~~space~~	SXx→SQ	1	Specifies whether there is room for another position.
SXx_SQ_exp_bu~~ffer~~_avail~~space~~	SXx→SQ	7	Specifies the space available in the output buffers. 0: buffers are full 1: 2K-bits available (32-bits for each of the 64 pixels in a clause) ... 64: 128K-bits available (16 128-bit entries for each of 64 pixels) 65-127: RESERVED

~~27.2.9~~27.2.8 SQ to TP: Control bus

Formatted: Bullets and Numbering

Once every clock, the fetch unit sends to the sequencer on which clause it is now working and if the data in the GPRs is ready or not. This way the sequencer can update the fetch counters for the reservation station fifos. The sequencer also provides the instruction and constants for the fetch to execute and the address in the register file where to write the fetch return data.

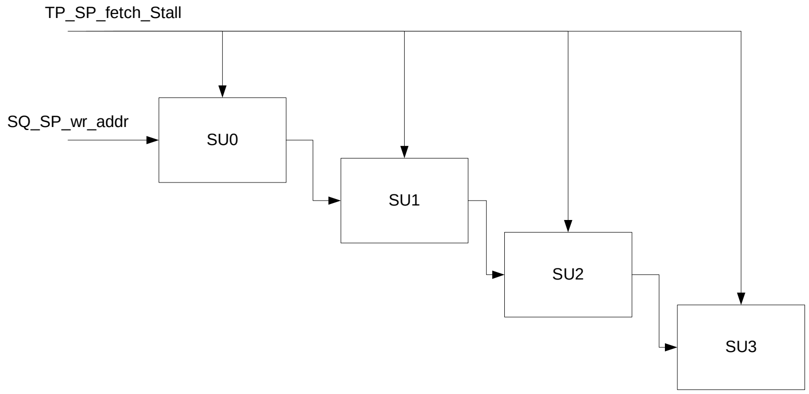
Name	Direction	Bits	Description
TPx_SQ_data_rdy	TPx→ SQ	1	Data ready
TPx_SQ_clause_num	TPx→ SQ	3	Clause number
TPx_SQ_type	TPx→ SQ	1	Type of data sent (0:PIXEL, 1:VERTEX)
SQ_TPx_send	SQ→TPx	1	Sending valid data
SQ_TPx_const	SQ→TPx	48	Fetch state sent over 4 clocks (192 bits total)
SQ_TPx_instr	SQ→TPx	24	Fetch instruction sent over 4 clocks
SQ_TPx_end_of_clause	SQ→TPx	1	Last instruction of the clause
SQ_TPx_Type	SQ→TPx	1	Type of data sent (0:PIXEL, 1:VERTEX)
SQ_TPx_gpr_phase	SQ→TPx	2	Write phase signal
SQ_TP0_lod_correct	SQ→TP0	6	LOD correct 3 bits per comp 2 components per quad
SQ_TP0_pix_mask	SQ→TP0	4	Pixel mask 1 bit per pixel
SQ_TP1_lod_correct	SQ→TP1	6	LOD correct 3 bits per comp 2 components per quad
SQ_TP1_pix_mask	SQ→TP1	4	Pixel mask 1 bit per pixel
SQ_TP2_lod_correct	SQ→TP2	6	LOD correct 3 bits per comp 2 components per quad
SQ_TP2_pix_mask	SQ→TP2	4	Pixel mask 1 bit per pixel
SQ_TP3_lod_correct	SQ→TP3	6	LOD correct 3 bits per comp 2 components per quad
SQ_TP3_pix_mask	SQ→TP3	4	Pixel mask 1 bit per pixel
SQ_TPx_clause_num	SQ→TPx	3	Clause number

SQ_TPx_write_gpr_index	SQ->TPx	7	Index into Register file for write of returned Fetch Data

~~27.2.10~~27.2.9 TP to SQ: Texture stall

Formatted: Bullets and Numbering

The TP sends this signal to the SQ and the SPs when its input buffer is full. ~~The SQ is going to send it to the SP X clocks after reception (maximum of 3 clocks of pipeline delay).~~



Name	Direction	Bits	Description
TP_SQ_fetch_stall	TP→ SQ	1	Do not send more texture request if asserted

~~27.2.11~~27.2.10 SQ to SP: Texture stall

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
SQ_SPx_fetch_stall	SQ→SPx	1	Do not send more texture request if asserted

~~27.2.12~~27.2.11 SQ to SP: GPR and auto counter

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
SQ_SPx_gpr_wr_addr	SQ→SPx	7	Write address
SQ_SPx_gpr_rd_addr	SQ→SPx	7	Read address
SQ_SPx_gpr_rd_en	SQ→SPx	1	Read Enable
SQ_SPx_gpr_wr_en	SQ→SPx	1	Write Enable for the GPRs
SQ_SPx_gpr_phase~~_mux~~	SQ→SPx	2	The phase mux (arbitrates between inputs, ALU SRC reads and writes)
SQ_SPx_channel_mask	SQ→SPx	4	The channel mask
SQ_SPx_gpr_input_~~mux~~sel	SQ→SPx	2	When the phase mux selects the inputs this tells from which source to read from: Interpolated data, VTX0, VTX1, autogen counter.
SQ_SPx_auto_count	SQ→SPx	12?	Auto count generated by the SQ, common for all shader pipes

~~27.2.13~~27.2.12 SQ to SPx: Instructions

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
SQ_SPx_instr_start	SQ→SPx	1	Instruction start
SQ_SP_instr	SQ→SPx	21	Transferred over 4 cycles 0: SRC A Select 2:0 SRC A Argument Modifier 3:3 SRC A swizzle 11:4 VectorDst 17:12 Unused 20:18 -- - 1: SRC B Select 2:0 SRC B Argument Modifier 3:3 SRC B swizzle 11:4 ScalarDst 17:12 Unused 20:18 -- - 2: SRC C Select 2:0 SRC C Argument Modifier 3:3 SRC C swizzle 11:4 Unused 20:12 -- - 3: Vector Opcode 4:0 Scalar Opcode 10:5 Vector Clamp 11:11 Scalar Clamp 12:12 Vector Write Mask 16:13 Scalar Write Mask 20:17
SQ_SPx_exp_alu_id	SQ→SPx	1	ALU ID
SQ_SPx_exporting	SQ→SPx	2	0: Not Exporting 1: Vector Exporting 2: Scalar Exporting
SQ_SPx_stall	SQ→SPx	1	Stall signal
SQ_SP0_~~exp_pvalid~~write_mask	SQ→SP0	4	Result of pixel kill in the shader pipe, which must be output for all pixel exports (depth and all color buffers). 4x4 because 16 pixels are computed per clock
SQ_SP1_ write_mask~~exp_pvalid~~	SQ→SP1	4	Result of pixel kill in the shader pipe, which must be output for all pixel exports (depth and all color buffers). 4x4 because 16 pixels are computed per clock
SQ_SP2_ write_mask~~exp_pvalid~~	SQ→SP2	4	Result of pixel kill in the shader pipe, which must be output for all pixel exports (depth and all color buffers). 4x4 because 16 pixels are computed per clock
SQ_SP3_ write_mask~~exp_pvalid~~	SQ→SP3	4	Result of pixel kill in the shader pipe, which must be output for all pixel exports (depth and all color buffers). 4x4 because 16 pixels are computed per clock

~~27.2.14~~27.2.13 SP to SQ: Constant address load/ Predicate Set

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
SP0_SQ_const_addr	SP0→SQ	36	Constant address load / predicate vector load (4 bits only) to the sequencer
SP0_SQ_valid	SP0→SQ	1	Data valid
SP1_SQ_const_addr	SP1→SQ	36	Constant address load / predicate vector load (4 bits only) to the sequencer

SP1_SQ_valid	SP1→SQ	1	Data valid
SP2_SQ_const_addr	SP2→SQ	36	Constant address load / predicate vector load (4 bits only) to the sequencer
SP2_SQ_valid	SP2→SQ	1	Data valid
SP3_SQ_const_addr	SP3→SQ	36	Constant address load / predicate vector load (4 bits only) to the sequencer
SP3_SQ_valid	SP3→SQ	1	Data valid

~~27.2.15~~27.2.14 SQ to SPx: constant broadcast

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
SQ_SPx_const	SQ→SPx	128	Constant broadcast

~~27.2.16~~27.2.15 SP0 to SQ: Kill vector load

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
SP0_SQ_kill_vect	SP0→SQ	4	Kill vector load
SP1_SQ_kill_vect	SP1→SQ	4	Kill vector load
SP2_SQ_kill_vect	SP2→SQ	4	Kill vector load
SP3_SQ_kill_vect	SP3→SQ	4	Kill vector load

~~27.2.17~~27.2.16 SQ to CP: RBBM bus

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
SQ_RBB_rs	SQ→CP	1	Read Strobe
SQ_RBB_rd	SQ→CP	32	Read Data
SQ_RBBM_nrtrtr	SQ→CP	1	Optional
SQ_RBBM_rtr	SQ→CP	1	Real-Time (Optional)

~~27.2.18~~27.2.17 CP to SQ: RBBM bus

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
rbbm_we	CP→SQ	1	Write Enable
rbbm_a	CP→SQ	15	Address -- Upper Extent is TBD (16:2)
rbbm_wd	CP→SQ	32	Data
rbbm_be	CP→SQ	4	Byte Enables
rbbm_re	CP→SQ	1	Read Enable
rbb_rs0	CP→SQ	1	Read Return Strobe 0
rbb_rs1	CP→SQ	1	Read Return Strobe 1
rbb_rd0	CP→SQ	32	Read Data 0
rbb_rd1	CP→SQ	32	Read Data 0
RBBM_SQ_soft_reset	CP→SQ	1	Soft Reset

27.2.18 SQ to CP: State report

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
SQ_CP_vs_event	SQ→CP	1	Vertex Shader Event
SQ_CP_vs_eventid	SQ→CP	2	Vertex Shader Event ID
SQ_CP_ps_event	SQ→CP	1	Pixel Shader Event
SQ_CP_ps_eventid	SQ→CP	2	Pixel Shader Event ID

eventid = 0 => *sEndOfState (i.e. VsEndOfState)
eventid = 1 => *sDone (i.e. VsDone)

So, the CP will assume the Vs is done with a state whenever it gets a pulse on the SQ_CP_vs_event and the SQ_CP_vs_eventid = 0.

Formatted: Bullets and Numbering

~~28.Examples of program executions~~

~~28.1.1 *Sequencer Control of a Vector of Vertices*~~

~~1.PA sends a vector of 64 vertices (actually vertex indices – 32 bits/index for 2048 bit total) to the RE's Vertex FIFO~~

- ~~state pointer as well as tag into position cache is sent along with vertices~~
- ~~space was allocated in the position cache for transformed position before the vector was sent~~
- ~~**also before the vector is sent to the RE, the CP has loaded the global instruction store with the vertex shader program (using the MH?)**~~
- ~~The vertex program is assumed to be loaded when we receive the vertex vector.~~
    - ~~the SEQ then accesses the IS base for this shader using the local state pointer (provided to all sequencers by the RBBM when the CP is done loading the program)~~

~~2.SEQ arbitrates between the Pixel FIFO and the Vertex FIFO – basically the Vertex FIFO always has priority~~

- ~~at this point the vector is removed from the Vertex FIFO~~
- ~~the arbiter is not going to select a vector to be transformed if the parameter cache is full unless the pipe as nothing else to do (ie no pixels are in the pixel fifo).~~

~~3.SEQ allocates space in the SP register file for index data plus GPRs used by the program~~

- ~~the number of GPRs required by the program is stored in a local state register, which is accessed using the state pointer that came down with the vertices~~
- ~~SEQ will not send vertex data until space in the register file has been allocated~~

~~4.SEQ sends the vector to the SP register file over the RE_SP interface (which has a bandwidth of 2048 bits/cycle)~~

- ~~the 64 vertex indices are sent to the 64 register files over 4 cycles~~
    - ~~RF0 of SU0, SU1, SU2, and SU3 is written the first cycle~~
    - ~~RF1 of SU0, SU1, SU2, and SU3 is written the second cycle~~
    - ~~RF2 of SU0, SU1, SU2, and SU3 is written the third cycle~~
    - ~~RF3 of SU0, SU1, SU2, and SU3 is written the fourth cycle~~
- ~~the index is written to the least significant 32 bits **(floating point format?) (what about compound indices)** of the 128-bit location within the register file (w); the remaining data bits are set to zero (x, y, z)~~

~~5.SEQ constructs a control packet for the vector and sends it to the first reservation station (the FIFO in front of fetch state machine 0, or TSM0 FIFO)~~

- ~~the control packet contains the state pointer, the tag to the position cache and a register file base pointer.~~

~~6.TSM0 accepts the control packet and fetches the instructions for fetch clause 0 from the global instruction store~~

- ~~TSM0 was first selected by the TSM arbiter before it could start~~

~~7.all instructions of fetch clause 0 are issued by TSM0~~

~~8.the control packet is passed to the next reservation station (the FIFO in front of ALU state machine 0, or ASM0 FIFO)~~

- ~~TSM0 does not wait for requests made to the Fetch Unit to complete; it passes the register file write index for the fetch data to the TU, which will write the data to the RF as it is received~~
- ~~once the TU has written all the data to the register files, it increments a counter that is associated with ASM0 FIFO; a count greater than zero indicates that the ALU state machine can go ahead start to execute the ALU clause~~

~~9.ASM0 accepts the control packet (after being selected by the ASM arbiter) and gets the instructions for ALU clause 0 from the global instruction store~~

~~10.all instructions of ALU clause 0 are issued by ASM0, then the control packet is passed to the next reservation station (the FIFO in front of fetch state machine 1, or TSM1 FIFO)~~

~~11.the control packet continues to travel down the path of reservation stations until all clauses have been executed~~

- ~~position can be exported in ALU clause 3 (or 4?); the data (and the tag) is sent over a position bus (which is shared with all four shader pipes) back to the PA's position cache~~
- ~~A parameter cache pointer is also sent along with the position data. This tells to the PA where the data is going to be in the parameter cache.~~
    - ~~there is a position export FIFO in the SP that buffers position data before it gets sent back to the PA~~

    - ~~the ASM arbiter will prevent a packet from starting an exporting clause if the position export FIFO is full~~
  - ~~parameter data is exported in clause 7 (as well as position data if it was not exported earlier)~~
    - ~~parameter data is sent to the Parameter Cache over a dedicated bus~~
    - ~~the SEQ allocates storage in the Parameter Cache, and the SEQ deallocates that space when there is no longer a need for the parameters (it is told by the PA when using a token).~~
    - ~~the ASM arbiter will prevent a packet from starting on ASM7 if the parameter cache (or the position buffer if position is being exported) is full~~

~~12.after the shader program has completed, the SEQ will free up the GPRs so that they can be used by another shader program~~

~~28.1.2 *Sequencer Control of a Vector of Pixels*~~

~~1.As with vertex shader programs, pixel shaders are loaded into the global instruction store by the CP~~

- ~~At this point it is assumed that the pixel program is loaded into the instruction store and thus ready to be read.~~

~~2.the RE's Pixel FIFO is loaded with the barycentric coordinates for pixel quads by the detailed walker~~
- ~~the state pointer and the LOD correction bits are also placed in the Pixel FIF0~~
- ~~the Pixel FIFO is wide enough to source four quad's worth of barycentrics per cycle~~

~~3.SEQ arbitrates between Pixel FIFO and Vertex FIFO – when there are no vertices pending OR there is no space left in the register files for vertices, the Pixel FIFO is selected~~

~~4.SEQ allocates space in the SP register file for all the GPRs used by the program~~
- ~~the number of GPRs required by the program is stored in a local state register, which is accessed using the state pointer~~
- ~~SEQ will not allow interpolated data to be sent to the shader until space in the register file has been allocated~~

~~5.SEQ controls the transfer of interpolated data to the SP register file over the RE_SP interface (which has a bandwidth of 2048 bits/cycle). See interpolated data bus diagrams for details.~~

~~6.SEQ constructs a control packet for the vector and sends it to the first reservation station (the FIFO in front of fetch state machine 0, or TSM0 FIFO)~~
- ~~note that there is a separate set of reservation stations/arbiters/state machines for vertices and for pixels~~
- ~~the control packet contains the state pointer, the register file base pointer, and the LOD correction bits~~
- ~~all other information (such as quad address for example) travels in a separate FIFO~~

~~7.TSM0 accepts the control packet and fetches the instructions for fetch clause 0 from the global instruction store~~
- ~~TSM0 was first selected by the TSM arbiter before it could start~~

~~8.all instructions of fetch clause 0 are issued by TSM0~~

~~9.the control packet is passed to the next reservation station (the FIFO in front of ALU state machine 0, or ASM0 FIFO)~~
- ~~TSM0 does not wait for fetch requests made to the Fetch Unit to complete; it passes the register file write index for the fetch data to the TU, which will write the data to the RF as it is received~~
- ~~once the TU has written all the data for a particular clause to the register files, it increments a counter that is associated with the ASM0 FIFO; a count greater than zero indicates that the ALU state machine can go ahead and pop the FIFO and start to execute the ALU clause~~

~~10.ASM0 accepts the control packet (after being selected by the ASM arbiter) and gets the instructions for ALU clause 0 from the global instruction store~~

~~11.all instructions of ALU clause 0 are issued by ASM0, then the control packet is passed to the next reservation station (the FIFO in front of fetch state machine 1, or TSM1 FIFO)~~

~~12.the control packet continues to travel down the path of reservation stations until all clauses have been executed~~
- ~~pixel data is exported in the last ALU clause (clause 7)~~
  - ~~it is sent to an output FIFO where it will be picked up by the render backend~~
  - ~~the ASM arbiter will prevent a packet from starting on ASM7 if the output FIFO is full~~

~~13.after the shader program has completed, the SEQ will free up the GPRs so that they can be used by another shader program~~

~~28.1.3 *Notes*~~

Formatted: Bullets and Numbering

~~14.The state machines and arbiters will operate ahead of time so that they will be able to immediately start the real threads or stall.~~

~~15.The register file base pointer for a vector needs to travel with the vector through the reservation stations, but the instruction store base pointer does not – this is because the RF pointer is different for all threads, but the IS pointer is only different for each state and thus can be accessed via the state pointer.~~

Formatted: Bullets and Numbering

~~29.~~28. Open issues

Need to do some testing on the size of the register file as well as on the register file allocation method (dynamic VS static).

Saving power?

~~Parameter caches in SX?~~

~~Using both IJ buffers for center + centroid interpolation?~~

R400 Sequencer Specification

SQ

Version ~~1.11~~2.0

Overview: This is an architectural specification for the R400 Sequencer block (SEQ). It provides an overview of the required capabilities and expected uses of the block. It also describes the block interfaces, internal sub-blocks, and provides internal state diagrams.

AUTOMATICALLY UPDATED FIELDS:

Document Location: C:\perforce\r400\doc_lib\design\blocks\sq\R400_Sequencer.doc

Revision Changes:

Rev 0.1 (Laurent Lefebvre) Date: May 7, 2001	First draft.
Rev 0.2 (Laurent Lefebvre) Date : July 9, 2001	Changed the interfaces to reflect the changes in the SP. Added some details in the arbitration section.
Rev 0.3 (Laurent Lefebvre) Date : August 6, 2001	Reviewed the Sequencer spec after the meeting on August 3, 2001.
Rev 0.4 (Laurent Lefebvre) Date : August 24, 2001	Added the dynamic allocation method for register file and an example (written in part by Vic) of the flow of pixels/vertices in the sequencer.
Rev 0.5 (Laurent Lefebvre) Date : September 7, 2001	Added timing diagrams (Vic)
Rev 0.6 (Laurent Lefebvre) Date : September 24, 2001	Changed the spec to reflect the new R400 architecture. Added interfaces.
Rev 0.7 (Laurent Lefebvre) Date : October 5, 2001	Added constant store management, instruction store management, control flow management and data dependant predication.
Rev 0.8 (Laurent Lefebvre) Date : October 8, 2001	Changed the control flow method to be more flexible. Also updated the external interfaces.
Rev 0.9 (Laurent Lefebvre) Date : October 17, 2001	Incorporated changes made in the 10/18/01 control flow meeting. Added a NOP instruction, removed the conditional_execute_or_jump. Added debug registers.
Rev 1.0 (Laurent Lefebvre) Date : October 19, 2001	Refined interfaces to RB. Added state registers.
Rev 1.1 (Laurent Lefebvre) Date : October 26, 2001	Added SEQ→SP0 interfaces. Changed delta precision. Changed VGT→SP0 interface. Debug Methods added.
Rev 1.2 (Laurent Lefebvre) Date : November 16, 2001	Interfaces greatly refined. Cleaned up the spec.
Rev 1.3 (Laurent Lefebvre) Date : November 26, 2001	Added the different interpolation modes.
Rev 1.4 (Laurent Lefebvre) Date : December 6, 2001	Added the auto incrementing counters. Changed the VGT→SQ interface. Added content on constant management. Updated GPRs.
Rev 1.5 (Laurent Lefebvre) Date : December 11, 2001	Removed from the spec all interfaces that weren't directly tied to the SQ. Added explanations on constant management. Added PA→SQ synchronization fields and explanation.
Rev 1.6 (Laurent Lefebvre) Date : January 7, 2002	Added more details on the staging register. Added detail about the parameter caches. Changed the call instruction to a Conditionnal_call instruction. Added details on constant management and updated the diagram.
Rev 1.7 (Laurent Lefebvre) Date : February 4, 2002	Added Real Time parameter control in the SX interface. Updated the control flow section.
Rev 1.8 (Laurent Lefebvre) Date : March 4, 2002	New interfaces to the SX block. Added the end of clause modifier, removed the end of clause instructions.
Rev 1.9 (Laurent Lefebvre) Date : March 18, 2002	Rearangement of the CF instruction bits in order to ensure byte alignement.
Rev 1.10 (Laurent Lefebvre) Date : March 25, 2002	Updated the interfaces and added a section on exporting rules.
Rev 1.11 (Laurent Lefebvre) Date : April 19, 2002	Added CP state report interface. Last version of the spec with the old control flow scheme
Rev 2.0 (Laurent Lefebvre) Date : April 19, 2002	New control flow scheme

1. Overview

~~The sequencer is based on the R300 design. It~~The sequencer chooses two ALU ~~clauses~~ threads and a fetch ~~clause~~ hread to execute, and executes all of the instructions in a ~~clause~~ block before looking for a new clause of the same type. Two ALU ~~clauses~~ threads are executed interleaved to hide the ALU latency. ~~Each vector will have eight fetch and eight ALU clauses, but clauses do not need to contain instructions. A vector of pixels or vertices ping-pongs along the sequencer FIFO, bouncing from fetch reservation station to alu reservation station. A FIFO exists between each reservation stage, holding up vectors until the vector currently occupying a reservation station has left. A vector at a reservation station can be chosen to execute. The sequencer looks at all eight alu reservation stations to choose an alu clause to execute and all eight fetch stations to choose a fetch clause to execute.~~ The arbitrator will give priority to ~~clauses/reservation stations closer to the bottom of the pipeline~~older threads. ~~It will not execute an alu clause until the fetch fetches initiated by the previous fetch clause have completed.~~ There are two separate sets of reservation stations, one for pixel vectors and one for vertices vectors. This way a pixel can pass a vertex and a vertex can pass a pixel.

To support the shader pipe the sequencer also contains the shader instruction cache, constant store, control flow constants and texture state. The four shader pipes also execute the same instruction thus there is only one sequencer for the whole chip.

The sequencer first arbitrates between vectors of 64 vertices that arrive directly from primitive assembly and vectors of 16 quads (64 pixels) that are generated in the scan converter.

The vertex or pixel program specifies how many GPRs it needs to execute. The sequencer will not start the next vector until the needed space is available in the GPRs.

Figure 2: Reservation stations and arbiters

~~There are two sets of the above figure, one for vertices and one for pixels.~~

~~Depending on the arbitration state, the sequencer will either choose a vertex or a pixel packet. The control packet consists of 3 bits of state, 7 bits for the base address of the Shader program and some information on the coverage to determine fetch LOD plus other various small state bits.~~

~~On receipt of a packet, the input state machine (not pictured but just before the first FIFO) allocated enough space in the GPRs to store the interpolated values and temporaries. Following this, the barycentric coordinates (and XY screen position if needed) are sent to the interpolator, which will use them to interpolate the parameters and place the results into the GPRs. Then, the input state machine stacks the packet in the first FIFO.~~

~~On receipt of a command, the level 0 fetch machine issues a fetch request to the TP and corresponding GPR address for the fetch address (ta). A small command (tcmd) is passed to the fetch system identifying the current level number (0) as well as the GPR write address for the fetch return data. One fetch request is sent every 4 clocks causing the texturing of sixteen 2x2s worth of data (or 64 vertices). Once all the requests are sent the packet is put in FIFO 1.~~

~~Upon receipt of the return data, the fetch unit writes the data to the register file using the write address that was provided by the level 0 fetch machine and sends the clause number (0) to the level 0 fetch state machine to signify that the write is done and thus the data is ready. Then, the level 0 fetch machine increments the counter of FIFO 1 to signify to the ALU 0 that the data is ready to be processed.~~

~~On receipt of a command, the level 0 ALU machine first decrements the input FIFO 1 counter and then issues a complete set of level 0 shader instructions. For each instruction, the ALU state machine generates 3 source addresses, one destination address and an instruction. Once the last instruction has been issued, the packet is put into FIFO 2.~~

~~There will always be two active ALU clauses at any given time (and two arbiters). One arbiter will arbitrate over the odd instructions (4 clocks cycles) and the other one will arbitrate over the even instructions (4 clocks cycles). The only constraints between the two arbiters is that they are not allowed to pick the same clause number as the other one is currently working on if the packet is not of the same type (render state).~~

~~If the packet is a vertex packet, upon reaching ALU clause 3, it can export the position if the position is ready. So the arbiter must prevent ALU clause 3 to be selected if the positional buffer is full (or can't be accessed). Along with the positional data, if needed the sprite size and/or edge flags can also be sent.~~

~~A special case is for multipass vertex shaders, which can export 12 parameters per last 6 clauses to the output buffer. If the output buffer is full or doesn't have enough space the sequencer will prevent such a vertex group to enter an exporting clause.~~

~~Multipass pixel shaders can export 12 parameters to memory from the last clause only (7).~~

~~All other clauses process in the same way until the packet finally reaches the last ALU machine (7).~~

~~Only one pair of interleaved ALU state machines may have access to the register file address bus or the instruction decode bus at one time. Similarly, only one fetch state machine may have access to the register file address bus at one time. Arbitration is performed by three arbiter blocks (two for the ALU state machines and one for the fetch state machines). The arbiters always favor the higher number state machines, preventing a bunch of half finished jobs from clogging up the register files.~~
Under this new scheme, the sequencer (SQ) will only use one global state management machine per vector type (pixel, vertex) that we call the reservation station (RS).

1.2 Data Flow graph (SP)

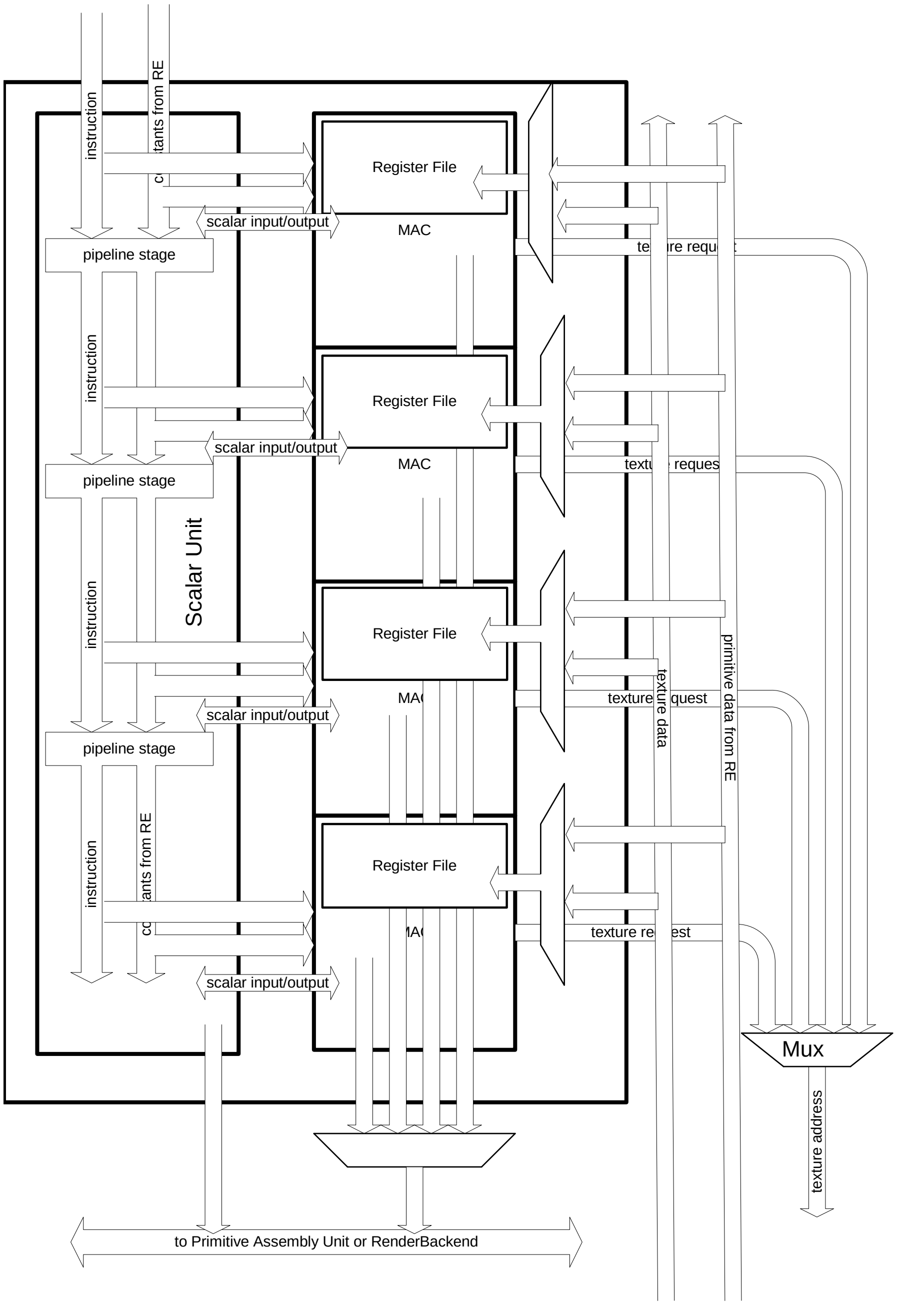

Figure 3: The shader Pipe

The gray area represents blocks that are replicated 4 times per shader pipe (16 times on the overall chip).

1.3 Control Graph

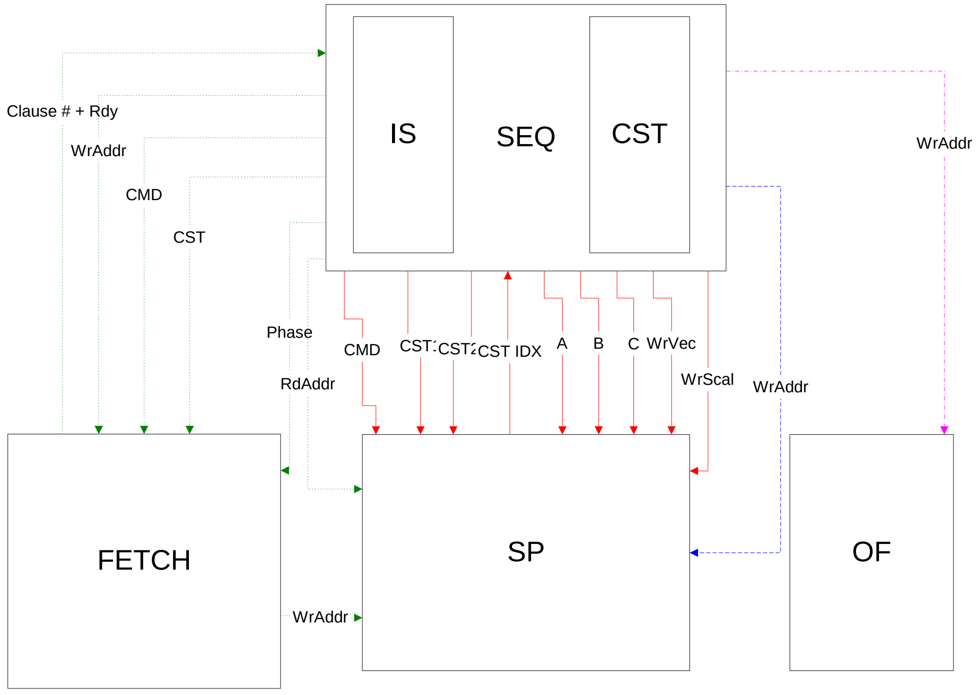

Figure 4: Sequencer Control interfaces

In green is represented the Fetch control interface, in red the ALU control interface, in blue the Interpolated/Vector control interface and in purple is the output file control interface.

2. Interpolated data bus

The interpolators contain an IJ buffer to pack the information as much as possible before writing it to the register file.

		XY						P1								P2						VTX		

Figure 6: Interpolation timing diagram

Above is an example of a tile the sequencer might receive from the SC. The write side is how the data get stacked into the XY and IJ buffers, the read side is how the data is passed to the GPRs. The IJ information is packed in the IJ buffer 4 quads at a time or two clocks. The sequencer allows at any given time as many as four quads to interpolate a parameter. They all have to come from the same primitive. Then the sequencer controls the write mask to the GPRs to write the valid data in.

3. Instruction Store

There is going to be only one instruction store for the whole chip. It will contain 4096 instructions of 96 bits each.

It is likely to be a 1 port memory; we use 1 clock to load the ALU instruction, 1 clocks to load the Fetch instruction, 1 clock to load 2 control flow instructions and 1 clock to write instructions.

The instruction store is loaded by the CP thru the register mapped registers.

The VS_BASE and PS_BASE context registers are used to specify for each context where its shader is in the instruction memory.

For the Real time commands the story is quite the same but for some small differences. There are no wrap-around points for real time so the driver must be careful not to overwrite regular shader data. The shared code (shared subroutines) uses the same path as real time.

4. Sequencer Instructions

All control flow instructions and move instructions are handled by the sequencer only. The ALUs will perform NOPs during this time (MOV PV,PV, PS,PS) if they have nothing else to do.

5. Constant Stores

5.1 Memory organizations

A likely size for the ALU constant store is 1024x128 bits. The read BW from the ALU constant store is 128 bits/clock and the write bandwidth is 32 bits/clock (directed by the CP bus size not by memory ports).

The maximum logical size of the constant store for a given shader is 256 constants. Or 512 for the pixel/vertex shader pair. The size of the re-mapping table is 128 lines (each line addresses 4 constants). The write granularity is 4 constants or 512 bits. It takes 16 clocks to write the four constants. Real time requires 256 lines in the physical memory (this is physically register mapped).

The texture state is also kept in a similar memory. The size of this memory is 320x96 bits (128 texture states for regular mode, 32 states for RT). The memory thus holds 128 texture states (192 bits per state). The logical size exposes 32 different states total, which are going to be shared between the pixel and the vertex shader. The size of the re-mapping table to for the texture state memory is 32 lines (each line addresses 1 texture state lines in the real memory). The CP write granularity is 1 texture state lines (or 192 bits). The driver sends 512 bits but the CP ignores the top 320 bits. It thus takes 6 clocks to write the texture state. Real time requires 32 lines in the physical memory (this is physically register mapped).

The control flow constant memory doesn't sit behind a renaming table. It is register mapped and thus the driver must reload its content each time there is a change in the control flow constants. Its size is 320*32 because it must hold 8 copies of the 32 dwords of control flow constants and the loop construct constants must be aligned.

The constant re-mapping tables for texture state and ALU constants are logically register mapped for regular mode and physically register mapped for RT operation.

5.2 Management of the Control Flow Constants

The control flow constants are register mapped, thus the CP writes to the according register to set the constant, the SQ decodes the address and writes to the block pointed by its current base pointer (CF_WR_BASE). On the read side, one level of indirection is used. A register (SQ_CONTEXT_MISC.CF_RD_BASE) keeps the current base pointer to the control flow block. This register is copied whenever there is a state change. Should the CP write to CF after the state change, the base register is updated with the (current pointer number +1)% number of states. This way, if the CP doesn't write to CF the state is going to use the previous CF constants.

5.3 Management of the re-mapping tables

5.3.1 *R400 Constant management*

The sequencer is responsible to manage two re-mapping tables (one for the constant store and one for the texture state). On a state change (by the driver), the sequencer will broadside copy the contents of its re-mapping tables to a new one. We have 8 different re-mapping tables we can use concurrently.

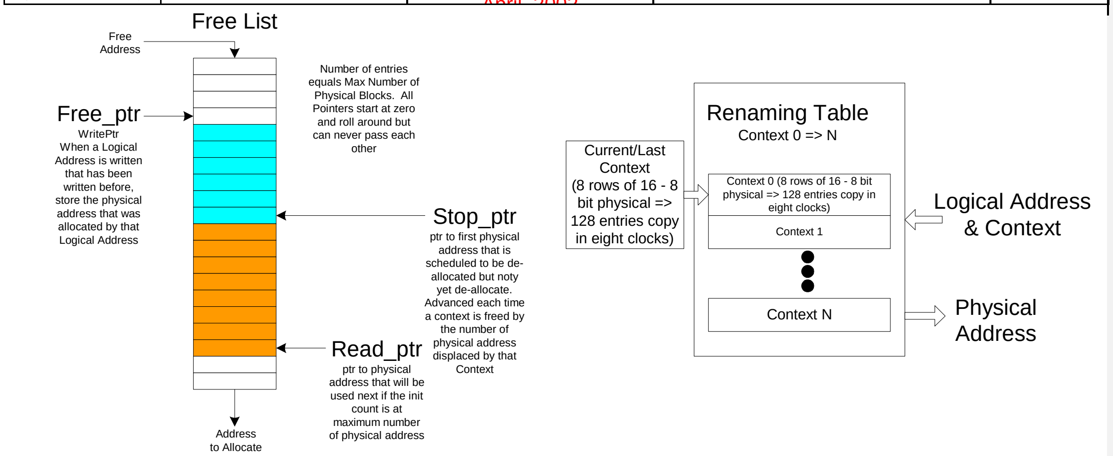
The constant memory update will be incremental, the driver only need to update the constants that actually changed between the two state changes.

For this model to work in its simplest form, the requirement is that the physical memory MUST be at least twice as large as the logical address space + the space allocated for Real Time. In our case, since the logical address space is 512 and the reserved RT space can be up to 256 entries, the memory must be of sizes 1280 and above. Similarly the size of the texture store must be of 32*2+32 = 96 entries and above.

5.3.2 *Proposal for R400LE constant management*

To make this scheme work with only 512+256 = 768 entries, upon reception of a CONTROL packet of state + 1, the sequencer would check for SQ_IDLE and PA_IDLE and if both are idle will erase the content of state to replace it with the new state (this is depicted in Figure 8: De-allocation mechanism~~Figure 9: De-allocation mechanism~~). Note that in the case a state is cleared a value of 0 is written to the corresponding de-allocation counter location so that when the SQ is going to report a state change, nothing will be de-allocated upon the first report.

The second path sets all context dirty bits that were used in the current state to 1 (thus allowing the new state to reuse these physical addresses if needed).



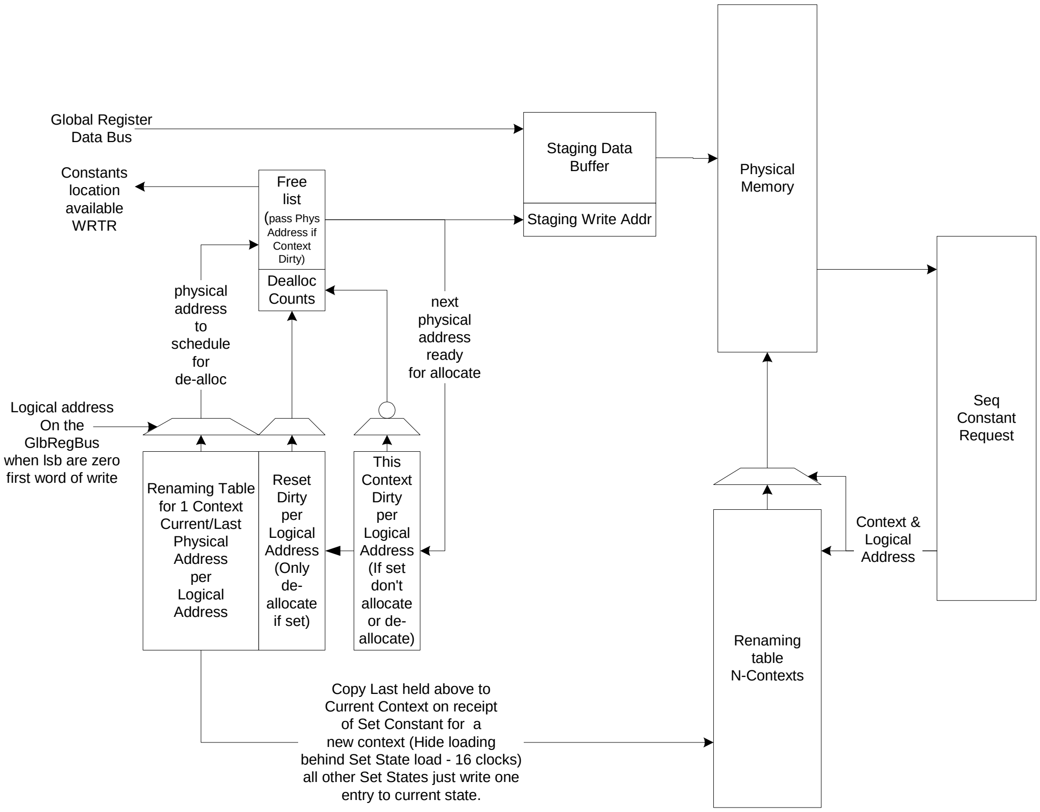


Figure 7~~8~~: Constant management

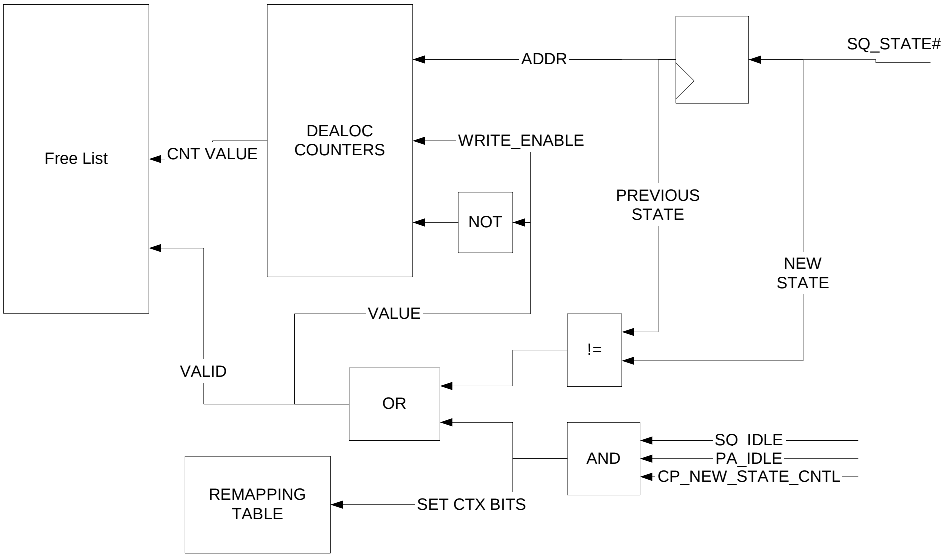

Figure 8~~9~~: De-allocation mechanism for R400LE

5.3.3 *Dirty bits*

Two sets of dirty bits will be maintained per logical address. The first one will be set to zero on reset and set when the logical address is addressed. The second one will be set to zero whenever a new context is written and set for each address written while in this context. The reset dirty is not set, then writing to that logical address will not require de-allocation of whatever address stored in the renaming table. If it is set and the context dirty is not set, then the physical address store needs to be de-allocated and a new physical address is necessary to store the incoming data. If they are both set, then the data will be written into the physical address held in the renaming for the current logical address. No de-allocation or allocation takes place. This will happen when the driver does a set constant twice to the same logical address between context changes. NOTE: It is important to detect and prevent this, failure to do it will allow multiple writes to allocate all physical memory and thus hang because a context will not fit for rendering to start and thus free up space.

5.3.4 *Free List Block*

A free list block that would consist of a counter (called the IFC or Initial Free Counter) that would reset to zero and incremented every time a chunk of physical memory is used until they have all been used once. This counter would be checked each time a physical block is needed, and if the original ones have not been used up, us a new one, else check the free list for an available physical block address. The count is the physical address for when getting a chunk from the counter.

Storage of a free list big enough to store all physical block addresses.

Maintain three pointers for the free list that are reset to zero. The first one we will call write_ptr. This pointer will identify the next location to write the physical address of a block to be de-allocated. Note: we can never free more physical memory locations than we have. Once recording address the pointer will be incremented to walk the free list like a ring.

The second pointer will be called stop_ptr. The stop_ptr pointer will be advanced by the number of address chunks de-allocates when a context finishes. The address between the stop_ptr and write_ptr cannot be reused because they are still in use. But as soon as the context using then is dismissed the stop_ptr will be advanced.

The third pointer will be called read_ptr. This pointer will point will point to the next address that can be used for allocation as long as the read_ptr does not equal the stop_ptr and the IFC is at its maximum count.

5.3.5 *De-allocate Block*

This block will maintain a free physical address block count for each context. While in current context, a count shall be maintained specifying how many blocks were written into the free list at the write_ptr pointer. This count will be reset upon reset or when this context is active on the back and different than the previous context. It is actually a count of blocks in the previous context that will no longer be used. This count will be used to advance the write_ptr pointer to make available the set of physical blocks freed when the previous context was done. This allows the discard or de-allocation of any number of blocks in one clock.

5.3.6 *Operation of Incremental model*

The basic operation of the model would start with the write_ptr, stop_ptr, read_ptr pointers in the free list set to zero and the free list counter is set to zero. Also all the dirty bits and the previous context will be initialized to zero. When the first set constants happen, the reset dirty bit will not be set, so we will allocate a physical location from the free list counter because its not at the max value. The data will be written into physical address zero. Both the additional copy of the renaming table and the context zeros of the big renaming table will be updated for the logical address that was written by set start with physical address of 0. This process will be repeated for any logical address that are not dirty until the context changes. If a logical address is hit that has its dirty bits set while in the same context, both dirty bits would be set, so the new data will be over-written to the last physical address assigned for this logical address. When the first draw command of the context is detected, the previous context stored in the additional renaming table will be copied to the larger renaming table in the current (new) context location. Then the set constant logical address with be loaded with a new physical address during the copy and if the reset dirty was set, the physical address it replaced in the renaming table would be entered at the write_ptr pointer location on the free list and the write_ptr will be incremented. The de-allocation counter for the previous context (eight) will be incremented. This as set states come in for this context one of the following will happen:

1.) No dirty bits are set for the logical address being updated. A line will be allocated of the free-list counter or the free list at read_ptr pointer if read_ptr != to stop_ptr .
2.) Reset dirty set and Context dirty not set. A new physical address is allocated, the physical address in the renaming table is put on the free list at write_ptr and it is incremented along with the de-allocate counter for the last context.
3.) Context dirty is set then the data will be written into the physical address specified by the logical address.

This process will continue as long as set states arrive. This block will provide backpressure to the CP whenever he has not free list entries available (counter at max and stop_ptr == read_ptr). The command stream will keep a count of contexts of constants in use and prevent more than max constants contexts from being sent.

Whenever a draw packet arrives, the content of the re-mapping table is written to the correct re-mapping table for the context number. Also if the next context uses less constants than the current one all exceeding lines are moved to the free list to be de-allocated later. This happens in parallel with the writing of the re-mapping table to the correct memory.

Now preferable when the constant context leaves the last ALU clause it will be sent to this block and compared with the previous context that left. (Init to zero) If they differ than the older context will no longer be referenced and thus can be de-allocated in the physical memory. This is accomplished by adding the number of blocks freed this context to the stop_ptr pointer. This will make all the physical addresses used by this context available to the read_ptr allocate pointer for future allocation.

This device allows representation of multiple contexts of constants data with N copies of the logical address space. It also allows the second context to be represented as the first set plus some new additional data by just storing the delta's. It allows memory to be efficiently used and when the constants updates are small it can store multiple context. However, if the updates are large, less contexts will be stored and potentially performance will be degraded. Although it will still perform as well as a ring could in this case.

5.4 Constant Store Indexing

In order to do constant store indexing, the sequencer must be loaded first with the indexes (that come from the GPRs). There are 144 wires from the exit of the SP to the sequencer (9 bits pointers x 16 vertexes/clock). Since the data must pass thru the Shader pipe for the float to fixed conversion, there is a latency of 4 clocks (1 instruction)

between the time the sequencer is loaded and the time one can index into the constant store. The assembly will look like this

```
MOVA  R1.X,R2.X       // Loads the sequencer with the content of R2.X, also copies the content of R2.X into R1.X
NOP                   // latency of the float to fixed conversion
ADD   R3,R4,C0[R2.X]// Uses the state from the sequencer to add R4 to C0[R2.X] into R3
```

Note that we don't really care about what is in the brackets because we use the state from the MOVA instruction. R2.X is just written again for the sake of simplicity and coherency.

The storage needed in the sequencer in order to support this feature is 2*64*9 bits = 1152 bits.

5.5 Real Time Commands

The real time commands constants are written by the CP using the register mapped registers allocated for RT. It works is the same way than when dealing with regular constant loads BUT in this case the CP is not sending a logical address but rather a physical address and the reads are not passing thru the re-mapping table but are directly read from the memory. The boundary between the two zones is defined by the CONST_EO_RT control register. Similarly, for the fetch state, the boundary between the two zones is defined by the TSTATE_EO_RT control register.

5.6 Constant Waterfalling

In order to have a reasonable performance in the case of constant store indexing using the address register, we are going to have the possibility of using the physical memory port for read only. This way we can read 1 constant per clock and thus have a worst-case waterfall mode of 1 vertex per clock. There is a small synchronization issue related with this as we need for the SQ to make sure that the constants where actually written to memory (not only sent to the sequencer) before it can allow the first vector of pixels or vertices of the state to go thru the ALUs. To do so, the sequencer keeps 8 bits (one per render state) and sets the bits whenever the last render state is written to memory and clears the bit whenever a state is freed.

6. Looping and Branches

Loops and branches are planned to be supported and will have to be dealt with at the sequencer level. We plan on supporting constant loops and branches using a control program.

6.1 The controlling state.

The R400 controling state consists of:

Boolean[256:0]
Loop_count[7:0][31:0]
Loop_Start[7:0][31:0]
Loop_Step[7:0][31:0]

That is 256 Booleans and 32 loops.

We have a stack of 4 elements for nested calls of subroutines and 4 loop counters to allow for nested loops.

This state is available on a per shader program basis.

6.2 The Control Flow Program

We'd like to be able to code up a program of the form:

```
1:      Loop
2:      Exec    TexFetch
3:              TexFetch
4:              ALU
5:              ALU
6:              TexFetch
7:      End Loop
8:      ALU Export
```

But realize that 3: may be dependent on 2: and 4: is almost certainly dependent on 2: and 3:. Without clausing, these dependencies need to be expressed in the Control Flow instructions. Additionally, without separate 'texture clauses' and 'ALU clauses' we need to know which instructions to dispatch to the Texture Unit and which to the ALU unit. This information will be encapsulated in the flow control instructions.

Each control flow instruction will contain 2 bits of information for each (non-control flow) instruction:

a) ALU or Texture
b) Serialize Execution

(b) would force the thread to stop execution at this point (before the instruction is executed) and wait until all textures have been fetched. Given the allocation of reserved bits, this would mean that the count of an 'Exec' instruction would be limited to about 8 (non-control-flow) instructions. If more than this were needed, a second Exec (with the same conditions) would be issued.

Another function that relies upon 'clauses' is allocation and order of execution. We need to assure that pixels and vertices are exported in the correct order (even if not all execution is ordered) and that space in the output buffers are allocated in order. Additionally data can't be exported until space is allocated. A new control flow instruction:

Alloc <buffer select -- position,parameter, pixel or vertex memory. And the size required>.

would be created to mark where such allocation needs to be done. To assure allocation is done in order, the actual allocation for a given thread can not be performed unless the equivalent allocation for all previous threads is already completed. The implementation would also assure that execution of instruction(s) following the serialization due to the Alloc will occur in order -- at least until the next serialization or change from ALU to Texture. In most cases this will allow the exports to occur without any further synchronization. Only 'final' allocations or position allocations are

guaranteed to be ordered. Because strict ordering is required for pixels, parameters and positions, this implies only a single alloc for these structures. Vertex exports to memory do not require ordering during allocation and so multiple 'allocs' may be done.

6.2.1 *Control flow instructions table*

Formatted: Bullets and Numbering

Here is the revised control flow instruction set.

Note that whenever a field is marked as RESERVED, it is assumed that all the bits of the field are cleared (0).

Execute					
47	46… 43	40 … 34	33 …16	15…12	11 … 0
Addressing	0001	RESERVED	Instructions type + serialize (9 instructions)	Count	Exec Address

Execute up to 9 instructions at the specified address in the instruction memory. The Instruction type field tells the sequencer the type of the instruction (LSB) (1 = Texture, 0 = ALU and whether to serialize or not the execution (MSB) (1 = Serialize, 0 = Non-Serialized).

NOP		
47	46 … 43	42 … 0
Addressing	0010	RESERVED

This is a regular NOP.

Conditional_Execute						
47	46 … 43	42	41 … 34	33…16	15 …12	11 … 0
Addressing	0011	Condition	Boolean address	Instructions type + serialize (9 instructions)	Count	Exec Address

If the specified Boolean (8 bits can address 256 Booleans) meets the specified condition then execute the specified instructions (up to 9 instructions). If the condition is not met, we go on to the next control flow instruction.

Conditional_Execute_Predicates							
47	46 … 43	42	41 … 36	35 … 34	33…16	15…12	11 … 0
Addressing	0010	Condition	RESERVED	Predicate vector	Instructions type + serialize (9 instructions)	Count	Exec Address

Check the AND/OR of all current predicate bits. If AND/OR matches the condition execute the specified number of instructions. We need to AND/OR this with the kill mask in order not to consider the pixels that aren't valid. If the condition is not met, we go on to the next control flow instruction.

Loop_Start				
47	46 … 43	42 … 17	16 … 12	11 … 0
Addressing	0101	RESERVED	loop ID	Jump address

Loop Start. Compares the loop iterator with the end value. If loop condition not met jump to the address. Forward jump only. Also computes the index value. The loop id must match between the start to end, and also indicates which control flow constants should be used with the loop.

Loop_End					
47	46 … 43	42 … 20~~17~~	19… 17	16 … 12	11 … 0
Addressing	0011	RESERVED	Predicate break	loop ID	start address

Loop end. Increments the counter by one, compares the loop count with the end value. If loop condition met, continue, else, jump BACK to the start of the loop. If predicate break != 0, then compares predicate vector n (specified by predicate break number). If all bits cleared then break the loop.

The way this is described does not prevent nested loops, and the inclusion of the loop id make this easy to do.

Conditionnal_Call						
47	46 … 43	42	41 …37	35 … 34	33 … 12	11 … 0
Addressing	0111	Condition	RESERVED	Predicate vector	RESERVED	Jump address

If the condition is met, jumps to the specified address and pushes the control flow program counter on the stack.

Return		
47	46 … 43	42 … 0
Addressing	1000	RESERVED

Pops the topmost address from the stack and jumps to that address. If nothing is on the stack, the program will just continue to the next instruction.

Conditionnal_Jump						
47	46 … 43	42	41… 34	33	32 … 12	11 … 0
Addressing	1001	Condition	Boolean address	FW only	RESERVED	Jump address

Allocate				
47	46 … 43	42…41	40 … 4	3 …0
Debug	1010	Buffer Select	RESERVED	Allocation size

Buffer Select takes a value of the following:
01 – position export (ordered export)
10 – parameter cache or pixel export (ordered export)
11 – pass thru (out of order exports).

If debug is set this is a debug alloc (ignore if debug DB_ON register is set to off).

End Of Program		
47	46 … 43	42… 0
RESERVED	1011	RESERVED

Marks the end of the program.

6.3 Implementation

Formatted: Bullets and Numbering

The envisioned implementation has a buffer that maintains the state of each thread. A thread lives in a given location in the buffer during its entire life, but the buffer has FIFO qualities in that threads leave in the order that they enter. Actually two buffers are maintained -- one for Vertices and one for Pixels. The intended implementation would allow for:

16 entries for vertices
48 entries for pixels.

From each buffer, arbitration logic attempts to select 1 thread for the texture unit and 1 (interleaved) thread for the ALU unit. Once a thread is selected it is read out of the buffer, marked as invalid, and submitted to appropriate execution unit. It is returned to the buffer (at the same place) with its status updated once all possible sequential instructions have been executed. A switch from ALU to TEX or visa-versa or a Serialize_Execution modifier forces the thread to be returned to the buffer.

Each entry in the buffer will be stored across two physical pieces of memory - most bits will be stored in a 1 read port device. Only bits needed for thread arbitration will be stored in a highly multi-ported structure. The bits kept in the 1 read port device will be termed 'state'. The bits kept in the multi-read ported device will be termed 'status'.

'State Bits' needed include:

1. Control Flow Instruction Pointer (12 bits),
2. Execution Count Marker 4 bits),
3. Loop Iterators (4x9 bits),
4. Call return pointers (4x12 bits),
5. Predicate Bits(4x64 bits),
6. Export ID (1 bit),
7. Parameter Cache base Ptr (7 bits),
8. GPR Base Ptr (8 bits),
9. Context Ptr (3 bits).
10. LOD corrections (6x16 bits)

Formatted: Bullets and Numbering

Absent from this list are 'Index' pointers. These are costly enough that I'm presuming that they are instead stored in the GPRs. The first seven fields above (Control Flow Ptr, Execution Count, Loop Counts, call return ptrs, Predicate bits, PC base ptr and export ID) are updated every time the thread is returned to the buffer based on how much progress has been mode on thread execution. GPR Base Ptr, Context Ptr and LOD corrections are unchanged throughout execution of the thread.

'Status Bits' needed include:

- Valid Thread
- Texture/ALU engine needed
- Texture Reads are outstanding
- Waiting on Texture Read to Complete
- Allocation Wait (2 bits)
- 00 – No allocation needed
- 01 – Position export allocation needed (ordered export)
- 10 – Parameter or pixel export needed (ordered export)
- 11 – pass thru (out of order export)
- Allocation Size (4 bits)
- Position Allocated
- First thread of a new context
- Event thread (NULL thread that needs to trickle down the pipe)
- Last (1 bit)

Formatted: Bullets and Numbering

All of the above fields from all of the entries go into the arbitration circuitry. The arbitration circuitry will select a winner for both the Texture Engine and for the ALU engine. There are actually two sets of arbitration -- one for pixels and one for vertices. A final selection is then done between the two. But the rest of this implementation summary only considers the 'first' level selection which is similar for both pixels and vertices.

Texture arbitration requires no allocation or ordering so it is purely based on selecting the 'oldest' thread that requires the Texture Engine.

ALU arbitration is a little more complicated. First, only threads where either of Texture_Reads_outstanding or Waiting_on_Texture_Read_to_Complete are '0' are considered. Then if Allocation_Wait is active, these threads are further filtered based on whether space is available. If the allocation is position allocation, then the thread is only considered if all 'older' threads have already done their position allocation (position allocated bits set). If the allocation is parameter or pixel allocation, then the thread is only considered if it is the oldest thread. Also a thread is not considered if it is a parameter or pixel or position allocation, has its First_thread_of_a_new_context bit set and would cause ALU interleaving with another thread performing the same parameter or pixel or position allocation. Finally the 'oldest' of the threads that pass through the above filters is selected. If the thread needed to allocate, then at this time the allocation is done, based on Allocation_Size. If a thread has its “last” bit set, then it is also removed from the buffer, never to return.

If I now redefine 'clauses' to mean 'how many times the thread is removed from the thread buffer for the purpose of exection by either the ALU or Texture engine', then the minimum number of clauses needed is 2 -- one to perform the allocation for exports (execution automatically halts after an 'Alloc' instruction) (but doesn't performs the actual allocation) and one for the actual ALU/export instructions. As the 'Alloc' instruction could be part of a texture clause (presumably the final instruction in such a clause), a thread could still execute in this minimal number of 2 clauses, even if it involved texture fetching.

The Texture_Reads_Outstanding bit must be updated by the sequencer, based on keeping track of how many Texture Clauses have been executed by a given thread that have not yet had there data returned. Any number above 0 results in this bit being set. We could consider forcing synchronization such that two texture clauses for a given thread may not be outstanding at any time (that would be my preference for simplicity reasons and because it would require only very little change in the texture pipe interface). This would allow the sequencer to set the bit on execution of the texture clause, and allow the texture unit to return a pointer to the thread buffer on completion that clears the bit.

~~Examples of control flow programs are located in the R400 programming guide document.~~

~~The basic model is as follows:~~

~~The render state defined the clause boundaries:~~
~~Vertex_shader_fetch[7:0][7:0] // eight 8 bit pointers to the location where each clauses control program is located~~
~~Vertex_shader_alu[7:0][7:0] // eight 8 bit pointers to the location where each clauses control program is located~~
~~Pixel_shader_fetch[7:0][7:0] // eight 8 bit pointers to the location where each clauses control program is located~~
~~Pixel_shader_alu[7:0][7:0] // eight 8 bit pointers to the location where each clauses control program is located~~

~~**A pointer value of FF means that the clause doesn’t contain any instructions**.~~

~~The control program for a given clause is executed to completion before moving to another clause, (with the exception of the pick two nature of the alu execution). The control program is the only program aware of the clause boundaries.~~

~~The control program has nine basic instructions:~~

~~Execute~~
~~Conditional_execute~~
~~Conditional_Execute_Predicates~~
~~Conditional_jump~~
~~Conditionnal_Call~~
~~Return~~
~~Loop_start~~
~~Loop_end~~
~~NOP~~

~~Execute, causes the specified number of instructions in instruction store to be executed.~~
~~Conditional_execute checks a condition first, and if true, causes the specified number of instructions in instruction store to be executed.~~
~~Loop_start resets the corresponding loop counter to the start value on the first pass after it checks for the end condition and if met jumps over to a specified address.~~
~~Loop_end increments (decrements?) the loop counter and jumps back the specified number of instructions.~~
~~Conditionnal_Call jumps to an address and pushes the IP counter on the stack if the condition is met. On the return instruction, the IP is popped from the stack.~~

~~Conditional_execute_Predicates executes a block of instructions if all bits in the predicate vectors meet the condition.~~
~~Conditional_jumps jumps to an address if the condition is met.~~
~~NOP is a regular NOP~~

~~NOTE THAT ALL JUMPS MUST JUMP TO EVEN CFP ADDRESSES since there are two control flow instructions per memory line. Thus the compiler must insert NOPs where needed to align the jumps on even CFP addresses.~~

~~Also if the jump is logically bigger than pshader_cntl_size (or vshader_cntl_size) we break the program (clause) and set the debug registers. If an execute or conditional_execute is lower than cntl_size or bigger than size we also break the program (clause) and set the debug registers.~~

~~We have to fit instructions into 48 bits in order to be able to put two control flow instruction per line in the instruction store.~~

~~A value of 1 in the Addressing means that the address specified in the Exec Address field (or in the jump address field) is an ABSOLUTE address. If the addressing field is cleared (should be the default) then the address is relative to the base of the current shader program.~~

~~**Note that whenever a field is marked as RESERVED, it is assumed that all the bits of the field are cleared (0).**~~

~~Execute up to 4k instructions at the specified address in the instruction memory. If Last is set, this is the last group of instructions of the clause.~~

~~This is a regular NOP. If Last is set, this is the last instruction of the clause.~~

~~If the specified Boolean (8 bits can address 256 Booleans) meets the specified condition then execute the specified instructions (up to 4k instructions). If Last is set, then if the condition is met, this is the last group of instructions to be executed in the clause. If the condition is not met, we go on to the next control flow instruction.~~

~~Check the AND/OR of all current predicate bits. If AND/OR matches the condition execute the specified number of instructions. We need to AND/OR this with the kill mask in order not to consider the pixels that aren't valid. If Last is set, then if the condition is met, this is the last group of instructions to be executed in the clause. If the condition is not met, we go on to the next control flow instruction.~~

~~Loop Start. Compares the loop iterator with the end value. If loop condition not met jump to the address. Forward jump only. Also computes the index value. The loop id must match between the start to end, and also indicates which control flow constants should be used with the loop.~~

~~Loop end. Increments the counter by one, compares the loop count with the end value. If loop condition met, continue, else, jump BACK to the start of the loop.~~

~~The way this is described does not prevent nested loops, and the inclusion of the loop id make this easy to do.~~

~~If the condition is met, jumps to the specified address and pushes the control flow program counter on the stack.~~

~~Pops the topmost address from the stack and jumps to that address. If nothing is on the stack, the program will just continue to the next instruction.~~

~~If condition met, jumps to the address. FORWARD jump only allowed if bit 31 set. Bit 31 is only an optimization for the compiler and should NOT be exposed to the API.~~

~~To prevent infinite loops, we will keep 9 bits loop iterators instead of 8 (we are only able to loop 256 times). If the counter goes higher than 255 then the loop_end or the loop_start instruction is going to break the loop and set the debug GPRs.~~

Formatted: Bullets and Numbering

~~6.3~~6.4 Data dependant predicate instructions

Data dependant conditionals will be supported in the R400. The only way we plan to support those is by supporting three vector/scalar predicate operations of the form:

PRED_SETE_# - similar to SETE except that the result is 'exported' to the sequencer.
PRED_SETNE_# - similar to SETNE except that the result is 'exported' to the sequencer.
PRED_SETGT_# - similar to SETGT except that the result is 'exported' to the sequencer
PRED_SETGTE_# - similar to SETGTE except that the result is 'exported' to the sequencer

For the scalar operations only we will also support the two following instructions:
PRED_SETE0_# – SETE0
PRED_SETE1_# – SETE1

The export is a single bit - 1 or 0 that is sent using the same data path as the MOVA instruction. The sequencer will maintain 4 sets of 64 bit predicate vectors (in fact 8 sets because we interleave two programs but only 4 will be exposed) and use it to control the write masking. This predicate is not maintained across clause boundaries. The # sign is used to specify which predicate set you want to use 0 thru 3.

Then we have two conditional execute bits. The first bit is a conditional execute “on” bit and the second bit tells us if we execute on 1 or 0. For example, the instruction:

P0_ADD_# R0,R1,R2

Is only going to write the result of the ADD into those GPRs whose predicate bit is 0. Alternatively, P1_ADD_# would only write the results to the GPRs whose predicate bit is set. The use of the P0 or P1 without precharging the sequencer with a PRED instruction is undefined.

{Issue: do we have to have a NOP between PRED and the first instruction that uses a predicate?}

Formatted: Bullets and Numbering

~~6.4~~6.5 HW Detection of PV,PS

Because of the control program, the compiler cannot detect statically dependant instructions. In the case of non-masked writes and subsequent reads the sequencer will insert uses of PV,PS as needed. This will be done by comparing the read address and the write address of consecutive instructions. For masked writes, the sequencer will insert NOPs wherever there is a dependant read/write.

The sequencer will also have to insert NOPs between PRED_SET and MOVA instructions and their uses.

Formatted: Bullets and Numbering

~~6.5~~6.6 Register file indexing

Because we can have loops in fetch clause, we need to be able to index into the register file in order to retrieve the data created in a fetch clause loop and use it into an ALU clause. The instruction will include the base address for register indexing and the instruction will contain these controls:

Bit7	Bit 6	
0	0	'absolute register'
0	1	'relative register'
1	0	'previous vector'
1	1	'previous scalar'

In the case of an absolute register we just take the address as is. In the case of a relative register read we take the base address and we add to it the loop_index and this becomes our new address that we give to the shader pipe.

The sequencer is going to keep a loop index computed as such:

Index = Loop_iterator*Loop_step + Loop_start.

We loop until loop_iterator = loop_count. Loop_step is a signed value [-128…127]. The computed index value is a 10 bit counter that is also signed. Its real range is [-256,256]. The tenth bit is only there so that we can provide an out of range value to the “indexing logic” so that it knows when the provided index is out of range and thus can make the necessary arrangements.
~~Predicated Instruction support for Texture clauses~~
~~For texture clauses, we support the following optimization: we keep 1 bit (thus 4 bits for the four predicate vectors) per predicate vector in the reservation stations. A value of 1 means that one ore more elements in the vector have a value of one (thus we have to do the texture fetches for the whole vector). A value of 0 means that no elements in the vector have his predicate bit set and we can thus skip over the texture fetch.~~ **~~We have to make sure the invalid pixels aren’t considered with this optimization.~~**

~~6.6~~6.7 Debugging the Shaders

In order to be able to debug the pixel/vertex shaders efficiently, we provide 2 methods.

~~6.6.1~~6.7.1 *Method 1: Debugging registers*

Current plans are to expose 2 debugging, or error notification, registers:
1. address register where the first error occurred
2. count of the number of errors

The sequencer will detect the following groups of errors:
- count overflow
- constant indexing overflow
- register indexing overflow

Compiler recognizable errors:
- jump errors
  relative jump address > size of the control flow program
- call stack
  call with stack full
  return with stack empty

A jump error will always cause the program to break. In this case, a break means that a clause will halt execution, but allowing further clauses to be executed.

With all the other errors, program can continue to run, potentially to worst-case limits. The program will only break if the DB_PROB_BREAK register is set.

If indexing outside of the constant or the register range, causing an overflow error, the hardware is specified to return the value with an index of 0. This could be exploited to generate error tokens, by reserving and initializing the 0th register (or constant) for errors.

{ISSUE : Interrupt to the driver or not?}

~~6.6.2~~6.7.2 *Method 2: Exporting the values in the GPRs ~~(12)~~*

The sequencer will have a debug active, count register and an address register for this mode~~ and 3 bits per clause specifying the execution mode for each clause~~.~~ The modes can be :~~
~~Normal~~

~~2)Debug Kill~~
~~2)~~1)~~Debug Addr + Count~~

Formatted: Bullets and Numbering

Under the normal mode execution follows the normal course. ~~Under the kill mode, all control flow instructions are executed but all normal shader instructions of the clause are replaced by NOPs. Only debug_export instructions of clause 7 will be executed under the debug kill setting. Under the other mode, normal execution is done until we reach an address specified by the address register and instruction count (useful for loops) specified by the count register. After we have hit the instruction n times (n=count) we switch the clause to the kill mode.~~

Under the debug mode~~ (debug kill OR debug Addr + count),~~ it is assumed that the program~~clause 7~~ is always exporting ~~12~~ n debug vectors and that all other exports to the SX block (position, color, z, ect) will been turned off (changed into NOPs) by the sequencer (even if they occur before the address stated by the ADDR debug register).

7. Pixel Kill Mask

A vector of 64 bits is kept by the sequencer per group of pixels/vertices. Its purpose is to optimize the texture fetch requests and allow the shader pipe to kill pixels using the following instructions:

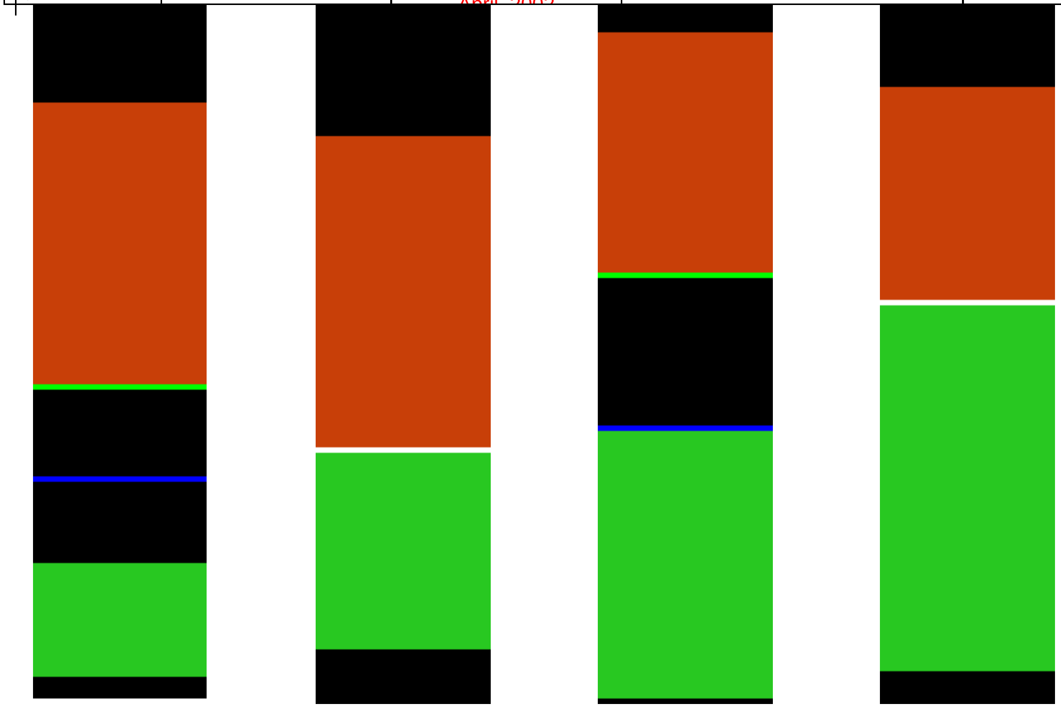
MASK_SETE
MASK_SETNE
MASK_SETGT
MASK_SETGTE

8. Multipass vertex shaders (HOS)

Multipass vertex shaders are able to export from the 6 last clauses but to memory ONLY.

9. Register file allocation

The register file allocation for vertices and pixels can either be static or dynamic. In both cases, the register file in managed using two round robins (one for pixels and one for vertices). In the dynamic case the boundary between pixels and vertices is allowed to move, in the static case it is fixed to 128-VERTEX_REG_SIZE for vertices and PIXEL_REG_SIZE for pixels.



Above is an example of how the algorithm works. Vertices come in from top to bottom; pixels come in from bottom to top. Vertices are in orange and pixels in green. The blue line is the tail of the vertices and the green line is the tail of the pixels. Thus anything between the two lines is shared. When pixels meets vertices the line turns white and the boundary is static until both vertices and pixels share the same “unallocated bubble”. Then the boundary is allowed to move again. The numbering of the GPRs starts from the bottom of the picture at index 0 and goes up to the top at index 127.

10. Fetch Arbitration

The fetch arbitration logic chooses one of the 8 potentially pending fetch clauses to be executed. The choice is made by looking at the fifos from 7 to 0 and picking the first one ready to execute. Once chosen, the clause state machine will send one 2x2 fetch per clock (or 4 fetches in one clock every 4 clocks) until all the fetch instructions of the clause are sent. This means that there cannot be any dependencies between two fetches of the same clause.

The arbitrator will not wait for the fetches to return prior to selecting another clause for execution. The fetch pipe will be able to handle up to X(?) in flight fetches and thus there can be a fair number of active clauses waiting for their fetch return data.

11. ALU Arbitration

ALU arbitration proceeds in almost the same way than fetch arbitration. The ALU arbitration logic chooses one of the 8 potentially pending ALU clauses to be executed. The choice is made by looking at the fifos from 7 to 0 and picking the first one ready to execute. There are two ALU arbiters, one for the even clocks and one for the odd clocks. For example, here is the sequencing of two interleaved ALU clauses (E and O stands for Even and Odd sets of 4 clocks):

Einst0 Oinst0 Einst1 Oinst1 Einst2 Oinst2 Einst0 Oinst3 Einst1 Oinst4 Einst2 Oinst0…
Proceeding this way hides the latency of 8 clocks of the ALUs. Also note that the interleaving also occurs across clause boundaries.

12. Handling Stalls

When the output file is full, the sequencer prevents the ALU arbitration logic from selecting the last clause (this way nothing can exit the shader pipe until there is place in the output file. If the packet is a vertex packet and the position buffer is full (POS_FULL) then the sequencer also prevents a thread from entering the exporting clause (3?). The sequencer will set the OUT_FILE_FULL signal n clocks before the output file is actually full and thus the ALU arbiter will be able read this signal and act accordingly by not preventing exporting clauses to proceed.

13. Content of the reservation station FIFOs

The reservation FIFOs contain the state of the vector of pixels and vertices. We have two sets of those: one for pixels, and one for vertices. They contain 3 bits of Render State 7 bits for the base address of the GPRs, some bits for LOD correction and coverage mask information in order to fetch fetch for only valid pixels, the quad address.

14. The Output File

The output file is where pixels are put before they go to the RBs. The write BW to this store is 256 bits/clock. Just before this output file are staging registers with write BW 512 bits/clock and read BW 256 bits/clock. The staging registers are 4x128 (and there are 16 of those on the whole chip).

15. IJ Format

The IJ information sent by the PA is of this format on a per quad basis:

We have a vector of IJ's (one IJ per pixel at the centroid of the fragment or at the center of the pixel depending on the mode bit). The interpolation is done at a different precision across the 2x2. The upper left pixel's parameters are always interpolated at full 20x24 mantissa precision. Then the result of the interpolation along with the difference in IJ in reduced precision is used to interpolate the parameter for the other three pixels of the 2x2. Here is how we do it:

Assuming P0 is the interpolated parameter at Pixel 0 having the barycentric coordinates I(0), J(0) and so on for P1,P2 and P3. Also assuming that A is the parameter value at V0 (interpolated with I), B is the parameter value at V1 (interpolated with J) and C is the parameter value at V2 (interpolated with (1-I-J).

$$\Delta 01I = I(1) - I(0)$$
$$\Delta 01J = J(1) - J(0)$$
$$\Delta 02I = I(2) - I(0)$$
$$\Delta 02J = J(2) - J(0)$$
$$\Delta 03I = I(3) - I(0)$$
$$\Delta 03J = J(3) - J(0)$$

P0	P1
P2	P3

$$P0 = C + I(0) * (A - C) + J(0) * (B - C)$$
$$P1 = P0 + \Delta 01I * (A - C) + \Delta 01J * (B - C)$$
$$P2 = P0 + \Delta 02I * (A - C) + \Delta 02J * (B - C)$$
$$P3 = P0 + \Delta 03I * (A - C) + \Delta 03J * (B - C)$$

P0 is computed at 20x24 mantissa precision and P1 to P3 are computed at 8X24 mantissa precision. So far no visual degradation of the image was seen using this scheme.

Multiplies (Full Precision): 2
Multiplies (Reduced precision): 6
Subtracts 19x24 (Parameters): 2

Adds: 8

FORMAT OF P0's IJ : Mantissa 20 Exp 4 for I + Sign
Mantissa 20 Exp 4 for J + Sign

FORMAT of Deltas (x3):Mantissa 8 Exp 4 for I + Sign
Mantissa 8 Exp 4 for J + Sign

Total number of bits : 20*2 + 8*6 + 4*8 + 4*2 = 128

All numbers are kept using the un-normalized floating point convention: if exponent is different than 0 the number is normalized if not, then the number is un-normalized. The maximum range for the IJs (Full precision) is +/- 63 and the range for the Deltas is +/- 127.

15.1 Interpolation of constant attributes

Because of the floating point imprecision, we need to take special provisions if all the interpolated terms are the same or if two of the barycentric coordinates are the same.

We start with the premise that if A = B and B = C and C = A, then P0,1,2,3 = A. Since one or more of the IJ terms may be zero, so we extend this to:

```
if (A=B and B=C and C=A)
   P0,1,2,3 = A;
else if ((I = 0) or (J = 0)) and
         ((J = 0) or (1-I-J = 0)) and
         ((1-J-I = 0) or (I = 0))) {
               if(I != 0) {
                   P0 = A;
               } else if(J != 0) {
                   P0 = B;
               } else {
                   P0 = C;
               }
            //rest of the quad interpolated normally
}
else
{
            normal interpolation
}
```

16. Staging Registers

In order for the reuse of the vertices to be 14, the sequencer will have to re-order the data sent IN ORDER by the VGT for it to be aligned with the parameter cache memory arrangement. Given the following group of vertices sent by the VGT:

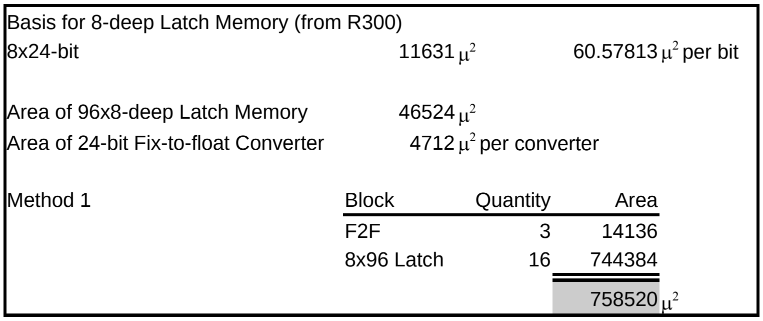
0 1 2 3 4 5 6 7 8 9 10 11 12 13 14 15 || 16 17 18 19 20 21 22 23 24 25 26 27 28 29 30 31 || 32 33 34 35 36 37 38 39 40 41 42 43 44 45 46 47 || 48 49 50 51 52 53 54 55 56 57 58 59 60 61 62 63

The sequencer will re-arrange them in this fashion:

0 1 2 3 16 17 18 19 32 33 34 35 48 49 50 51 || 4 5 6 7 20 21 22 23 36 37 38 39 52 53 54 55 || 8 9 10 11 24 25 26 27 40 41 42 43 56 57 58 59 || 12 13 14 15 28 29 30 31 44 45 46 47 60 61 62 63

The || markers show the SP divisions. In the event a shader pipe is broken, the VGT will send padding to account for the missing pipe. For example, if SP1 is broken, vertices 4 5 6 7 20 21 22 23 36 37 38 39 52 53 54 55 will still be sent by the VGT to the SQ **BUT** will not be processed by the SP and thus should be considered invalid (by the SU and VGT).

The most straightforward, *non-compressed* interface method would be to convert, in the VGT, the data to 32-bit floating point prior to transmission to the VSISRs. In this scenario, the data would be transmitted to (and stored in) the VSISRs in full 32-bit floating point. This method requires three 24-bit fixed-to-float converters in the VGT. Unfortunately, it also requires and additional 3,072 bits of storage across the VSISRs. This interface is illustrated in Figure 11~~Figure 12~~. The area of the fixed-to-float converters and the VSISRs for this method is roughly estimated as 0.759sqmm using the R300 process. The gate count estimate is shown in Figure 10~~Figure 11~~.



Basis for 8-deep Latch Memory (from R300)			
8x24-bit	11631 μ^2		60.57813 μ^2 per bit
Area of 96x8-deep Latch Memory	46524 μ^2		
Area of 24-bit Fix-to-float Converter	4712 μ^2 per converter		
Method 1	Block	Quantity	Area
	F2F	3	14136
	8x96 Latch	16	744384
			758520 μ^2

Figure 10~~11~~:Area Estimate for VGT to Shader Interface

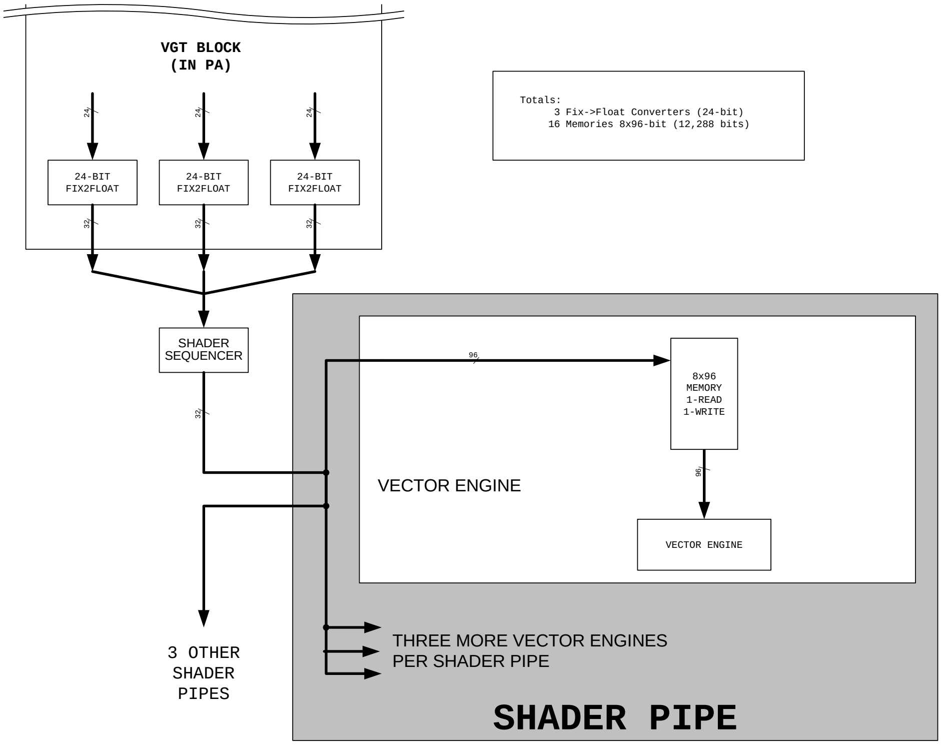


Figure 11~~12~~:VGT to Shader Interface

17. The parameter cache

The parameter cache is where the vertex shaders export their data. It consists of 16 128x128 memories (1R/1W). The reuse engine will make it so that all vertexes of a given primitive will hit different memories. The allocation method for these memories is a simple round robin. The parameter cache pointers are mapped in the following way: 4MSBs are the memory number and the 7 LSBs are the address within this memory.

MEMORY NUMBER 4 bits	ADDRESS 7 bits

The PA generates the parameter cache addresses as the positions come from the SQ. All it needs to do is keep a Current_Location pointer (7 bits only) and as the positions comes increment the memory number. When the memory number field wraps around, the PA increments the Current_Location by VS_EXPORT_COUNT~~_7~~ (a snooped register from the SQ). As an example, say the memories are all empty to begin with and the vertex shader is exporting 8 parameters per vertex (VS_EXPORT_COUNT~~_7~~ = 8). The first position received is going to have the PC address 00000000000 the second one 00010000000, third one 00100000000 and so on up to 11110000000. Then the next position received (the 17th) is going to have the address 00000001000, the 18th 00010001000, the 19th 00100001000 and so on. The Current_location is NEVER reset BUT on chip resets. The only thing to be careful about is that if the SX doesn't send you a full group of positions (<64) then you need to fill the address space so that the next group starts correctly aligned (for example if you receive only 33 positions then you need to add 2*VS_EXPORT_COUNT ~~_7~~to Current_Location and reset the memory count to 0 before the next vector begins).

17.1 Export restrictions

Formatted: Bullets and Numbering

17.1.1 *Pixel exports:*

Pixels can export 1,2,3 or 4 color buffers to the SX(+z). The exports will be done in order. The PRED_OPTIMIZE function has to be turned of if the exports are done using interleaved predicated instructions. The exports will always be ordered to the SX.

17.1.2 *Vertex exports:*

Formatted: Bullets and Numbering

Position or parameter caches can be exported in any order in the shader program. It is always better to export posistion as soon as possible. Position has to be exported in a single export block (no texture instructions can be placed between the exports). Parameter cache exports can be done in any order with texture instructions interleaved. The PRED_OPTIMIZE function has to be turned of if the exports are done using interleaved predicated instructions to the Parameter cache (see Arbitration restrictions for details). The exports will always be allocated in order to the SX.

17.1.3 *Pass thru exports:*

Formatted: Bullets and Numbering

Pass thru exports have to be done in groups of the form:

```
Alloc 4 (8 or 12)
Execute ALU(ADDR) ALU(DATA) ALU(DATA) ALU(DATA)…
```

They cannot have texture instructions interleaved in the export block. These exports **are not guaranteed to be ordered**.

Also, when doing a pass thru export, Position MUST be exported AFTER all pass thru exports. This position export is used to synchronize the chip when doing a transition from pass thru shader to regular shader and vice versa.

17.2 Arbitration restrictions

Formatted: Bullets and Numbering

Here are the Sequencer arbitration restrictions:

Formatted: Bullets and Numbering

1) Cannot execute a serialized thread if the corresponding texture pending bit is set
2) Cannot allocate position if any older thread has not allocated position
3) If last thread is marked as not valid AND marked as last and we are about to execute the second to oldest thread also marked last then:
    a. Both threads must be from the same context (cannot allow a first thread)
    b. Must turn off the predicate optimization for the second thread
4) Cannot execute a texture clause if texture reads are pending
5) Cannot execute last if texture pending (even if not serial)

~~18. Vertex position exporting~~

Formatted: Bullets and Numbering

~~On clause 3 the vertex shader can export to the PA both the vertex position and the point sprite. It can also do so at clause 7 if not done at clause 3. The storage needed to perform the position export is at least 64x128 memories for the position and 64x32 memories for the sprite size. It is going to be taken in the pixel output fifo from the SX blocks. The clause where the position export occurs is specified by the EXPORT_LATE register. If turned on, it means that the export is going to occur at ALU clause 7 if unset position export occurs at clause 3.~~

~~19. Exporting Arbitration~~

Formatted: Bullets and Numbering

~~Here are the rules for co-issuing exporting ALU clauses.~~

~~1)Position exports and position exports cannot be co-issued.~~

Formatted: Bullets and Numbering

~~All other types of exports can be co-issued as long as there is place in the receiving buffer.~~

~~20. Exporting Rules~~

Formatted: Bullets and Numbering

~~20.1 Parameter caches exports~~

~~We support masking and out of order exports to the parameter caches. So one can export multiple times to the same PC line using different masks.~~

Formatted: Bullets and Numbering

~~20.2 Memory exports~~

~~Memory exports don't support masking. However, you can export out of order to memory locations.~~

Formatted: Bullets and Numbering

~~20.3 Position exports~~

~~Position exports have to be done IN ORDER and don't support masking.~~

Formatted: Bullets and Numbering

~~21.~~18. Export Types

The export type (or the location where the data should be put) is specified using the destination address field in the ALU instruction. Here is a list of all possible export modes:

Formatted: Bullets and Numbering

~~21.1~~18.1 Vertex Shading

0:15	- 16 parameter cache
16:31	- Empty (Reserved?)
32	- Export Address
33:40	- 8 vertex exports to the frame buffer and index
41:47	- Empty
48:55	- 8 debug export (interpret as normal vertex export)
60	- export addressing mode
61	- Empty
62	- position
63	- sprite size export that goes with position export (point_h,point_w,edgeflag,misc)

Formatted: Bullets and Numbering

~~21.2~~18.2 Pixel Shading

0	- Color for buffer 0 (primary)
1	- Color for buffer 1
2	- Color for buffer 2
3	- Color for buffer 3
4:7	- Empty
8	- Buffer 0 Color/Fog (primary)
9	- Buffer 1 Color/Fog
10	- Buffer 2 Color/Fog
11	- Buffer 3 Color/Fog
12:15	- Empty
16:31	- Empty (Reserved?)
32	- Export Address
33:40	- 8 exports for multipass pixel shaders.
41:47	- Empty
48:55	- 8 debug exports (interpret as normal pixel export)
60	- export addressing mode
61:62	- Empty
63	- Z for primary buffer (Z exported to 'alpha' component)

~~22.~~19. Special Interpolation modes

Formatted: Bullets and Numbering

~~22.1~~19.1 Real time commands

We are unable to use the parameter memory since there is no way for a command stream to write into it. Instead we need to add three 16x128 memories (one for each of three vertices x 16 interpolants). These will be mapped onto the register bus and written by type 0 packets, and output to the the parameter busses (the sequencer and/or PA need to be able to address the reatime parameter memory as well as the regular parameter store. For higher performance we should be able able to view them as two banks of 16 and do double buffering allowing one to be loaded, while the other is rasterized with. Most overlay shaders will need 2 or 4 scalar coordinates, one option might be to restrict the memory to 16x64 or 32x64 allowing only two interpolated scalars per cycle, the only problem I see with this is, if we view support for 16 vector-4 interpolants important (true only if we map Microsoft's high priority stream to the realtime stream), then the PA/sequencer need to support a realtime-specific mode where we need to address 32 vectors of parameters instead of 16. This mode is triggered by the primitive type: REAL TIME. The actual memories are in the in the SX blocks. The parameter data memories are hooked on the RBBM bus and are loaded by the CP using register mapped memory.

~~22.2~~19.2 Sprites/ XY screen coordinates/ FB information

Formatted: Bullets and Numbering

When working with sprites, one may want to overwrite the parameter 0 with SC generated data. Also, XY screen coordinates may be needed in the shader program. This functionality is controlled by the gen_I0 register (in SQ) in conjunction with the SND_XY register (in SC). Also it is possible to send the faceness information (for OGL front/back special operations) to the shader using the same control register. Here is a list of all the modes and how they interact together:

Gen_st is a bit taken from the interface between the SC and the SQ. This is the MSB of the primitive type. If the bit is set, it means we are dealing with Point AA, Line AA or sprite and in this case the vertex values are going to generated between 0 and 1.

Param_Gen_I0 disable, snd_xy disable, no gen_st – I0 = No modification
Param_Gen_I0 disable, snd_xy disable, gen_st – I0 = No modification
Param_Gen_I0 disable, snd_xy enable, no gen_st – I0 = No modification
Param_Gen_I0 disable, snd_xy enable, gen_st – I0 = No modification
Param_Gen_I0 enable, snd_xy disable, no gen_st – I0 = garbage, garbage, garbage, faceness
Param_Gen_I0 enable, snd_xy disable, gen_st – I0 = garbage, garbage, s, t
Param_Gen_I0 enable, snd_xy enable, no gen_st – I0 = screen x, screen y, garbage, faceness
Param_Gen_I0 enable, snd_xy enable, gen_st – I0 = screen x, screen y, s, t

~~22.3~~19.3 Auto generated counters

Formatted: Bullets and Numbering

In the cases we are dealing with multipass shaders, the sequencer is going to generate a vector count to be able to both use this count to write the 1st pass data to memory and then use the count to retrieve the data on the 2nd pass. The count is always generated in the same way but it is passed to the shader in a slightly different way depending on the shader type (pixel or vertex). This is toggled on and off using the GEN_INDEX register. The sequencer is going to keep two counters, one for pixels and one for vertices. Every time a full vector of vertices or pixels is written to the GPRs the counter is incremented. Every time a state change is detected, the corresponding counter is reset. While there is only one count broadcast to the GPRs, the LSB are hardwired to specific values making the index different for all elements in the vector.

~~22.3.1~~19.3.1 *Vertex shaders*

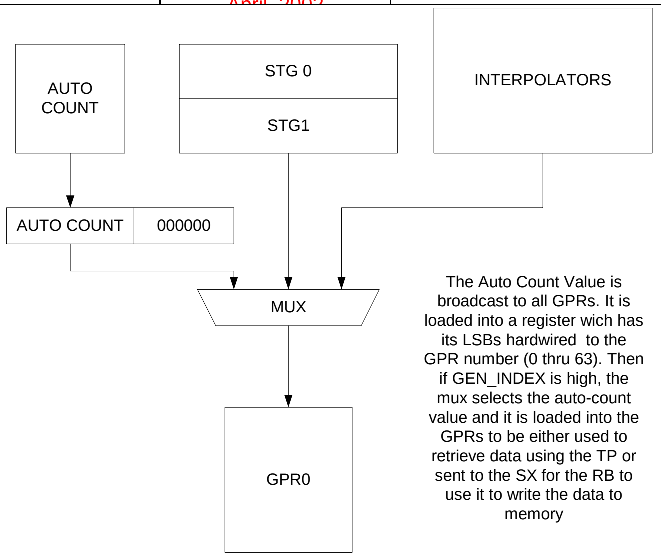
Formatted: Bullets and Numbering

In the case of vertex shaders, if GEN_INDEX is set, the data will be put into the x field of the third register (it means that the compiler must allocate 3 GPRs in all multipass vertex shader modes).

~~22.3.2~~19.3.2 *Pixel shaders*

Formatted: Bullets and Numbering

In the case of pixel shaders, if GEN_INDEX is set and Param_Gen_I0 is enabled, the data will be put in the x field of the 2nd register (R1.x), else if GEN_INDEX is set the data will be put into the x field of the 1st register (R0.x).



The Auto Count Value is broadcast to all GPRs. It is loaded into a register wich has its LSBs hardwired to the GPR number (0 thru 63). Then if GEN_INDEX is high, the mux selects the auto-count value and it is loaded into the GPRs to be either used to retrieve data using the TP or sent to the SX for the RB to use it to write the data to memory

Figure 12~~13~~: GPR input mux Control

Formatted: Bullets and Numbering

~~23.~~20. State management

Every clock, the sequencer will report to the CP the oldest states still in the pipe. These are the states of the programs as they enter the last ALU clause.

Formatted: Bullets and Numbering

~~23.1~~20.1 Parameter cache synchronization

In order for the sequencer not to begin a group of pixels before the associated group of vertices has finished, the sequencer will keep a 6 bit count per state (for a total of 8 counters). These counters are initialized to 0 and every time a vertex shader exports its data TO THE PARAMETER CACHE, the corresponding pointer is incremented. When the SC sends a new vector of pixels with the SC_SQ_new_vector bit asserted, the sequencer will first check if the count is greater than 0 before accepting the transmission (it will in fact accept the transmission but then lower its ready to receive). Then the sequencer waits for the count to go to one and decrements it. The sequencer can then issue the group of pixels to the interpolators. Every time the state changes, the new state counter is initialized to 0.

Formatted: Bullets and Numbering

~~24.~~21. XY Address imports

The SC will be able to send the XY addresses to the GPRs. It does so by interleaving the writes of the IJs (to the IJ buffer) with XY writes (to the XY buffer). Then when writing the data to the GPRs, the sequencer is going to interpolate the IJ data or pass the XY data thru a Fix→float converter and expander and write the converted values to the GPRs. The Xys are currently SCREEN SPACE COORDINATES. The values in the XY buffers will wrap. See section 19.2~~22.2~~ for details on how to control the interpolation in this mode.

Formatted: Bullets and Numbering

~~24.1~~21.1 Vertex indexes imports

In order to import vertex indexes, we have 16 8x96 staging registers. These are loaded one line at a time by the VGT block (96 bits). They are loaded in floating point format and can be transferred in 4 or 8 clocks to the GPRs.

~~25.~~22. Registers

Formatted: Bullets and Numbering

~~25.1~~22.1 Control

REG_DYNAMIC	Dynamic allocation (pixel/vertex) of the register file on or off.
REG_SIZE_PIX	Size of the register file's pixel portion (minimal size when dynamic allocation turned on)
REG_SIZE_VTX	Size of the register file's vertex portion (minimal size when dynamic allocation turned on)
ARBITRATION_POLICY	policy of the arbitration between vertexes and pixels
INST_BASE_VTX	start point for the vertex instruction store (RT always ends at vertex_base and Begins at 0)
INST_BASE_PIX	start point for the pixel shader instruction store
ONE_THREAD	debug state register. Only allows one program at a time into the GPRs
ONE_ALU	debug state register. Only allows one ALU program at a time to be executed (instead of 2)
INSTRUCTION	This is where the CP puts the base address of the instruction writes and type (auto-incremented on reads/writes) Register mapped
CONSTANTS	512*4 ALU constants + 32*6 Texture state 32 bits registers (logically mapped)
CONSTANTS_RT	256*4 ALU constants + 32*6 texture states? (physically mapped)
CONSTANT_EO_RT	This is the size of the space reserved for real time in the constant store (from 0 to CONSTANT_EO_RT). The re-mapping table operates on the rest of the memory
TSTATE_EO_RT	This is the size of the space reserved for real time in the fetch state store (from 0 to TSTATE_EO_RT). The re-mapping table operates on the rest of the memory

~~EXPORT_LATEControls whether or not we are exporting position from clause 3. If set, position exports occur at clause 7.~~

Formatted: Bullets and Numbering

~~25.2~~22.2 Context

~~VS_FETCH_{0…7}~~	~~eight 8 bit pointers to the location where each clauses control program is located~~
~~VS_ALU_{0…7}~~	~~eight 8 bit pointers to the location where each clauses control program is located~~
~~PS_FETCH_{0…7}~~	~~eight 8 bit pointers to the location where each clauses control program is located~~
~~PS_ALU_{0…7}~~	~~eight 8 bit pointers to the location where each clauses control program is located~~
PS_BASE	base pointer for the pixel shader in the instruction store
VS_BASE	base pointer for the vertex shader in the instruction store
VS_CF_SIZE	size of the vertex shader (# of instructions in control program/2)
PS_CF_SIZE	size of the pixel shader (# of instructions in control program/2)
PS_SIZE	size of the pixel shader (cntl+instructions)
VS_SIZE	size of the vertex shader (cntl+instructions)
PS_NUM_REG	number of GPRs to allocate for pixel shader programs
VS_NUM_REG	number of GPRs to allocate for vertex shader programs
PARAM_SHADE	One 16 bit register specifying which parameters are to be gouraud shaded (0 = flat, 1 = gouraud)
~~PROVO_VERT~~	~~0 : vertex 0, 1: vertex 1, 2: vertex 2, 3: Last vertex of the primitive~~
PARAM_WRAP	64 bits: for which parameters (and channels (xyzw)) do we do the cyl wrapping (0=linear, 1=cylindrical).
PS_EXPORT_MODE	0xxxx : Normal mode 1xxxx : Multipass mode If normal, bbbz where bbb is how many colors (0-4) and z is export z or not If multipass 1-12 exports for color.
VS_EXPORT_MODE	0: position (1 vector), 1: position (2 vectors), 3:multipass
VS_EXPORT_COUNT	Number of locations exported by the VS (and thus number of interpolated parameters) ~~{0…6}~~ ~~Six 4 bit counters representing the # of interpolated parameters exported in clause 7 (located in VS_EXPORT_COUNT_6) OR # of exported vectors to memory per clause in multipass mode (per clause)~~
PARAM_GEN_I0	Do we overwrite or not the parameter 0 with XY data and generated T and S values

GEN_INDEX	Auto generates an address from 0 to XX. Puts the results into R0-1 for pixel shaders and R2 for vertex shaders
CONST_BASE_VTX (9 bits)	Logical Base address for the constants of the Vertex shader
CONST_BASE_PIX (9 bits)	Logical Base address for the constants of the Pixel shader
CONST_SIZE_PIX (8 bits)	Size of the logical constant store for pixel shaders
CONST_SIZE_VTX (8 bits)	Size of the logical constant store for vertex shaders
INST_PRED_OPTIMIZE	Turns on the predicate bit optimization (if of, conditional_execute_predicates is always executed).
CF_BOOLEANS	256 boolean bits
CF_LOOP_COUNT	32x8 bit counters (number of times we traverse the loop)
CF_LOOP_START	32x8 bit counters (init value used in index computation)
CF_LOOP_STEP	32x8 bit counters (step value used in index computation)

Formatted: Bullets and Numbering

~~26.~~23. DEBUG Registers

~~26.1~~23.1 Context

DB_PROB_ADDR	instruction address where the first problem occurred
DB_PROB_COUNT	number of problems encountered during the execution of the program
DB_PROB_BREAK	break the clause if an error is found.
DB_ON	turns on an off debug method 2
DB_INST_COUNT	instruction counter for debug method 2
DB_BREAK_ADDR	break address for method number 2
~~DB_CLAUSE_MODE_ALU_{0…7}~~	~~clause mode for debug method 2 (0: normal, 1: addr, 2: kill)~~
~~DB_CLAUSE_MODE_FETCH_{0…7}~~	~~clause mode for debug method 2 (0: normal, 1: addr, 2: kill)~~

Formatted: Bullets and Numbering

~~26.2~~23.2 Control

DB_ALUCST_MEMSIZE	Size of the physical ALU constant memory
DB_TSTATE_MEMSIZE	Size of the physical texture state memory

Formatted: Bullets and Numbering

~~27.~~24. Interfaces

~~27.1~~24.1 External Interfaces

Whenever an x is used, it means that the bus is broadcast to all units of the same name. For example, if a bus is named SQ→SPx it means that SQ is going to broadcast the same information to all SP instances.

Formatted: Bullets and Numbering

~~27.2~~24.2 SC to SP Interfaces

Formatted: Bullets and Numbering

~~27.2.1~~24.2.1 *SC_SP#*

There is one of these interfaces at front of each of the SP (buffer to stage pixel interpolators). This interface transmits the I,J data for pixel interpolation. For the entire system, two quads per clock are transferred to the 4 SPs, so each of these 4 interfaces transmits one half of a quad per clock. The interface below describes a half of a quad worth of data.

The actual data which is transferred per quad is

Ref Pix I => S4.20 Floating Point I value
Ref Pix J => S4.20 Floating Point J value
Delta Pix I (x3) => S4.8 Floating Point Delta I value
Delta Pix J (x3) => S4.8 Floating Point Delta J value

This equates to a total of 128 bits which transferred over 2 clocks
and therefor needs an interface 64 bits wide

Additionally, X,Y data (12-bit unsigned fixed) is conditionally sent across this data bus over the same wires in an additional clock. The X,Y data is sent on the lower 24 bits of the data bus with faceness in the msb.
Transfers across these interfaces are synchronized with the SC_SQ IJ Control Bus transfers.

The data transfer across each of these busses is controlled by a IJ_BUF_INUSE_COUNT in the SC. Each time the SC has sent a pixel vector's worth of data to the SPs, he will increment the IJ_BUF_INUSE_COUNT count. Prior to sending the next pixel vectors data, he will check to make sure the count is less than MAX_BUFER_MINUS_2, if not the SC will stall until the SQ returns a pipelined pulse to decrement the count when he has scheduled a buffer free. Note: We could/may optimize for the case of only sending only IJ to use all the buffers to pre-load more. Currently it is planned for the SP to hold 2 double buffers of I,J data and two buffers of X,Y data, so if either X,Y or Centers and Centroids are on, then the SC can send two Buffers.

In at least the initial version, the SC shall send 16 quads per pixel vector even if the vector is not full. This will increment buffer write address pointers correctly all the time. (We may revisit this for both the SX,SP,SQ and add a EndOfVector signal on all interfaces to quit early. We opted for the simple mode first with a belief that only the end of packet and multiple new vector signals should cause a partial vector and that this would not really be significant performance hit.)

Name	Bits	Description
SC_SP#_data	64	IJ information sent over 2 clocks (or X,Y in 24 LSBs with faceness in upper bit) **Type 0 or 1**, First clock I, second clk J Field ULC URC LLC LRC Bits [63:39] [38:26] [25:13] [12:0] Format SE4M20 SE4M8 SE4M8 SE4M8 **Type 2** Field Face X Y Bits [63] [23:12] [11:0] Format Bit Unsigned Unsigned
SC_SP#_valid	1	Valid
SC_SP#_last_quad_data	1	This bit will be set on the last transfer of data per quad.
SC_SP#_type	2	0 -> Indicates centroids 1 -> Indicates centers 2 -> Indicates X,Y Data and faceness on data bus The SC shall look at state data to determine how many types to send for the interpolation process.

The # is included for clarity in the spec and will be replaced with a prefix of u#_ in the verilog module statement for the SC and the SP block will have neither because the instantiation will insert the prefix.

~~27.2.2~~24.2.2 SC_SQ

Formatted: Bullets and Numbering

This is the control information sent to the sequencer in order to synchronize and control the interpolation and/or loading data into the GPRs needed to execute a shader program on the sent pixels. This data will be sent over two clocks per transfer with 1 to 16 transfers. Therefore the bus (approx 92 bits) could be folded in half to approx 47 bits.

Name	Bits	Description
SC_SQ_data	46	Control Data sent to the SQ 1 clk transfers Event – valid data consist of event_id and state_id. Instruct SQ to post an event vector to send state id and event_id through request fifo and onto the reservation stations making sure state id and/or event_id gets back to the CP. Events only follow end of packets so no pixel vectors will be in progress.

		Empty Quad Mask – Transfer Control data consisting of pc_dealloc or new_vector. Receipt of this is to transfer pc_dealloc or new_vector without any valid quad data. New vector will always be posted to request fifo and pc_dealloc will be attached to any pixel vector outstanding or posted in request fifo if no valid quad outstanding. 2 clk transfers Quad Data Valid – Sending quad data with or without new_vector or pc_dealloc. New vector will be posted to request fifo with or without a pixel vector and pc_dealloc will be posted with a pixel vector unless none is in progress. In this case the pc_dealloc will be posted in the request queue. Filler quads will be transferred with The Quad mask set but the pixel corresponding pixel mask set to zero.
SC_SQ_valid	1	SC sending valid data, 2nd clk could be all zeroes

SC_SQ_data – first clock and second clock transfers are shown in the table below.

Name	BitField	Bits	Description
1st Clock Transfer			
SC_SQ_event	0	1	This transfer is a 1 clock event vector Force quad_mask = new_vector=pc_dealloc=0
SC_SQ_event_id	[2:1]	2	This field identifies the event 0 => denotes an End Of State Event 1 => TBD
SC_SQ_pc_dealloc	[5:3]	3	Deallocation token for the Parameter Cache
SC_SQ_new_vector	6	1	The SQ must wait for Vertex shader done count > 0 and after dispatching the Pixel Vector the SQ will decrement the count.
SC_SQ_quad_mask	[10:7]	4	Quad Write mask left to right SP0 => SP3
SC_SQ_end_of_prim	11	1	End Of the primitive
SC_SQ_state_id	[14:12]	3	State/constant pointer (6*3+3)
SC_SQ_pix_mask	[30:15]	16	Valid bits for all pixels SP0=>SP3 (UL,UR,LL,LR)
SC_SQ_prim_type	[33:31]	3	Stippled line and Real time command need to load tex cords from alternate buffer 000: Normal 010: Realtime 101: Line AA 110: Point AA (Sprite)
SC_SQ_provok_vtx	[35:34]	2	Provoking vertex for flat shading
SC_SQ_pc_ptr0	[46:36]	11	Parameter Cache pointer for vertex 0
2nd Clock Transfer			
SC_SQ_pc_ptr1	[10:0]	11	Parameter Cache pointer for vertex 1
SC_SQ_pc_ptr2	[21:11]	11	Parameter Cache pointer for vertex 2
SC_SQ_lod_correct	[45:22]	24	LOD correction per quad (6 bits per quad)

Name	Bits	Description

SQ_SC_free_buff	1	Pipelined bit that instructs SC to decrement count of buffers in use.
SQ_SC_dec_cntr_cnt	1	Pipelined bit that instructs SC to decrement count of new vector and/or event sent to prevent SC from overflowing SQ interpolator/Reservation request fifo.

The scan converter will submit a partial vector whenever:

1.) He gets a primitive marked with an end of packet signal.
2.) A current pixel vector is being assembled with at least one or more valid quads and the vector has been marked for deallocate when a primitive marked new_vector arrives. The Scan Converter will submit a partial vector (up to 16quads with zero pixel mask to fill out the vector) prior to submitting the new_vector marker\primitive.

(This will prevent a hang which can be demonstrated when all primitives in a packet three vectors are culled except for a one quad primitive that gets marked pc_dealloc (vertices maximum size). In this case two new_vectors are submitted and processed, but then one valid quad with the pc_dealloc creates a vector and then the new would wait for another vertex vector to be processed, but the one being waited for could never export until the pc_dealloc signal made it through and thus the hang.)

~~27.2.3~~24.2.3 SQ to SX: Interpolator bus

Formatted: Bullets and Numbering

Name	**Direction**	**Bits**	**Description**
SQ_SXx_interp_flat_vtx	SQ→SPx	2	Provoking vertex for flat shading
SQ_SXx_interp_flat_gouraud	SQ→SPx	1	Flat or gouraud shading
SQ_SXx_interp_cyl_wrap	SQ→SPx	4	Wich channel needs to be cylindrical wrapped
SQ_SXx_pc_ptr0	SQ→SXx	11	Parameter Cache Pointer
SQ_SXx_pc_ptr1	SQ→SXx	11	Parameter Cache Pointer
SQ_SXx_pc_ptr2	SQ→SXx	11	Parameter Cache Pointer
SQ_SXx_rt_sel	SQ→SXx	1	Selects between RT and Normal data
SQ_SXx_pc_wr_en	SQ→SXx	1	Write enable for the PC memories
SQ_SXx_pc_wr_addr	SQ→SXx	7	Write address for the PCs
SQ_SXx_pc_channel_mask	SQ→SXx	4	Channel mask

~~27.2.4~~24.2.4 SQ to SP: Staging Register Data

Formatted: Bullets and Numbering

This is a broadcast bus that sends the VSISR information to the staging registers of the shader pipes.

Name	**Direction**	**Bits**	**Description**
SQ_SPx_vsr_data	SQ→SPx	96	Pointers of indexes or HOS surface information
SQ_SPx_vsr_double	SQ→SPx	1	0: Normal 96 bits per vert 1: double 192 bits per vert
SQ_SP0_ vsr_valid	SQ→SP0	1	Data is valid
SQ_SP1_ vsr_ valid	SQ→SP1	1	Data is valid
SQ_SP2_ vsr_ valid	SQ→SP2	1	Data is valid
SQ_SP3_ vsr_ valid	SQ→SP3	1	Data is valid
SQ_SPx_vsr_read	SQ→SPx	1	Increment the read pointers

~~27.2.5~~24.2.5 VGT to SQ : Vertex interface

Formatted: Bullets and Numbering

~~27.2.5.1~~24.2.5.1 Interface Signal Table

The area difference between the two methods is not sufficient to warrant complicating the interface or the state requirements of the VSISRs. **Therefore, the POR for this interface is that the VGT will transmit the data to the VSISRs (via the Shader Sequencer) in full, 32-bit floating-point format.** The VGT can transmit up to six 32-bit floating-point values to each VSISR where four or more values require two transmission clocks. The data bus is 96 bits wide.

Name	Bits	Description
VGT_SQ_vsisr_data	96	Pointers of indexes or HOS surface information
VGT_SQ_vsisr_double	1	0: Normal 96 bits per vert 1: double 192 bits per vert
VGT_SQ_end_of_vector	1	Indicates the last VSISR data set for the current process vector (for double vector data, "end_of_vector" is set on the first vector)
VGT_SQ_indx_valid	1	Vsisr data is valid
VGT_SQ_state	3	Render State (6*3+3 for constants). This signal is guaranteed to be correct when "VGT_SQ_vgt_end_of_vector" is high.
VGT_SQ_send	1	Data on the VGT_SQ is valid receive (see write-up for standard R400 SEND/RTR interface handshaking)
SQ_VGT_rtr	1	Ready to receive (see write-up for standard R400 SEND/RTR interface handshaking)

Formatted

Depending on the type the number of export location changes:

Formatted: Bullets and Numbering

- Type 00 : Pixels without Z
  - o 00 = 1 buffer
  - o 01 = 2 buffers
  - o 10 = 3 buffers
  - o 11 = 4 buffer
- Type 01: Pixels with Z
  - o 00 = 2 Buffers (color + Z)
  - o 01 = 3 buffers (2 color + Z)
  - o 10 = 4 buffers (3 color + Z)
  - o 11 = 5 buffers (4 color + Z)
- Type 10 : Position export
  - o 00 = 1 position
  - o 01 = 2 positions
  - o 1X = Undefined
- Type 11: Pass Thru
  - o 00 = 4 buffers
  - o 01 = 8 buffers
  - o 10 = 12 buffers
  - o 11 = Undefined

Below the thick black line is the end of transfer packet that tells the SX that a given export is finished. The report packet **will always arrive either before or at the same time than the next export to the same ALU id**.~~These fields are sent every time the sequencer picks an exporting clause for execution.~~

~~27.2.7~~24.2.7 *SX to SQ : Output file control*

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
SXx_SQ_exp_count_rdy	SXx→SQ	1	Raised by SX0 to indicate that the following two fields reflect the result of the most recent export
SXx_SQ_exp_pos_avail	SXx→SQ	1	Specifies whether there is room for another position.
SXx_SQ_exp_buf_avail	SXx→SQ	7	Specifies the space available in the output buffers. 0: buffers are full 1: 2K-bits available (32-bits for each of the 64 pixels in a clause) ... 64: 128K-bits available (16 128-bit entries for each of 64 pixels) 65-127: RESERVED

~~27.2.8~~24.2.8 *SQ to TP: Control bus*

Formatted: Bullets and Numbering

Once every clock, the fetch unit sends to the sequencer on which ~~clause~~ RS line it is now working and if the data in the GPRs is ready or not. This way the sequencer can update the fetch valid bits ~~counters~~ flags for the reservation station ~~fifos~~. The sequencer also provides the instruction and constants for the fetch to execute and the address in the register file where to write the fetch return data.

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
SP0_SQ_const_addr	SP0→SQ	36	Constant address load / predicate vector load (4 bits only) to the sequencer
SP0_SQ_valid	SP0→SQ	1	Data valid
SP1_SQ_const_addr	SP1→SQ	36	Constant address load / predicate vector load (4 bits only) to the sequencer

SP1_SQ_valid	SP1→SQ	1	Data valid
SP2_SQ_const_addr	SP2→SQ	36	Constant address load / predicate vector load (4 bits only) to the sequencer
SP2_SQ_valid	SP2→SQ	1	Data valid
SP3_SQ_const_addr	SP3→SQ	36	Constant address load / predicate vector load (4 bits only) to the sequencer
SP3_SQ_valid	SP3→SQ	1	Data valid

~~27.2.14~~24.2.14 *SQ to SPx: constant broadcast*

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
SQ_SPx_const	SQ→SPx	128	Constant broadcast

~~27.2.15~~24.2.15 *SP0 to SQ: Kill vector load*

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
SP0_SQ_kill_vect	SP0→SQ	4	Kill vector load
SP1_SQ_kill_vect	SP1→SQ	4	Kill vector load
SP2_SQ_kill_vect	SP2→SQ	4	Kill vector load
SP3_SQ_kill_vect	SP3→SQ	4	Kill vector load

~~27.2.16~~24.2.16 *SQ to CP: RBBM bus*

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
SQ_RBB_rs	SQ→CP	1	Read Strobe
SQ_RBB_rd	SQ→CP	32	Read Data
SQ_RBBM_nrtrtr	SQ→CP	1	Optional
SQ_RBBM_rtr	SQ→CP	1	Real-Time (Optional)

~~27.2.17~~24.2.17 *CP to SQ: RBBM bus*

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
rbbm_we	CP→SQ	1	Write Enable
rbbm_a	CP→SQ	15	Address -- Upper Extent is TBD (16:2)
rbbm_wd	CP→SQ	32	Data
rbbm_be	CP→SQ	4	Byte Enables
rbbm_re	CP→SQ	1	Read Enable
rbb_rs0	CP→SQ	1	Read Return Strobe 0
rbb_rs1	CP→SQ	1	Read Return Strobe 1
rbb_rd0	CP→SQ	32	Read Data 0
rbb_rd1	CP→SQ	32	Read Data 0
RBBM_SQ_soft_reset	CP→SQ	1	Soft Reset

~~27.2.18~~24.2.18 *SQ to CP: State report*

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
SQ_CP_vs_event	SQ→CP	1	Vertex Shader Event
SQ_CP_vs_eventid	SQ→CP	2	Vertex Shader Event ID
SQ_CP_ps_event	SQ→CP	1	Pixel Shader Event
SQ_CP_ps_eventid	SQ→CP	2	Pixel Shader Event ID

eventid = 0 => *sEndOfState (i.e. VsEndOfState)
eventid = 1 => *sDone (i.e. VsDone)

So, the CP will assume the Vs is done with a state whenever it gets a pulse on the SQ_CP_vs_event and the SQ_CP_vs_eventid = 0.

Formatted: Bullets and Numbering

24.3 Example of control flow program execution

We now provide some examples of execution to better illustrate the new design.

Given the program:

Alu 0
Alu 1
Tex 0
Tex 1
Alu 3 Serial
Alu 4
Tex 2
Alu 5
Alu 6 Serial
Tex 3
Alu 7
Alloc Position 1 buffer
Alu 8 Export
Tex 4
Alloc Parameter 3 buffers
Alu 9 Export 0
Tex 5
Alu 10 Serial Export 2
Alu 11 Export 1 End

Would be converted into the following CF instructions:

```
Execute Alu 0 Alu 0 Tex 0 Tex 0 Alu 1 Alu 0 Tex 0 Alu 0 Alu 1 Tex 0
Execute Alu 0
Alloc Position 1
Execute Alu 0 Tex 0
Alloc Param 3
Execute Alu 0 Tex 0 Alu 1 Alu 0 End
```

And the execution of this program would look like this:

Put thread in Vertex RS:

Control Flow Instruction Pointer (12 bits), (CFP)
Execution Count Marker (3 or 4 bits), (ECM)
Loop Iterators (4x9 bits), (LI)
Call return pointers (4x12 bits), (CRP)
Predicate Bits(4x64 bits), (PB)
Export ID (1 bit), (EXID)
GPR Base Ptr (8 bits), (GPR)
Export Base Ptr (7 bits), (EB)
Context Ptr (3 bits).(CPTR)
LOD correction bits (16x6 bits) (LOD)

State Bits									
CFP	ECM	LI	CRP	PB	EXID	GPR	EB	CPTR	LOD
0	0	0	0	0	0	0	0	0	0

Valid Thread (VALID)
Texture/ALU engine needed (TYPE)
Texture Reads are outstanding (PENDING)
Waiting on Texture Read to Complete (SERIAL)
Allocation Wait (2 bits) (ALLOC)

00 – No allocation needed
01 – Position export allocation needed (ordered export)
10 – Parameter or pixel export needed (ordered export)
11 – pass thru (out of order export)
Allocation Size (4 bits) (SIZE)
Position Allocated (POS_ALLOC)
First thread of a new context (FIRST)
Last (1 bit), (LAST)

Status Bits

VALID	TYPE	PENDING	SERIAL	ALLOC	SIZE	POS_ALLOC	FIRST	LAST
1	ALU	0	0	0	0	0	1	0

Then the thread is picked up for the execution of the first control flow instruction:

```
Execute Alu 0 Alu 0 Tex 0 Tex 0 Alu 1 Alu 0 Tex 0 Alu 0 Alu 1 Tex 0
```

It executes the first two ALU instructions and goes back to the RS for a resource request change. Here is the state returned to the RS:

State Bits

CFP	ECM	LI	CRP	PB	EXID	GPR	EB	CPTR	LOD
0	2	0	0	0	0	0	0	0	0

Status Bits

VALID	TYPE	PENDING	SERIAL	ALLOC	SIZE	POS_ALLOC	FIRST	LAST
1	TEX	0	0	0	0	0	1	0

Then when the texture pipe frees up, the arbiter picks up the thread to issue the texture reads. The thread comes back in this state:

State Bits

CFP	ECM	LI	CRP	PB	EXID	GPR	EB	CPTR	LOD
0	4	0	0	0	0	0	0	0	0

Status Bits

VALID	TYPE	PENDING	SERIAL	ALLOC	SIZE	POS_ALLOC	FIRST	LAST
1	ALU	1	1	0	0	0	1	0

Because of the serial bit the arbiter must wait for the texture to return and clear the PENDING bit before it can pick the thread up. Lets say that the texture reads are complete, then the arbiter picks up the thread and returns it in this state:

State Bits

CFP	ECM	LI	CRP	PB	EXID	GPR	EB	CPTR	LOD
0	6	0	0	0	0	0	0	0	0

Status Bits

VALID	TYPE	PENDING	SERIAL	ALLOC	SIZE	POS_ALLOC	FIRST	LAST
1	TEX	0	0	0	0	0	1	0

Again the TP frees up, the arbiter picks up the thread and executes. It returns in this state:

State Bits									
CFP	ECM	LI	CRP	PB	EXID	GPR	EB	CPTR	LOD
0	7	0	0	0	0	0	0	0	0

Status Bits								
VALID	TYPE	PENDING	SERIAL	ALLOC	SIZE	POS_ALLOC	FIRST	LAST
1	ALU	1	0	0	0	0	1	0

Now, even if the texture has not returned we can still pick up the thread for ALU execution because the serial bit is not set. The thread will however come back to the RS for the second ALU instruction because it has the serial bit set.

State Bits									
CFP	ECM	LI	CRP	PB	EXID	GPR	EB	CPTR	LOD
0	8	0	0	0	0	0	0	0	0

Status Bits								
VALID	TYPE	PENDING	SERIAL	ALLOC	SIZE	POS_ALLOC	FIRST	LAST
1	ALU	1	1	0	0	0	1	0

As soon as the TP clears the pending bit the thread is picked up and returns:

State Bits									
CFP	ECM	LI	CRP	PB	EXID	GPR	EB	CPTR	LOD
0	9	0	0	0	0	0	0	0	0

Status Bits								
VALID	TYPE	PENDING	SERIAL	ALLOC	SIZE	POS_ALLOC	FIRST	LAST
1	TEX	0	0	0	0	0	1	0

Picked up by the TP and returns:

```
Execute Alu 0
```

State Bits									
CFP	ECM	LI	CRP	PB	EXID	GPR	EB	CPTR	LOD
1	0	0	0	0	0	0	0	0	0

Status Bits								
VALID	TYPE	PENDING	SERIAL	ALLOC	SIZE	POS_ALLOC	FIRST	LAST
1	ALU	1	0	0	0	0	1	0

Picked up by the ALU and returns (lets say the TP has not returned yet):

```
Alloc Position 1
```

State Bits									
CFP	ECM	LI	CRP	PB	EXID	GPR	EB	CPTR	LOD
2	0	0	0	0	0	0	0	0	0

Status Bits

VALID	TYPE	PENDING	SERIAL	ALLOC	SIZE	POS_ALLOC	FIRST	LAST
1	ALU	1	0	01	1	0	1	0

If the SX has the place for the export, the SQ is going to allocate and pick up the thread for execution. It returns to the RS in this state:

```
Execute Alu 0 Tex 0
```

State Bits

CFP	ECM	LI	CRP	PB	EXID	GPR	EB	CPTR	LOD
3	1	0	0	0	0	0	0	0	0

Status Bits

VALID	TYPE	PENDING	SERIAL	ALLOC	SIZE	POS_ALLOC	FIRST	LAST
1	TEX	1	0	0	0	1	1	0

Now, since the TP has not returned yet, we must wait for it to return because we cannot issue multiple texture requests. The TP returns, clears the PENDING bit and we proceed:

```
Alloc Param 3
```

State Bits

CFP	ECM	LI	CRP	PB	EXID	GPR	EB	CPTR	LOD
4	0	0	0	0	1	0	0	0	0

Status Bits

VALID	TYPE	PENDING	SERIAL	ALLOC	SIZE	POS_ALLOC	FIRST	LAST
1	ALU	1	0	10	3	1	1	0

Once again the SQ makes sure the SX has enough room in the Parameter cache before it can pick up this thread.

```
Execute Alu 0 Tex 0 Alu 1 Alu 0 End
```

State Bits

CFP	ECM	LI	CRP	PB	EXID	GPR	EB	CPTR	LOD
5	1	0	0	0	1	0	100	0	0

Status Bits

VALID	TYPE	PENDING	SERIAL	ALLOC	SIZE	POS_ALLOC	FIRST	LAST
1	TEX	1	0	0	0	1	1	0

This executes on the TP and then returns:

State Bits

CFP	ECM	LI	CRP	PB	EXID	GPR	EB	CPTR	LOD
5	2	0	0	0	1	0	100	0	0

Status Bits

VALID	TYPE	PENDING	SERIAL	ALLOC	SIZE	POS_ALLOC	FIRST	LAST
1	ALU	1	1	0	0	1	1	1

Waits for the TP to return because of the textures reads are pending (and SERIAL in this case). Then executes and does not return to the RS because the LAST bit is set. This is the end of this thread and before dropping it on the floor, the SQ notifies the SX of export completion.

Formatted: Bullets and Numbering

~~28.~~25. Open issues

Need to do some testing on the size of the register file as well as on the register file allocation method (dynamic VS static).

Saving power?

R400 Sequencer Specification

SQ

Version 2.01~~0~~

Overview: This is an architectural specification for the R400 Sequencer block (SEQ). It provides an overview of the required capabilities and expected uses of the block. It also describes the block interfaces, internal sub-blocks, and provides internal state diagrams.

Revision Changes:

Rev 0.1 (Laurent Lefebvre) Date: May 7, 2001	First draft.
Rev 0.2 (Laurent Lefebvre) Date : July 9, 2001	Changed the interfaces to reflect the changes in the SP. Added some details in the arbitration section.
Rev 0.3 (Laurent Lefebvre) Date : August 6, 2001	Reviewed the Sequencer spec after the meeting on August 3, 2001.
Rev 0.4 (Laurent Lefebvre) Date : August 24, 2001	Added the dynamic allocation method for register file and an example (written in part by Vic) of the flow of pixels/vertices in the sequencer.
Rev 0.5 (Laurent Lefebvre) Date : September 7, 2001	Added timing diagrams (Vic)
Rev 0.6 (Laurent Lefebvre) Date : September 24, 2001	Changed the spec to reflect the new R400 architecture. Added interfaces.
Rev 0.7 (Laurent Lefebvre) Date : October 5, 2001	Added constant store management, instruction store management, control flow management and data dependant predication.
Rev 0.8 (Laurent Lefebvre) Date : October 8, 2001	Changed the control flow method to be more flexible. Also updated the external interfaces.
Rev 0.9 (Laurent Lefebvre) Date : October 17, 2001	Incorporated changes made in the 10/18/01 control flow meeting. Added a NOP instruction, removed the conditional_execute_or_jump. Added debug registers.
Rev 1.0 (Laurent Lefebvre) Date : October 19, 2001	Refined interfaces to RB. Added state registers.
Rev 1.1 (Laurent Lefebvre) Date : October 26, 2001	Added SEQ→SP0 interfaces. Changed delta precision. Changed VGT→SP0 interface. Debug Methods added.
Rev 1.2 (Laurent Lefebvre) Date : November 16, 2001	Interfaces greatly refined. Cleaned up the spec.
Rev 1.3 (Laurent Lefebvre) Date : November 26, 2001	Added the different interpolation modes.
Rev 1.4 (Laurent Lefebvre) Date : December 6, 2001	Added the auto incrementing counters. Changed the VGT→SQ interface. Added content on constant management. Updated GPRs.
Rev 1.5 (Laurent Lefebvre) Date : December 11, 2001	Removed from the spec all interfaces that weren't directly tied to the SQ. Added explanations on constant management. Added PA→SQ synchronization fields and explanation.
Rev 1.6 (Laurent Lefebvre) Date : January 7, 2002	Added more details on the staging register. Added detail about the parameter caches. Changed the call instruction to a Conditionnal_call instruction. Added details on constant management and updated the diagram.
Rev 1.7 (Laurent Lefebvre) Date : February 4, 2002	Added Real Time parameter control in the SX interface. Updated the control flow section.
Rev 1.8 (Laurent Lefebvre) Date : March 4, 2002	New interfaces to the SX block. Added the end of clause modifier, removed the end of clause instructions.
Rev 1.9 (Laurent Lefebvre) Date : March 18, 2002	Rearangement of the CF instruction bits in order to ensure byte alignement.
Rev 1.10 (Laurent Lefebvre) Date : March 25, 2002	Updated the interfaces and added a section on exporting rules.
Rev 1.11 (Laurent Lefebvre) Date : April 19, 2002	Added CP state report interface. Last version of the spec with the old control flow scheme
Rev 2.0 (Laurent Lefebvre) Date : April 19, 2002	New control flow scheme

Rev 2.01 (Laurent Lefebvre) Date : May 2, 2002	Changed slightly the control flow instructions to allow force jumps and calls.

1. Overview

The sequencer chooses two ALU threads and a fetch hread to execute, and executes all of the instructions in a block before looking for a new clause of the same type. Two ALU threads are executed interleaved to hide the ALU latency. The arbitrator will give priority to older threads. There are two separate reservation stations, one for pixel vectors and one for vertices vectors. This way a pixel can pass a vertex and a vertex can pass a pixel.

To support the shader pipe the sequencer also contains the shader instruction cache, constant store, control flow constants and texture state. The four shader pipes also execute the same instruction thus there is only one sequencer for the whole chip.

The sequencer first arbitrates between vectors of 64 vertices that arrive directly from primitive assembly and vectors of 16 quads (64 pixels) that are generated in the scan converter.

The vertex or pixel program specifies how many GPRs it needs to execute. The sequencer will not start the next vector until the needed space is available in the GPRs.

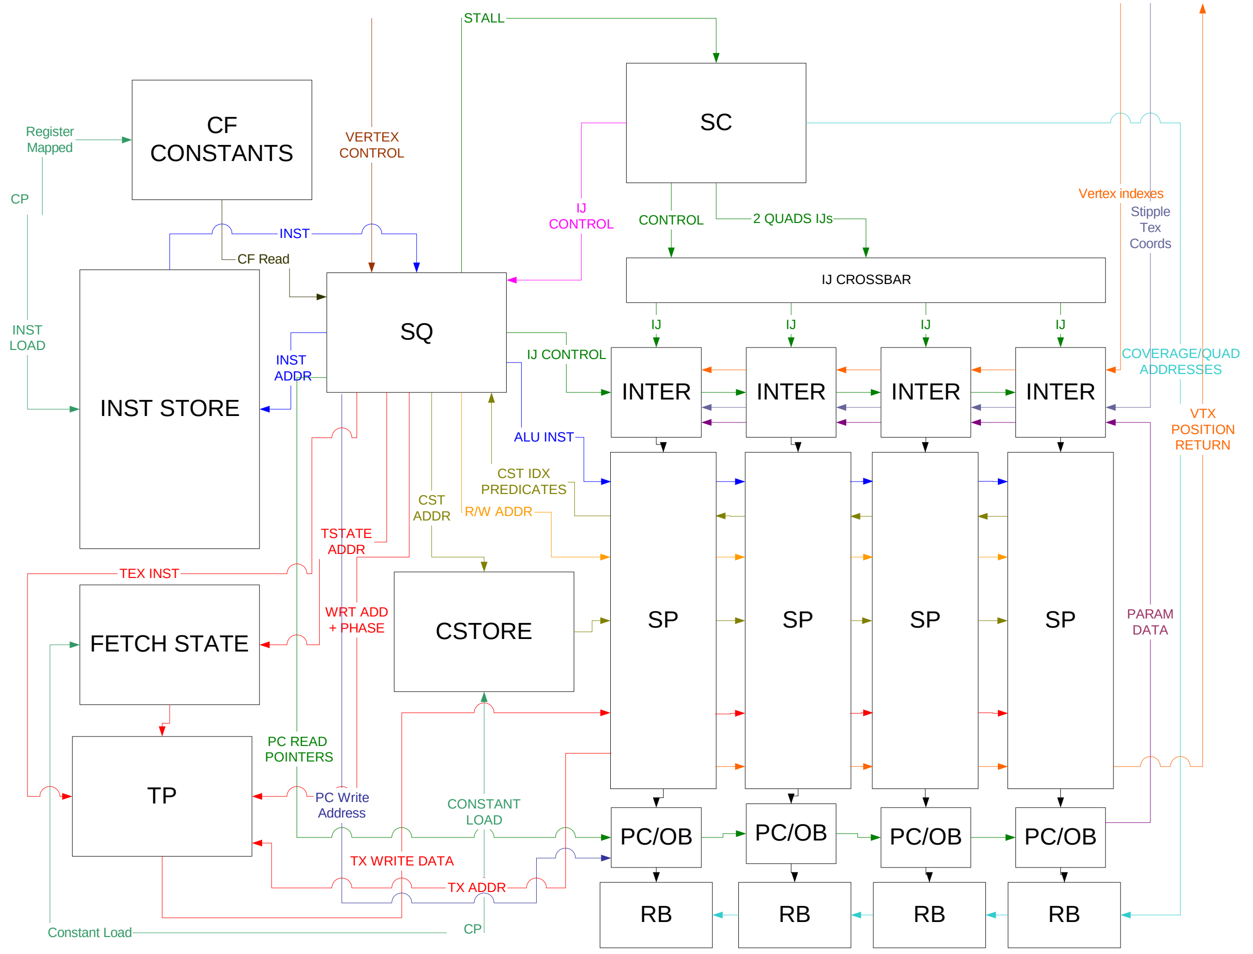

Figure 1: General Sequencer overview

1.1 Top Level Block Diagram

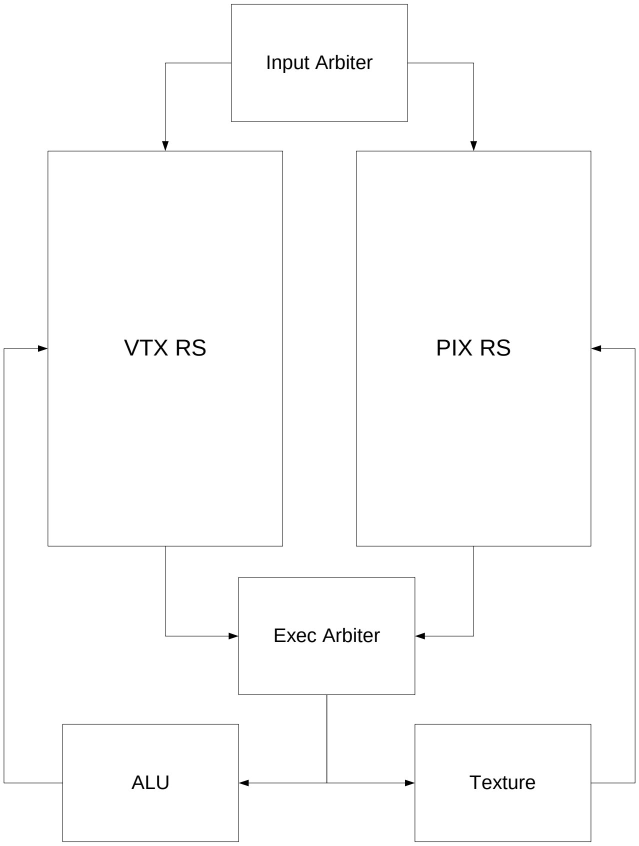

Figure 2: Reservation stations and arbiters

Under this new scheme, the sequencer (SQ) will only use one global state management machine per vector type (pixel, vertex) that we call the reservation station (RS).

1.2 Data Flow graph (SP)

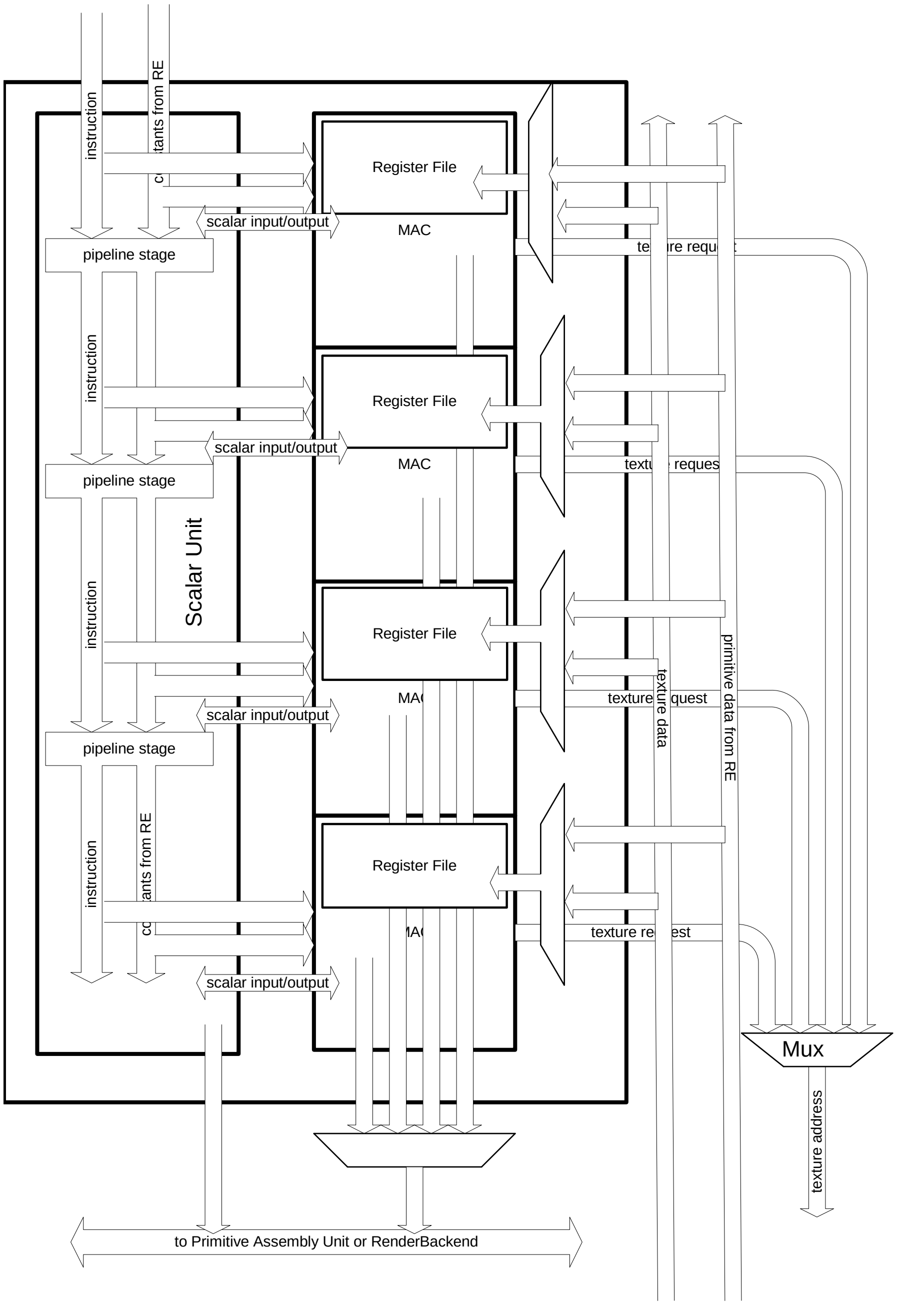

Figure 3: The shader Pipe

The gray area represents blocks that are replicated 4 times per shader pipe (16 times on the overall chip).

1.3 Control Graph

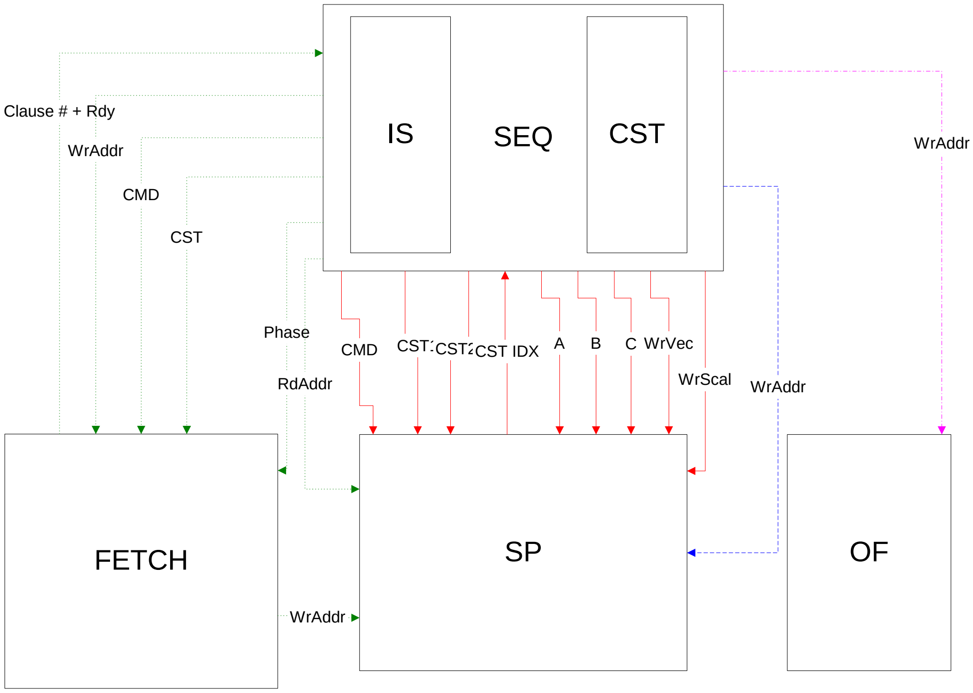

Figure 4: Sequencer Control interfaces

In green is represented the Fetch control interface, in red the ALU control interface, in blue the Interpolated/Vector control interface and in purple is the output file control interface.

2. Interpolated data bus

The interpolators contain an IJ buffer to pack the information as much as possible before writing it to the register file.

Figure 6: Interpolation timing diagram

Above is an example of a tile the sequencer might receive from the SC. The write side is how the data get stacked into the XY and IJ buffers, the read side is how the data is passed to the GPRs. The IJ information is packed in the IJ buffer 4 quads at a time or two clocks. The sequencer allows at any given time as many as four quads to interpolate a parameter. They all have to come from the same primitive. Then the sequencer controls the write mask to the GPRs to write the valid data in.

3. Instruction Store

There is going to be only one instruction store for the whole chip. It will contain 4096 instructions of 96 bits each.

It is likely to be a 1 port memory; we use 1 clock to load the ALU instruction, 1 clocks to load the Fetch instruction, 1 clock to load 2 control flow instructions and 1 clock to write instructions.

The instruction store is loaded by the CP thru the register mapped registers.

The VS_BASE and PS_BASE context registers are used to specify for each context where its shader is in the instruction memory.

For the Real time commands the story is quite the same but for some small differences. There are no wrap-around points for real time so the driver must be careful not to overwrite regular shader data. The shared code (shared subroutines) uses the same path as real time.

4. Sequencer Instructions

All control flow instructions and move instructions are handled by the sequencer only. The ALUs will perform NOPs during this time (MOV PV,PV, PS,PS) if they have nothing else to do.

5. Constant Stores

5.1 Memory organizations

A likely size for the ALU constant store is 1024x128 bits. The read BW from the ALU constant store is 128 bits/clock and the write bandwidth is 32 bits/clock (directed by the CP bus size not by memory ports).

The maximum logical size of the constant store for a given shader is 256 constants. Or 512 for the pixel/vertex shader pair. The size of the re-mapping table is 128 lines (each line addresses 4 constants). The write granularity is 4 constants or 512 bits. It takes 16 clocks to write the four constants. Real time requires 256 lines in the physical memory (this is physically register mapped).

The texture state is also kept in a similar memory. The size of this memory is 320x96 bits (128 texture states for regular mode, 32 states for RT). The memory thus holds 128 texture states (192 bits per state). The logical size exposes 32 different states total, which are going to be shared between the pixel and the vertex shader. The size of the re-mapping table to for the texture state memory is 32 lines (each line addresses 1 texture state lines in the real memory). The CP write granularity is 1 texture state lines (or 192 bits). The driver sends 512 bits but the CP ignores the top 320 bits. It thus takes 6 clocks to write the texture state. Real time requires 32 lines in the physical memory (this is physically register mapped).

The control flow constant memory doesn't sit behind a renaming table. It is register mapped and thus the driver must reload its content each time there is a change in the control flow constants. Its size is 320*32 because it must hold 8 copies of the 32 dwords of control flow constants and the loop construct constants must be aligned.

The constant re-mapping tables for texture state and ALU constants are logically register mapped for regular mode and physically register mapped for RT operation.

5.2 Management of the Control Flow Constants

The control flow constants are register mapped, thus the CP writes to the according register to set the constant, the SQ decodes the address and writes to the block pointed by its current base pointer (CF_WR_BASE). On the read side, one level of indirection is used. A register (SQ_CONTEXT_MISC.CF_RD_BASE) keeps the current base pointer to the control flow block. This register is copied whenever there is a state change. Should the CP write to CF after the state change, the base register is updated with the (current pointer number +1)% number of states. This way, if the CP doesn't write to CF the state is going to use the previous CF constants.

5.3 Management of the re-mapping tables

5.3.1 *R400 Constant management*

The sequencer is responsible to manage two re-mapping tables (one for the constant store and one for the texture state). On a state change (by the driver), the sequencer will broadside copy the contents of its re-mapping tables to a new one. We have 8 different re-mapping tables we can use concurrently.

The constant memory update will be incremental, the driver only need to update the constants that actually changed between the two state changes.

For this model to work in its simplest form, the requirement is that the physical memory MUST be at least twice as large as the logical address space + the space allocated for Real Time. In our case, since the logical address space is 512 and the reserved RT space can be up to 256 entries, the memory must be of sizes 1280 and above. Similarly the size of the texture store must be of 32*2+32 = 96 entries and above.

5.3.2 *Proposal for R400LE constant management*

To make this scheme work with only 512+256 = 768 entries, upon reception of a CONTROL packet of state + 1, the sequencer would check for SQ_IDLE and PA_IDLE and if both are idle will erase the content of state to replace it with the new state (this is depicted in Figure 8: De-allocation mechanism~~Figure 8: De-allocation mechanismFigure 8: De-allocation mechanism~~). Note that in the case a state is cleared a value of 0 is written to the corresponding de-allocation counter location so that when the SQ is going to report a state change, nothing will be de-allocated upon the first report.

The second path sets all context dirty bits that were used in the current state to 1 (thus allowing the new state to reuse these physical addresses if needed).

Figure 7: Constant management

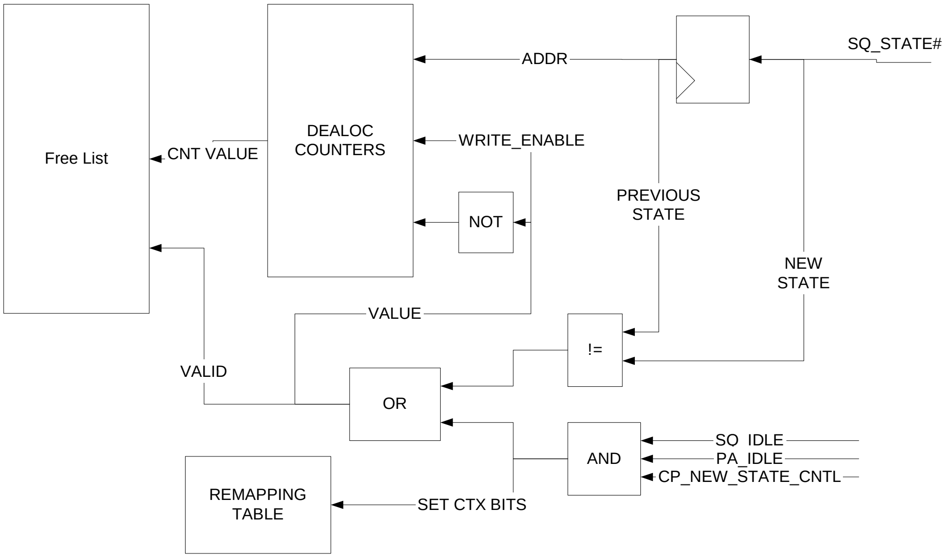

Figure 8: De-allocation mechanism for R400LE

5.3.3 *Dirty bits*

Two sets of dirty bits will be maintained per logical address. The first one will be set to zero on reset and set when the logical address is addressed. The second one will be set to zero whenever a new context is written and set for each address written while in this context. The reset dirty is not set, then writing to that logical address will not require de-allocation of whatever address stored in the renaming table. If it is set and the context dirty is not set, then the physical address store needs to be de-allocated and a new physical address is necessary to store the incoming data. If they are both set, then the data will be written into the physical address held in the renaming for the current logical address. No de-allocation or allocation takes place. This will happen when the driver does a set constant twice to the same logical address between context changes. NOTE: It is important to detect and prevent this, failure to do it will allow multiple writes to allocate all physical memory and thus hang because a context will not fit for rendering to start and thus free up space.

5.3.4 *Free List Block*

A free list block that would consist of a counter (called the IFC or Initial Free Counter) that would reset to zero and incremented every time a chunk of physical memory is used until they have all been used once. This counter would be checked each time a physical block is needed, and if the original ones have not been used up, us a new one, else check the free list for an available physical block address. The count is the physical address for when getting a chunk from the counter.

Storage of a free list big enough to store all physical block addresses.

Maintain three pointers for the free list that are reset to zero. The first one we will call write_ptr. This pointer will identify the next location to write the physical address of a block to be de-allocated. Note: we can never free more physical memory locations than we have. Once recording address the pointer will be incremented to walk the free list like a ring.

The second pointer will be called stop_ptr. The stop_ptr pointer will be advanced by the number of address chunks de-allocates when a context finishes. The address between the stop_ptr and write_ptr cannot be reused because they are still in use. But as soon as the context using then is dismissed the stop_ptr will be advanced.

The third pointer will be called read_ptr. This pointer will point will point to the next address that can be used for allocation as long as the read_ptr does not equal the stop_ptr and the IFC is at its maximum count.

5.3.5 *De-allocate Block*

This block will maintain a free physical address block count for each context. While in current context, a count shall be maintained specifying how many blocks were written into the free list at the write_ptr pointer. This count will be reset upon reset or when this context is active on the back and different than the previous context. It is actually a count of blocks in the previous context that will no longer be used. This count will be used to advance the write_ptr pointer to make available the set of physical blocks freed when the previous context was done. This allows the discard or de-allocation of any number of blocks in one clock.

5.3.6 *Operation of Incremental model*

The basic operation of the model would start with the write_ptr, stop_ptr, read_ptr pointers in the free list set to zero and the free list counter is set to zero. Also all the dirty bits and the previous context will be initialized to zero. When the first set constants happen, the reset dirty bit will not be set, so we will allocate a physical location from the free list counter because its not at the max value. The data will be written into physical address zero. Both the additional copy of the renaming table and the context zeros of the big renaming table will be updated for the logical address that was written by set start with physical address of 0. This process will be repeated for any logical address that are not dirty until the context changes. If a logical address is hit that has its dirty bits set while in the same context, both dirty bits would be set, so the new data will be over-written to the last physical address assigned for this logical address. When the first draw command of the context is detected, the previous context stored in the additional renaming table will be copied to the larger renaming table in the current (new) context location. Then the set constant logical address with be loaded with a new physical address during the copy and if the reset dirty was set, the physical address it replaced in the renaming table would be entered at the write_ptr pointer location on the free list and the write_ptr will be incremented. The de-allocation counter for the previous context (eight) will be incremented. This as set states come in for this context one of the following will happen:

1.) No dirty bits are set for the logical address being updated. A line will be allocated of the free-list counter or the free list at read_ptr pointer if read_ptr != to stop_ptr .
2.) Reset dirty set and Context dirty not set. A new physical address is allocated, the physical address in the renaming table is put on the free list at write_ptr and it is incremented along with the de-allocate counter for the last context.
3.) Context dirty is set then the data will be written into the physical address specified by the logical address.

This process will continue as long as set states arrive. This block will provide backpressure to the CP whenever he has not free list entries available (counter at max and stop_ptr == read_ptr). The command stream will keep a count of contexts of constants in use and prevent more than max constants contexts from being sent.

Whenever a draw packet arrives, the content of the re-mapping table is written to the correct re-mapping table for the context number. Also if the next context uses less constants than the current one all exceeding lines are moved to the free list to be de-allocated later. This happens in parallel with the writing of the re-mapping table to the correct memory.

Now preferable when the constant context leaves the last ALU clause it will be sent to this block and compared with the previous context that left. (Init to zero) If they differ than the older context will no longer be referenced and thus can be de-allocated in the physical memory. This is accomplished by adding the number of blocks freed this context to the stop_ptr pointer. This will make all the physical addresses used by this context available to the read_ptr allocate pointer for future allocation.

This device allows representation of multiple contexts of constants data with N copies of the logical address space. It also allows the second context to be represented as the first set plus some new additional data by just storing the delta's. It allows memory to be efficiently used and when the constants updates are small it can store multiple context. However, if the updates are large, less contexts will be stored and potentially performance will be degraded. Although it will still perform as well as a ring could in this case.

5.4 Constant Store Indexing

In order to do constant store indexing, the sequencer must be loaded first with the indexes (that come from the GPRs). There are 144 wires from the exit of the SP to the sequencer (9 bits pointers x 16 vertexes/clock). Since the data must pass thru the Shader pipe for the float to fixed conversion, there is a latency of 4 clocks (1 instruction)

between the time the sequencer is loaded and the time one can index into the constant store. The assembly will look like this

```
MOVA  R1.X,R2.X       // Loads the sequencer with the content of R2.X, also copies the content of R2.X into R1.X
NOP                   // latency of the float to fixed conversion
ADD   R3,R4,C0[R2.X]// Uses the state from the sequencer to add R4 to C0[R2.X] into R3
```

Note that we don't really care about what is in the brackets because we use the state from the MOVA instruction. R2.X is just written again for the sake of simplicity and coherency.

The storage needed in the sequencer in order to support this feature is 2*64*9 bits = 1152 bits.

5.5 Real Time Commands

The real time commands constants are written by the CP using the register mapped registers allocated for RT. It works is the same way than when dealing with regular constant loads BUT in this case the CP is not sending a logical address but rather a physical address and the reads are not passing thru the re-mapping table but are directly read from the memory. The boundary between the two zones is defined by the CONST_EO_RT control register. Similarly, for the fetch state, the boundary between the two zones is defined by the TSTATE_EO_RT control register.

5.6 Constant Waterfalling

In order to have a reasonable performance in the case of constant store indexing using the address register, we are going to have the possibility of using the physical memory port for read only. This way we can read 1 constant per clock and thus have a worst-case waterfall mode of 1 vertex per clock. There is a small synchronization issue related with this as we need for the SQ to make sure that the constants where actually written to memory (not only sent to the sequencer) before it can allow the first vector of pixels or vertices of the state to go thru the ALUs. To do so, the sequencer keeps 8 bits (one per render state) and sets the bits whenever the last render state is written to memory and clears the bit whenever a state is freed.

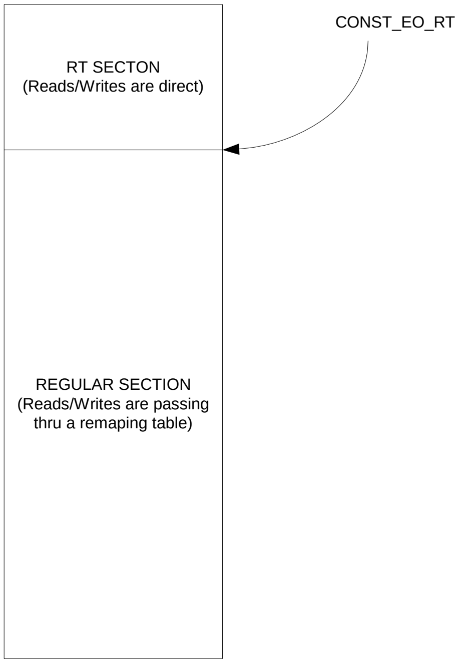

Figure 9: The instruction store

6. Looping and Branches

Loops and branches are planned to be supported and will have to be dealt with at the sequencer level. We plan on supporting constant loops and branches using a control program.

6.1 The controlling state.

The R400 controling state consists of:

Boolean[256:0]
Loop_count[7:0][31:0]
Loop_Start[7:0][31:0]
Loop_Step[7:0][31:0]

That is 256 Booleans and 32 loops.

We have a stack of 4 elements for nested calls of subroutines and 4 loop counters to allow for nested loops.

This state is available on a per shader program basis.

6.2 The Control Flow Program

We'd like to be able to code up a program of the form:

```
1:      Loop
2:      Exec    TexFetch
3:              TexFetch
4:              ALU
5:              ALU
6:              TexFetch
7:      End Loop
8:      ALU Export
```

But realize that 3: may be dependent on 2: and 4: is almost certainly dependent on 2: and 3:. Without clausing, these dependencies need to be expressed in the Control Flow instructions. Additionally, without separate 'texture clauses' and 'ALU clauses' we need to know which instructions to dispatch to the Texture Unit and which to the ALU unit. This information will be encapsulated in the flow control instructions.

Each control flow instruction will contain 2 bits of information for each (non-control flow) instruction:

a) ALU or Texture
b) Serialize Execution

(b) would force the thread to stop execution at this point (before the instruction is executed) and wait until all textures have been fetched. Given the allocation of reserved bits, this would mean that the count of an 'Exec' instruction would be limited to about 8 (non-control-flow) instructions. If more than this were needed, a second Exec (with the same conditions) would be issued.

Another function that relies upon 'clauses' is allocation and order of execution. We need to assure that pixels and vertices are exported in the correct order (even if not all execution is ordered) and that space in the output buffers are allocated in order. Additionally data can't be exported until space is allocated. A new control flow instruction:

Alloc <buffer select -- position,parameter, pixel or vertex memory. And the size required>.

would be created to mark where such allocation needs to be done. To assure allocation is done in order, the actual allocation for a given thread can not be performed unless the equivalent allocation for all previous threads is already completed. The implementation would also assure that execution of instruction(s) following the serialization due to the Alloc will occur in order -- at least until the next serialization or change from ALU to Texture. In most cases this will allow the exports to occur without any further synchronization. Only 'final' allocations or position allocations are

guaranteed to be ordered. Because strict ordering is required for pixels, parameters and positions, this implies only a single alloc for these structures. Vertex exports to memory do not require ordering during allocation and so multiple 'allocs' may be done.

6.2.1 *Control flow instructions table*

Here is the revised control flow instruction set.

Note that whenever a field is marked as RESERVED, it is assumed that all the bits of the field are cleared (0).

Execute					
47	46… 43	40 … 34	33 …16	15…12	11 … 0
Addressing	0001	RESERVED	Instructions type + serialize (9 instructions)	Count	Exec Address

Execute up to 9 instructions at the specified address in the instruction memory. The Instruction type field tells the sequencer the type of the instruction (LSB) (1 = Texture, 0 = ALU and whether to serialize or not the execution (MSB) (1 = Serialize, 0 = Non-Serialized).

NOP		
47	46 … 43	42 … 0
Addressing	0010	RESERVED

This is a regular NOP.

Conditional_Execute						
47	46 … 43	42	41 … 34	33…16	15 …12	11 … 0
Addressing	0011	Condition	Boolean address	Instructions type + serialize (9 instructions)	Count	Exec Address

If the specified Boolean (8 bits can address 256 Booleans) meets the specified condition then execute the specified instructions (up to 9 instructions). If the condition is not met, we go on to the next control flow instruction.

Conditional_Execute_Predicates							
47	46 … 43	42	41 … 36	35 … 34	33…16	15…12	11 … 0
Addressing	0010	Condition	RESERVED	Predicate vector	Instructions type + serialize (9 instructions)	Count	Exec Address

Check the AND/OR of all current predicate bits. If AND/OR matches the condition execute the specified number of instructions. We need to AND/OR this with the kill mask in order not to consider the pixels that aren't valid. If the condition is not met, we go on to the next control flow instruction.

Loop_Start					
47	46 … 43	42 … 17	20 … 16	15…12~~16 … 12~~	11 … 0
Addressing	0101	RESERVED	loop ID	RESERVED~~loop ID~~	Jump address

Loop Start. Compares the loop iterator with the end value. If loop condition not met jump to the address. Forward jump only. Also computes the index value. The loop id must match between the start to end, and also indicates which control flow constants should be used with the loop.

Loop_End						
47	46 … 43	42 … 2~~0~~4	23… 21	20 … 16~~19… 17~~	15…12~~16 … 12~~	11 … 0
Addressing	0011	RESERVED	Predicate break	loop ID ~~Predicate break~~	RESERVED ~~loop ID~~	start address

Loop end. Increments the counter by one, compares the loop count with the end value. If loop condition met, continue, else, jump BACK to the start of the loop. If predicate break != 0, then compares predicate vector n (specified by predicate break number). If all bits cleared then break the loop.

The way this is described does not prevent nested loops, and the inclusion of the loop id make this easy to do.

Conditionnal_Call						
47	46 … 43	42	~~35~~ 41 … 34	33 … 13~~2~~	12	11 … 0
Addressing	0111	Condition	~~Predicate vector~~Boolean address	RESERVED	Force Call	Jump address

If the condition is met, jumps to the specified address and pushes the control flow program counter on the stack. If force call is set the condition is ignored and the call is made always.

Return		
47	46 … 43	42 … 0
Addressing	1000	RESERVED

Pops the topmost address from the stack and jumps to that address. If nothing is on the stack, the program will just continue to the next instruction.

Conditionnal_Jump							
47	46 … 43	42	41… 34	33	32 … 13~~2~~	12	11 … 0
Addressing	1001	Condition	Boolean address	FW only	RESERVED	Force Jump	Jump address

If force jump is set the condition is ignored and the jump is made always. If FW only is set then only forward jumps are allowed.

Allocate				
47	46 … 43	42…41	40 … 4	3 …0
Debug	1010	Buffer Select	RESERVED	Allocation size

Buffer Select takes a value of the following:
01 – position export (ordered export)
10 – parameter cache or pixel export (ordered export)
11 – pass thru (out of order exports).

If debug is set this is a debug alloc (ignore if debug DB_ON register is set to off).

End Of Program		
47	46 … 43	42… 0
RESERVED	1011	RESERVED

Marks the end of the program.

6.3 Implementation

The envisioned implementation has a buffer that maintains the state of each thread. A thread lives in a given location in the buffer during its entire life, but the buffer has FIFO qualities in that threads leave in the order that they enter. Actually two buffers are maintained -- one for Vertices and one for Pixels. The intended implementation would allow for:

16 entries for vertices
48 entries for pixels.

From each buffer, arbitration logic attempts to select 1 thread for the texture unit and 1 (interleaved) thread for the ALU unit. Once a thread is selected it is read out of the buffer, marked as invalid, and submitted to appropriate execution unit. It is returned to the buffer (at the same place) with its status updated once all possible sequential instructions have been executed. A switch from ALU to TEX or visa-versa or a Serialize_Execution modifier forces the thread to be returned to the buffer.

Each entry in the buffer will be stored across two physical pieces of memory - most bits will be stored in a 1 read port device. Only bits needed for thread arbitration will be stored in a highly multi-ported structure. The bits kept in the 1 read port device will be termed 'state'. The bits kept in the multi-read ported device will be termed 'status'.

'State Bits' needed include:

1. Control Flow Instruction Pointer (~~12~~ 13 bits),
2. Execution Count Marker 4 bits),
3. Loop Iterators (4x9 bits),
4. Call return pointers (4x12 bits),
5. Predicate Bits (~~4x~~64 bits),
6. Export ID (1 bit),
7. Parameter Cache base Ptr (7 bits),
8. GPR Base Ptr (8 bits),
9. Context Ptr (3 bits).
10. LOD corrections (6x16 bits)
11. Valid bits (64 bits)

Formatted: Bullets and Numbering

Absent from this list are 'Index' pointers. These are costly enough that I'm presuming that they are instead stored in the GPRs. The first seven fields above (Control Flow Ptr, Execution Count, Loop Counts, call return ptrs, Predicate bits, PC base ptr and export ID) are updated every time the thread is returned to the buffer based on how much progress has been mode on thread execution. GPR Base Ptr, Context Ptr and LOD corrections are unchanged throughout execution of the thread.

'Status Bits' needed include:

- Valid Thread
- Texture/ALU engine needed
- Texture Reads are outstanding
- Waiting on Texture Read to Complete
- Allocation Wait (2 bits)
- 00 – No allocation needed
- 01 – Position export allocation needed (ordered export)
- 10 – Parameter or pixel export needed (ordered export)
- 11 – pass thru (out of order export)
- Allocation Size (4 bits)
- Position Allocated
- First thread of a new context
- Event thread (NULL thread that needs to trickle down the pipe)
- Last (1 bit)
- Pulse SX (1 bit)

Formatted: Bullets and Numbering

All of the above fields from all of the entries go into the arbitration circuitry. The arbitration circuitry will select a winner for both the Texture Engine and for the ALU engine. There are actually two sets of arbitration -- one for pixels and one for vertices. A final selection is then done between the two. But the rest of this implementation summary only considers the 'first' level selection which is similar for both pixels and vertices.

Texture arbitration requires no allocation or ordering so it is purely based on selecting the 'oldest' thread that requires the Texture Engine.

ALU arbitration is a little more complicated. First, only threads where either of Texture_Reads_outstanding or Waiting_on_Texture_Read_to_Complete are '0' are considered. Then if Allocation_Wait is active, these threads are further filtered based on whether space is available. If the allocation is position allocation, then the thread is only considered if all 'older' threads have already done their position allocation (position allocated bits set). If the allocation is parameter or pixel allocation, then the thread is only considered if it is the oldest thread. Also a thread is not considered if it is a parameter or pixel or position allocation, has its First_thread_of_a_new_context bit set and would cause ALU interleaving with another thread performing the same parameter or pixel or position allocation. Finally the 'oldest' of the threads that pass through the above filters is selected. If the thread needed to allocate, then at this time the allocation is done, based on Allocation_Size. If a thread has its “last” bit set, then it is also removed from the buffer, never to return.

If I now redefine 'clauses' to mean 'how many times the thread is removed from the thread buffer for the purpose of exection by either the ALU or Texture engine', then the minimum number of clauses needed is 2 -- one to perform the allocation for exports (execution automatically halts after an 'Alloc' instruction) (but doesn't performs the actual allocation) and one for the actual ALU/export instructions. As the 'Alloc' instruction could be part of a texture clause (presumably the final instruction in such a clause), a thread could still execute in this minimal number of 2 clauses, even if it involved texture fetching.

The Texture_Reads_Outstanding bit must be updated by the sequencer, based on keeping track of how many Texture Clauses have been executed by a given thread that have not yet had there data returned. Any number above 0 results in this bit being set. We could consider forcing synchronization such that two texture clauses for a given thread may not be outstanding at any time (that would be my preference for simplicity reasons and because it would require only very little change in the texture pipe interface). This would allow the sequencer to set the bit on execution of the texture clause, and allow the texture unit to return a pointer to the thread buffer on completion that clears the bit.

6.4 Data dependant predicate instructions

Data dependant conditionals will be supported in the R400. The only way we plan to support those is by supporting three vector/scalar predicate operations of the form:

PRED_SETE_# - similar to SETE except that the result is 'exported' to the sequencer.
PRED_SETNE_# - similar to SETNE except that the result is 'exported' to the sequencer.
PRED_SETGT_# - similar to SETGT except that the result is 'exported' to the sequencer
PRED_SETGTE_# - similar to SETGTE except that the result is 'exported' to the sequencer

For the scalar operations only we will also support the two following instructions:
PRED_SETE0_# – SETE0
PRED_SETE1_# – SETE1

The export is a single bit - 1 or 0 that is sent using the same data path as the MOVA instruction. The sequencer will maintain 4 sets of 64 bit predicate vectors (in fact 8 sets because we interleave two programs but only 4 will be exposed) and use it to control the write masking. This predicate is not maintained across clause boundaries. The # sign is used to specify which predicate set you want to use 0 thru 3.

Then we have two conditional execute bits. The first bit is a conditional execute “on” bit and the second bit tells us if we execute on 1 or 0. For example, the instruction:

P0_ADD_# R0,R1,R2

Is only going to write the result of the ADD into those GPRs whose predicate bit is 0. Alternatively, P1_ADD_# would only write the results to the GPRs whose predicate bit is set. The use of the P0 or P1 without precharging the sequencer with a PRED instruction is undefined.

{Issue: do we have to have a NOP between PRED and the first instruction that uses a predicate?}

6.5 HW Detection of PV,PS

Because of the control program, the compiler cannot detect statically dependant instructions. In the case of non-masked writes and subsequent reads the sequencer will insert uses of PV,PS as needed. This will be done by comparing the read address and the write address of consecutive instructions. For masked writes, the sequencer will insert NOPs wherever there is a dependant read/write.

The sequencer will also have to insert NOPs between PRED_SET and MOVA instructions and their uses.

6.6 Register file indexing

Because we can have loops in fetch clause, we need to be able to index into the register file in order to retrieve the data created in a fetch clause loop and use it into an ALU clause. The instruction will include the base address for register indexing and the instruction will contain these controls:

Bit7	Bit 6	
0	0	'absolute register'
0	1	'relative register'
1	0	'previous vector'
1	1	'previous scalar'

In the case of an absolute register we just take the address as is. In the case of a relative register read we take the base address and we add to it the loop_index and this becomes our new address that we give to the shader pipe.

The sequencer is going to keep a loop index computed as such:

Index = Loop_iterator*Loop_step + Loop_start.

We loop until loop_iterator = loop_count. Loop_step is a signed value [-128…127]. The computed index value is a 10 bit counter that is also signed. Its real range is [-256,256]. The tenth bit is only there so that we can provide an out of range value to the "indexing logic" so that it knows when the provided index is out of range and thus can make the necessary arrangements.

6.7 Debugging the Shaders

In order to be able to debug the pixel/vertex shaders efficiently, we provide 2 methods.

6.7.1 *Method 1: Debugging registers*

Current plans are to expose 2 debugging, or error notification, registers:
1. address register where the first error occurred
2. count of the number of errors

The sequencer will detect the following groups of errors:
- count overflow
- constant indexing overflow
- register indexing overflow

Compiler recognizable errors:
- jump errors
    - relative jump address > size of the control flow program
- call stack
    - call with stack full
    - return with stack empty

A jump error will always cause the program to break. In this case, a break means that a clause will halt execution, but allowing further clauses to be executed.

With all the other errors, program can continue to run, potentially to worst-case limits. The program will only break if the DB_PROB_BREAK register is set.

If indexing outside of the constant or the register range, causing an overflow error, the hardware is specified to return the value with an index of 0. This could be exploited to generate error tokens, by reserving and initializing the 0th register (or constant) for errors.

{ISSUE : Interrupt to the driver or not?}

6.7.2 *Method 2: Exporting the values in the GPRs*

1) The sequencer will have a debug active, count register and an address register for this mode.

Under the normal mode execution follows the normal course.

Under the debug mode it is assumed that the program is always exporting n debug vectors and that all other exports to the SX block (position, color, z, ect) will been turned off (changed into NOPs) by the sequencer (even if they occur before the address stated by the ADDR debug register).

7. Pixel Kill Mask

A vector of 64 bits is kept by the sequencer per group of pixels/vertices. Its purpose is to optimize the texture fetch requests and allow the shader pipe to kill pixels using the following instructions:

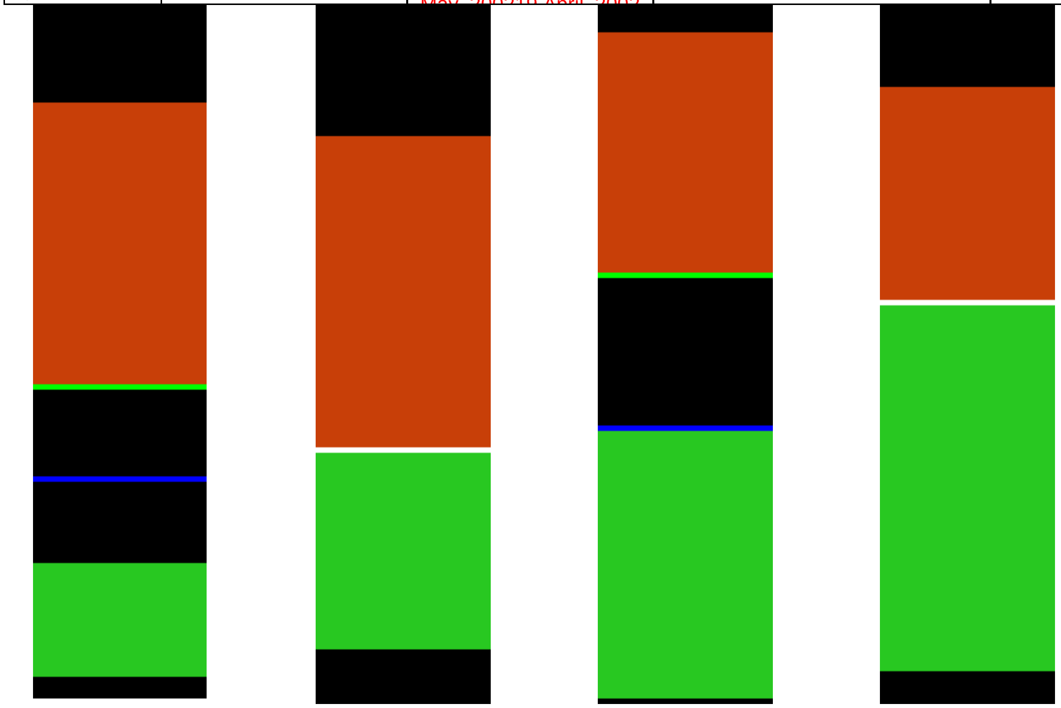
MASK_SETE
MASK_SETNE
MASK_SETGT
MASK_SETGTE

8. Multipass vertex shaders (HOS)

Multipass vertex shaders are able to export from the 6 last clauses but to memory ONLY.

9. Register file allocation

The register file allocation for vertices and pixels can either be static or dynamic. In both cases, the register file in managed using two round robins (one for pixels and one for vertices). In the dynamic case the boundary between pixels and vertices is allowed to move, in the static case it is fixed to 128-VERTEX_REG_SIZE for vertices and PIXEL_REG_SIZE for pixels.



Above is an example of how the algorithm works. Vertices come in from top to bottom; pixels come in from bottom to top. Vertices are in orange and pixels in green. The blue line is the tail of the vertices and the green line is the tail of the pixels. Thus anything between the two lines is shared. When pixels meets vertices the line turns white and the boundary is static until both vertices and pixels share the same “unallocated bubble”. Then the boundary is allowed to move again. The numbering of the GPRs starts from the bottom of the picture at index 0 and goes up to the top at index 127.

10. Fetch Arbitration

The fetch arbitration logic chooses one of the 8 potentially pending fetch clauses to be executed. The choice is made by looking at the fifos from 7 to 0 and picking the first one ready to execute. Once chosen, the clause state machine will send one 2x2 fetch per clock (or 4 fetches in one clock every 4 clocks) until all the fetch instructions of the clause are sent. This means that there cannot be any dependencies between two fetches of the same clause.

The arbitrator will not wait for the fetches to return prior to selecting another clause for execution. The fetch pipe will be able to handle up to X(?) in flight fetches and thus there can be a fair number of active clauses waiting for their fetch return data.

11. ALU Arbitration

ALU arbitration proceeds in almost the same way than fetch arbitration. The ALU arbitration logic chooses one of the 8 potentially pending ALU clauses to be executed. The choice is made by looking at the fifos from 7 to 0 and picking the first one ready to execute. There are two ALU arbiters, one for the even clocks and one for the odd clocks. For example, here is the sequencing of two interleaved ALU clauses (E and O stands for Even and Odd sets of 4 clocks):

Einst0 Oinst0 Einst1 Oinst1 Einst2 Oinst2 Einst0 Oinst3 Einst1 Oinst4 Einst2 Oinst0…
Proceeding this way hides the latency of 8 clocks of the ALUs. Also note that the interleaving also occurs across clause boundaries.

12. Handling Stalls

When the output file is full, the sequencer prevents the ALU arbitration logic from selecting the last clause (this way nothing can exit the shader pipe until there is place in the output file. If the packet is a vertex packet and the position buffer is full (POS_FULL) then the sequencer also prevents a thread from entering the exporting clause (3?). The sequencer will set the OUT_FILE_FULL signal n clocks before the output file is actually full and thus the ALU arbiter will be able read this signal and act accordingly by not preventing exporting clauses to proceed.

13. Content of the reservation station FIFOs

The reservation FIFOs contain the state of the vector of pixels and vertices. We have two sets of those: one for pixels, and one for vertices. They contain 3 bits of Render State 7 bits for the base address of the GPRs, some bits for LOD correction and coverage mask information in order to fetch fetch for only valid pixels, the quad address.

14. The Output File

The output file is where pixels are put before they go to the RBs. The write BW to this store is 256 bits/clock. Just before this output file are staging registers with write BW 512 bits/clock and read BW 256 bits/clock. The staging registers are 4x128 (and there are 16 of those on the whole chip).

15. IJ Format

The IJ information sent by the PA is of this format on a per quad basis:

We have a vector of IJ's (one IJ per pixel at the centroid of the fragment or at the center of the pixel depending on the mode bit). The interpolation is done at a different precision across the 2x2. The upper left pixel's parameters are always interpolated at full 20x24 mantissa precision. Then the result of the interpolation along with the difference in IJ in reduced precision is used to interpolate the parameter for the other three pixels of the 2x2. Here is how we do it:

Assuming P0 is the interpolated parameter at Pixel 0 having the barycentric coordinates I(0), J(0) and so on for P1,P2 and P3. Also assuming that A is the parameter value at V0 (interpolated with I), B is the parameter value at V1 (interpolated with J) and C is the parameter value at V2 (interpolated with (1-I-J).

$$\Delta 01I = I(1) - I(0)$$
$$\Delta 01J = J(1) - J(0)$$
$$\Delta 02I = I(2) - I(0)$$
$$\Delta 02J = J(2) - J(0)$$
$$\Delta 03I = I(3) - I(0)$$
$$\Delta 03J = J(3) - J(0)$$

P0	P1
P2	P3

$$P0 = C + I(0) * (A - C) + J(0) * (B - C)$$
$$P1 = P0 + \Delta 01I * (A - C) + \Delta 01J * (B - C)$$
$$P2 = P0 + \Delta 02I * (A - C) + \Delta 02J * (B - C)$$
$$P3 = P0 + \Delta 03I * (A - C) + \Delta 03J * (B - C)$$

P0 is computed at 20x24 mantissa precision and P1 to P3 are computed at 8X24 mantissa precision. So far no visual degradation of the image was seen using this scheme.

Multiplies (Full Precision): 2
Multiplies (Reduced precision): 6
Subtracts 19x24 (Parameters): 2

Adds: 8

FORMAT OF P0's IJ : Mantissa 20 Exp 4 for I + Sign
Mantissa 20 Exp 4 for J + Sign

FORMAT of Deltas (x3):Mantissa 8 Exp 4 for I + Sign
Mantissa 8 Exp 4 for J + Sign

Total number of bits : 20*2 + 8*6 + 4*8 + 4*2 = 128

All numbers are kept using the un-normalized floating point convention: if exponent is different than 0 the number is normalized if not, then the number is un-normalized. The maximum range for the IJs (Full precision) is +/- 63 and the range for the Deltas is +/- 127.

15.1 Interpolation of constant attributes

Because of the floating point imprecision, we need to take special provisions if all the interpolated terms are the same or if two of the barycentric coordinates are the same.

We start with the premise that if A = B and B = C and C = A, then P0,1,2,3 = A. Since one or more of the IJ terms may be zero, so we extend this to:

```
if (A=B and B=C and C=A)
   P0,1,2,3 = A;
else if ((I = 0) or (J = 0)) and
          ((J = 0) or (1-I-J = 0)) and
          ((1-J-I = 0) or (I = 0))) {
                if(I != 0) {
                    P0 = A;
                } else if(J != 0) {
                    P0 = B;
                } else {
                    P0 = C;
               }
             //rest of the quad interpolated normally
}
else
{
             normal interpolation
}
```

16. Staging Registers

In order for the reuse of the vertices to be 14, the sequencer will have to re-order the data sent IN ORDER by the VGT for it to be aligned with the parameter cache memory arrangement. Given the following group of vertices sent by the VGT:

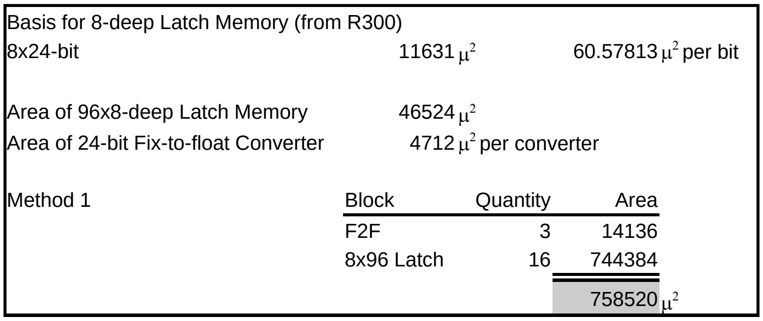
0 1 2 3 4 5 6 7 8 9 10 11 12 13 14 15 || 16 17 18 19 20 21 22 23 24 25 26 27 28 29 30 31 || 32 33 34 35 36 37 38 39 40 41 42 43 44 45 46 47 || 48 49 50 51 52 53 54 55 56 57 58 59 60 61 62 63

The sequencer will re-arrange them in this fashion:

0 1 2 3 16 17 18 19 32 33 34 35 48 49 50 51 || 4 5 6 7 20 21 22 23 36 37 38 39 52 53 54 55 || 8 9 10 11 24 25 26 27 40 41 42 43 56 57 58 59 || 12 13 14 15 28 29 30 31 44 45 46 47 60 61 62 63

The || markers show the SP divisions. In the event a shader pipe is broken, the VGT will send padding to account for the missing pipe. For example, if SP1 is broken, vertices 4 5 6 7 20 21 22 23 36 37 38 39 52 53 54 55 will still be sent by the VGT to the SQ **BUT** will not be processed by the SP and thus should be considered invalid (by the SU and VGT).

The most straightforward, *non-compressed* interface method would be to convert, in the VGT, the data to 32-bit floating point prior to transmission to the VSISRs. In this scenario, the data would be transmitted to (and stored in) the VSISRs in full 32-bit floating point. This method requires three 24-bit fixed-to-float converters in the VGT. Unfortunately, it also requires and additional 3,072 bits of storage across the VSISRs. This interface is illustrated in Figure 11~~Figure 11~~~~Figure 11~~. The area of the fixed-to-float converters and the VSISRs for this method is roughly estimated as 0.759sqmm using the R300 process. The gate count estimate is shown in Figure 10~~Figure 10~~~~Figure 10~~.



Basis for 8-deep Latch Memory (from R300)			
8x24-bit	11631 μ²		60.57813 μ² per bit
Area of 96x8-deep Latch Memory	46524 μ²		
Area of 24-bit Fix-to-float Converter	4712 μ² per converter		

Method 1	Block	Quantity	Area
	F2F	3	14136
	8x96 Latch	16	744384
			758520 μ²

Figure 10:Area Estimate for VGT to Shader Interface

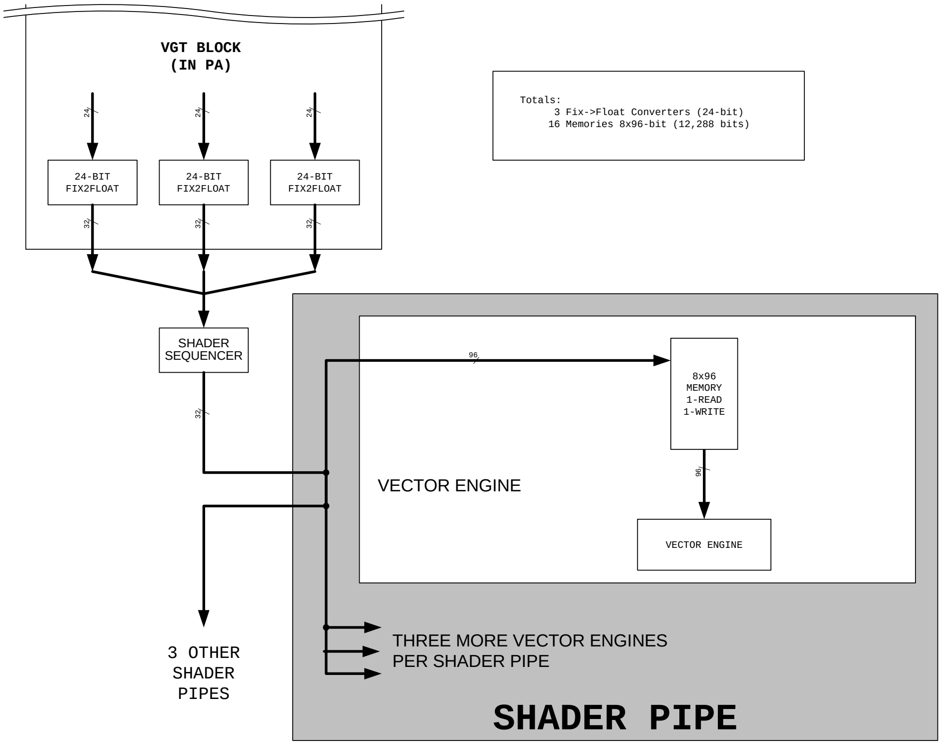


Figure 11:VGT to Shader Interface

17. The parameter cache

The parameter cache is where the vertex shaders export their data. It consists of 16 128x128 memories (1R/1W). The reuse engine will make it so that all vertexes of a given primitive will hit different memories. The allocation method for these memories is a simple round robin. The parameter cache pointers are mapped in the following way: 4MSBs are the memory number and the 7 LSBs are the address within this memory.

MEMORY NUMBER 4 bits	ADDRESS 7 bits

The PA generates the parameter cache addresses as the positions come from the SQ. All it needs to do is keep a Current_Location pointer (7 bits only) and as the positions comes increment the memory number. When the memory number field wraps around, the PA increments the Current_Location by VS_EXPORT_COUNT (a snooped register from the SQ). As an example, say the memories are all empty to begin with and the vertex shader is exporting 8 parameters per vertex (VS_EXPORT_COUNT = 8). The first position received is going to have the PC address 00000000000 the second one 00010000000, third one 00100000000 and so on up to 11110000000. Then the next position received (the 17th) is going to have the address 00000001000, the 18th 00010001000, the 19th 00100001000 and so on. The Current_location is NEVER reset BUT on chip resets. The only thing to be careful about is that if the SX doesn't send you a full group of positions (<64) then you need to fill the address space so that the next group starts correctly aligned (for example if you receive only 33 positions then you need to add 2*VS_EXPORT_COUNT to Current_Location and reset the memory count to 0 before the next vector begins).

17.1 Export restrictions

17.1.1 *Pixel exports:*

Pixels can export 1,2,3 or 4 color buffers to the SX(+z). The exports will be done in order. The PRED_OPTIMIZE function has to be turned of if the exports are done using interleaved predicated instructions. The exports will always be ordered to the SX.

17.1.2 *Vertex exports:*

Position or parameter caches can be exported in any order in the shader program. It is always better to export posistion as soon as possible. Position has to be exported in a single export block (no texture instructions can be placed between the exports). Parameter cache exports can be done in any order with texture instructions interleaved. The PRED_OPTIMIZE function has to be turned of if the exports are done using interleaved predicated instructions to the Parameter cache (see Arbitration restrictions for details). The exports will always be allocated in order to the SX.

17.1.3 *Pass thru exports:*

Pass thru exports have to be done in groups of the form:

```
Alloc 4 (8 or 12)
Execute ALU(ADDR) ALU(DATA) ALU(DATA) ALU(DATA)…
```

They cannot have texture instructions interleaved in the export block. These exports **are not guaranteed to be ordered**.

Also, when doing a pass thru export, Position MUST be exported AFTER all pass thru exports. This position export is used to synchronize the chip when doing a transition from pass thru shader to regular shader and vice versa.

17.2 Arbitration restrictions

Here are the Sequencer arbitration restrictions:

1) Cannot execute a serialized thread if the corresponding texture pending bit is set
2) Cannot allocate position if any older thread has not allocated position
3) If last thread is marked as not valid AND marked as last and we are about to execute the second to oldest thread also marked last then:
    a. Both threads must be from the same context (cannot allow a first thread)
    b. Must turn off the predicate optimization for the second thread
4) Cannot execute a texture clause if texture reads are pending
5) Cannot execute last if texture pending (even if not serial)

18. Export Types

The export type (or the location where the data should be put) is specified using the destination address field in the ALU instruction. Here is a list of all possible export modes:

18.1 Vertex Shading

0:15	- 16 parameter cache
16:31	- Empty (Reserved?)
32	- Export Address
33:40	- 8 vertex exports to the frame buffer and index
41:47	- Empty
48:55	- 8 debug export (interpret as normal vertex export)
60	- export addressing mode
61	- Empty
62	- position

63	- sprite size export that goes with position export (point_h,point_w,edgeflag,misc)

18.2 Pixel Shading

0	- Color for buffer 0 (primary)
1	- Color for buffer 1
2	- Color for buffer 2
3	- Color for buffer 3
4:7	- Empty
8	- Buffer 0 Color/Fog (primary)
9	- Buffer 1 Color/Fog
10	- Buffer 2 Color/Fog
11	- Buffer 3 Color/Fog
12:15	- Empty
16:31	- Empty (Reserved?)
32	- Export Address
33:40	- 8 exports for multipass pixel shaders.
41:47	- Empty
48:55	- 8 debug exports (interpret as normal pixel export)
60	- export addressing mode
61:62	- Empty
63	- Z for primary buffer (Z exported to 'alpha' component)

19. Special Interpolation modes

19.1 Real time commands

We are unable to use the parameter memory since there is no way for a command stream to write into it. Instead we need to add three 16x128 memories (one for each of three vertices x 16 interpolants). These will be mapped onto the register bus and written by type 0 packets, and output to the the parameter busses (the sequencer and/or PA need to be able to address the realtime parameter memory as well as the regular parameter store. For higher performance we should be able able to view them as two banks of 16 and do double buffering allowing one to be loaded, while the other is rasterized with. Most overlay shaders will need 2 or 4 scalar coordinates, one option might be to restrict the memory to 16x64 or 32x64 allowing only two interpolated scalars per cycle, the only problem I see with this is, if we view support for 16 vector-4 interpolants important (true only if we map Microsoft's high priority stream to the realtime stream), then the PA/sequencer need to support a realtime-specific mode where we need to address 32 vectors of parameters instead of 16. This mode is triggered by the primitive type: REAL TIME. The actual memories are in the in the SX blocks. The parameter data memories are hooked on the RBBM bus and are loaded by the CP using register mapped memory.

19.2 Sprites/ XY screen coordinates/ FB information

When working with sprites, one may want to overwrite the parameter 0 with SC generated data. Also, XY screen coordinates may be needed in the shader program. This functionality is controlled by the gen_I0 register (in SQ) in conjunction with the SND_XY register (in SC). Also it is possible to send the faceness information (for OGL front/back special operations) to the shader using the same control register. Here is a list of all the modes and how they interact together:

Gen_st is a bit taken from the interface between the SC and the SQ. This is the MSB of the primitive type. If the bit is set, it means we are dealing with Point AA, Line AA or sprite and in this case the vertex values are going to generated between 0 and 1.

Param_Gen_I0 disable, snd_xy disable, no gen_st – I0 = No modification
Param_Gen_I0 disable, snd_xy disable, gen_st – I0 = No modification
Param_Gen_I0 disable, snd_xy enable, no gen_st – I0 = No modification
Param_Gen_I0 disable, snd_xy enable, gen_st – I0 = No modification
Param_Gen_I0 enable, snd_xy disable, no gen_st – I0 = garbage, garbage, garbage, faceness

Param_Gen_I0 enable, snd_xy disable, gen_st – I0 = garbage, garbage, s, t
Param_Gen_I0 enable, snd_xy enable, no gen_st – I0 = screen x, screen y, garbage, faceness
Param_Gen_I0 enable, snd_xy enable, gen_st – I0 = screen x, screen y, s, t

19.3 Auto generated counters

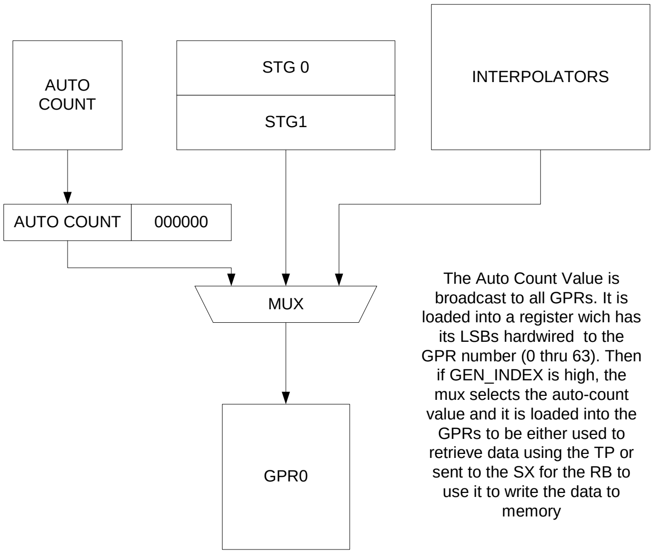
In the cases we are dealing with multipass shaders, the sequencer is going to generate a vector count to be able to both use this count to write the 1st pass data to memory and then use the count to retrieve the data on the 2nd pass. The count is always generated in the same way but it is passed to the shader in a slightly different way depending on the shader type (pixel or vertex). This is toggled on and off using the GEN_INDEX register. The sequencer is going to keep two counters, one for pixels and one for vertices. Every time a full vector of vertices or pixels is written to the GPRs the counter is incremented. Every time a state change is detected, the corresponding counter is reset. While there is only one count broadcast to the GPRs, the LSB are hardwired to specific values making the index different for all elements in the vector.

19.3.1 *Vertex shaders*

In the case of vertex shaders, if GEN_INDEX is set, the data will be put into the x field of the third register (it means that the compiler must allocate 3 GPRs in all multipass vertex shader modes).

19.3.2 *Pixel shaders*

In the case of pixel shaders, if GEN_INDEX is set and Param_Gen_I0 is enabled, the data will be put in the x field of the 2nd register (R1.x), else if GEN_INDEX is set the data will be put into the x field of the 1st register (R0.x).



The Auto Count Value is broadcast to all GPRs. It is loaded into a register wich has its LSBs hardwired to the GPR number (0 thru 63). Then if GEN_INDEX is high, the mux selects the auto-count value and it is loaded into the GPRs to be either used to retrieve data using the TP or sent to the SX for the RB to use it to write the data to memory

Figure 12: GPR input mux Control

20. State management

Every clock, the sequencer will report to the CP the oldest states still in the pipe. These are the states of the programs as they enter the last ALU clause.

20.1 Parameter cache synchronization

In order for the sequencer not to begin a group of pixels before the associated group of vertices has finished, the sequencer will keep a 6 bit count per state (for a total of 8 counters). These counters are initialized to 0 and every time a vertex shader exports its data TO THE PARAMETER CACHE, the corresponding pointer is incremented. When the SC sends a new vector of pixels with the SC_SQ_new_vector bit asserted, the sequencer will first check if the count is greater than 0 before accepting the transmission (it will in fact accept the transmission but then lower its ready to receive). Then the sequencer waits for the count to go to one and decrements it. The sequencer can then issue the group of pixels to the interpolators. Every time the state changes, the new state counter is initialized to 0.

21. XY Address imports

The SC will be able to send the XY addresses to the GPRs. It does so by interleaving the writes of the IJs (to the IJ buffer) with XY writes (to the XY buffer). Then when writing the data to the GPRs, the sequencer is going to interpolate the IJ data or pass the XY data thru a Fix→float converter and expander and write the converted values to the GPRs. The Xys are currently SCREEN SPACE COORDINATES. The values in the XY buffers will wrap. See section 19.2 for details on how to control the interpolation in this mode.

21.1 Vertex indexes imports

In order to import vertex indexes, we have 16 8x96 staging registers. These are loaded one line at a time by the VGT block (96 bits). They are loaded in floating point format and can be transferred in 4 or 8 clocks to the GPRs.

22. Registers

22.1 Control

REG_DYNAMIC	Dynamic allocation (pixel/vertex) of the register file on or off.
REG_SIZE_PIX	Size of the register file's pixel portion (minimal size when dynamic allocation turned on)
REG_SIZE_VTX	Size of the register file's vertex portion (minimal size when dynamic allocation turned on)
ARBITRATION_POLICY	policy of the arbitration between vertexes and pixels
INST_BASE_VTX	start point for the vertex instruction store (RT always ends at vertex_base and Begins at 0)
INST_BASE_PIX	start point for the pixel shader instruction store
ONE_THREAD	debug state register. Only allows one program at a time into the GPRs
ONE_ALU	debug state register. Only allows one ALU program at a time to be executed (instead of 2)
INSTRUCTION	This is where the CP puts the base address of the instruction writes and type (auto-incremented on reads/writes) Register mapped
CONSTANTS	512*4 ALU constants + 32*6 Texture state 32 bits registers (logically mapped)
CONSTANTS_RT	256*4 ALU constants + 32*6 texture states? (physically mapped)
CONSTANT_EO_RT	This is the size of the space reserved for real time in the constant store (from 0 to CONSTANT_EO_RT). The re-mapping table operates on the rest of the memory

TSTATE_EO_RT This is the size of the space reserved for real time in the fetch state store (from 0 to TSTATE_EO_RT). The re-mapping table operates on the rest of the memory

22.2 Context

PS_BASE	base pointer for the pixel shader in the instruction store
VS_BASE	base pointer for the vertex shader in the instruction store
VS_CF_SIZE	size of the vertex shader (# of instructions in control program/2)
PS_CF_SIZE	size of the pixel shader (# of instructions in control program/2)
PS_SIZE	size of the pixel shader (cntl+instructions)
VS_SIZE	size of the vertex shader (cntl+instructions)
PS_NUM_REG	number of GPRs to allocate for pixel shader programs
VS_NUM_REG	number of GPRs to allocate for vertex shader programs
PARAM_SHADE	One 16 bit register specifying which parameters are to be gouraud shaded (0 = flat, 1 = gouraud)
PARAM_WRAP	64 bits: for which parameters (and channels (xyzw)) do we do the cyl wrapping (0=linear, 1=cylindrical).
PS_EXPORT_MODE	0xxxx : Normal mode

	1xxxx : Multipass mode
	If normal, bbbz where bbb is how many colors (0-4) and z is export z or not
	If multipass 1-12 exports for color.
VS_EXPORT_MODE	0: position (1 vector), 1: position (2 vectors), 3:multipass
VS_EXPORT_COUNT	Number of locations exported by the VS (and thus number of interpolated parameters)
PARAM_GEN_I0	Do we overwrite or not the parameter 0 with XY data and generated T and S values
GEN_INDEX	Auto generates an address from 0 to XX. Puts the results into R0-1 for pixel shaders and R2 for vertex shaders
CONST_BASE_VTX (9 bits)	Logical Base address for the constants of the Vertex shader
CONST_BASE_PIX (9 bits)	Logical Base address for the constants of the Pixel shader
CONST_SIZE_PIX (8 bits)	Size of the logical constant store for pixel shaders
CONST_SIZE_VTX (8 bits)	Size of the logical constant store for vertex shaders
INST_PRED_OPTIMIZE	Turns on the predicate bit optimization (if of, conditional_execute_predicates is always executed).
CF_BOOLEANS	256 boolean bits
CF_LOOP_COUNT	32x8 bit counters (number of times we traverse the loop)
CF_LOOP_START	32x8 bit counters (init value used in index computation)
CF_LOOP_STEP	32x8 bit counters (step value used in index computation)

23. DEBUG Registers

23.1 Context

DB_PROB_ADDR	instruction address where the first problem occurred
DB_PROB_COUNT	number of problems encountered during the execution of the program
DB_PROB_BREAK	break the clause if an error is found.
DB_ON	turns on an off debug method 2
DB_INST_COUNT	instruction counter for debug method 2
DB_BREAK_ADDR	break address for method number 2

23.2 Control

DB_ALUCST_MEMSIZE	Size of the physical ALU constant memory
DB_TSTATE_MEMSIZE	Size of the physical texture state memory

24. Interfaces

24.1 External Interfaces

Whenever an x is used, it means that the bus is broadcast to all units of the same name. For example, if a bus is named SQ→SPx it means that SQ is going to broadcast the same information to all SP instances.

24.2 SC to SP Interfaces

24.2.1 *SC_SP#*

There is one of these interfaces at front of each of the SP (buffer to stage pixel interpolators). This interface transmits the I,J data for pixel interpolation. For the entire system, two quads per clock are transferred to the 4 SPs, so each of these 4 interfaces transmits one half of a quad per clock. The interface below describes a half of a quad worth of data.

The actual data which is transferred per quad is

Ref Pix I => S4.20 Floating Point I value
Ref Pix J => S4.20 Floating Point J value

Delta Pix I (x3) => S4.8 Floating Point Delta I value
Delta Pix J (x3) => S4.8 Floating Point Delta J value
This equates to a total of 128 bits which transferred over 2 clocks
and therefor needs an interface 64 bits wide

Additionally, X,Y data (12-bit unsigned fixed) is conditionally sent across this data bus over the same wires in an additional clock. The X,Y data is sent on the lower 24 bits of the data bus with faceness in the msb.
Transfers across these interfaces are synchronized with the SC_SQ IJ Control Bus transfers.

The data transfer across each of these busses is controlled by a IJ_BUF_INUSE_COUNT in the SC. Each time the SC has sent a pixel vector's worth of data to the SPs, he will increment the IJ_BUF_INUSE_COUNT count. Prior to sending the next pixel vectors data, he will check to make sure the count is less than MAX_BUFER_MINUS_2, if not the SC will stall until the SQ returns a pipelined pulse to decrement the count when he has scheduled a buffer free. Note: We could/may optimize for the case of only sending only IJ to use all the buffers to pre-load more. Currently it is planned for the SP to hold 2 double buffers of I,J data and two buffers of X,Y data, so if either X,Y or Centers and Centroids are on, then the SC can send two Buffers.

In at least the initial version, the SC shall send 16 quads per pixel vector even if the vector is not full. This will increment buffer write address pointers correctly all the time. (We may revisit this for both the SX,SP,SQ and add a EndOfVector signal on all interfaces to quit early. We opted for the simple mode first with a belief that only the end of packet and multiple new vector signals should cause a partial vector and that this would not really be significant performance hit.)

Name	Bits	Description
SC_SP#_data	64	IJ information sent over 2 clocks (or X,Y in 24 LSBs with faceness in upper bit) **Type 0 or 1**, First clock I, second clk J Field ULC URC LLC LRC Bits [63:39] [38:26] [25:13] [12:0] Format SE4M20 SE4M8 SE4M8 SE4M8 **Type 2** Field Face X Y Bits [63] [23:12] [11:0] Format Bit Unsigned Unsigned
SC_SP#_valid	1	Valid
SC_SP#_last_quad_data	1	This bit will be set on the last transfer of data per quad.
SC_SP#_type	2	0 -> Indicates centroids 1 -> Indicates centers 2 -> Indicates X,Y Data and faceness on data bus The SC shall look at state data to determine how many types to send for the interpolation process.

The # is included for clarity in the spec and will be replaced with a prefix of u#_ in the verilog module statement for the SC and the SP block will have neither because the instantiation will insert the prefix.

24.2.2 *SC_SQ*

This is the control information sent to the sequencer in order to synchronize and control the interpolation and/or loading data into the GPRs needed to execute a shader program on the sent pixels. This data will be sent over two clocks per transfer with 1 to 16 transfers. Therefore the bus (approx 92 bits) could be folded in half to approx 47 bits.

Name	Bits	Description
SC_SQ_data	46	Control Data sent to the SQ 1 clk transfers Event – valid data consist of event_id and state_id. Instruct SQ to post an event vector to send state id and event_id through request fifo and onto the reservation stations

		making sure state id and/or event_id gets back to the CP. Events only follow end of packets so no pixel vectors will be in progress. Empty Quad Mask – Transfer Control data consisting of pc_dealloc or new_vector. Receipt of this is to transfer pc_dealloc or new_vector without any valid quad data. New vector will always be posted to request fifo and pc_dealloc will be attached to any pixel vector outstanding or posted in request fifo if no valid quad outstanding. 2 clk transfers Quad Data Valid – Sending quad data with or without new_vector or pc_dealloc. New vector will be posted to request fifo with or without a pixel vector and pc_dealloc will be posted with a pixel vector unless none is in progress. In this case the pc_dealloc will be posted in the request queue. Filler quads will be transferred with The Quad mask set but the pixel corresponding pixel mask set to zero.
SC_SQ_valid	1	SC sending valid data, 2nd clk could be all zeroes

SC_SQ_data – first clock and second clock transfers are shown in the table below.

Name	**BitField**	**Bits**	**Description**
1st Clock Transfer			
SC_SQ_event	0	1	This transfer is a 1 clock event vector Force quad_mask = new_vector=pc_dealloc=0
SC_SQ_event_id	[2:1]	2	This field identifies the event 0 => denotes an End Of State Event 1 => TBD
SC_SQ_pc_dealloc	[5:3]	3	Deallocation token for the Parameter Cache
SC_SQ_new_vector	6	1	The SQ must wait for Vertex shader done count > 0 and after dispatching the Pixel Vector the SQ will decrement the count.
SC_SQ_quad_mask	[10:7]	4	Quad Write mask left to right SP0 => SP3
SC_SQ_end_of_prim	11	1	End Of the primitive
SC_SQ_state_id	[14:12]	3	State/constant pointer (6*3+3)
SC_SQ_pix_mask	[30:15]	16	Valid bits for all pixels SP0=>SP3 (UL,UR,LL,LR)
SC_SQ_prim_type	[33:31]	3	Stippled line and Real time command need to load tex cords from alternate buffer 000: Normal 010: Realtime 101: Line AA 110: Point AA (Sprite)
SC_SQ_provok_vtx	[35:34]	2	Provoking vertex for flat shading
SC_SQ_pc_ptr0	[46:36]	11	Parameter Cache pointer for vertex 0
2nd Clock Transfer			
SC_SQ_pc_ptr1	[10:0]	11	Parameter Cache pointer for vertex 1

SC_SQ_pc_ptr2	[21:11]	11	Parameter Cache pointer for vertex 2
SC_SQ_lod_correct	[45:22]	24	LOD correction per quad (6 bits per quad)

Name	Bits	Description
SQ_SC_free_buff	1	Pipelined bit that instructs SC to decrement count of buffers in use.
SQ_SC_dec_cntr_cnt	1	Pipelined bit that instructs SC to decrement count of new vector and/or event sent to prevent SC from overflowing SQ interpolator/Reservation request fifo.

The scan converter will submit a partial vector whenever:

1.) He gets a primitive marked with an end of packet signal.

2.) A current pixel vector is being assembled with at least one or more valid quads and the vector has been marked for deallocate when a primitive marked new_vector arrives. The Scan Converter will submit a partial vector (up to 16quads with zero pixel mask to fill out the vector) prior to submitting the new_vector marker\primitive.

(This will prevent a hang which can be demonstrated when all primitives in a packet three vectors are culled except for a one quad primitive that gets marked pc_dealloc (vertices maximum size). In this case two new_vectors are submitted and processed, but then one valid quad with the pc_dealloc creates a vector and then the new would wait for another vertex vector to be processed, but the one being waited for could never export until the pc_dealloc signal made it through and thus the hang.)

24.2.3 *SQ to SX: Interpolator bus*

Name	Direction	Bits	Description
SQ_SXx_interp_flat_vtx	SQ→SPx	2	Provoking vertex for flat shading
SQ_SXx_interp_flat_gouraud	SQ→SPx	1	Flat or gouraud shading
SQ_SXx_interp_cyl_wrap	SQ→SPx	4	Wich channel needs to be cylindrical wrapped
SQ_SXx_pc_ptr0	SQ→SXx	11	Parameter Cache Pointer
SQ_SXx_pc_ptr1	SQ→SXx	11	Parameter Cache Pointer
SQ_SXx_pc_ptr2	SQ→SXx	11	Parameter Cache Pointer
SQ_SXx_rt_sel	SQ→SXx	1	Selects between RT and Normal data
SQ_SXx_pc_wr_en	SQ→SXx	1	Write enable for the PC memories
SQ_SXx_pc_wr_addr	SQ→SXx	7	Write address for the PCs
SQ_SXx_pc_channel_mask	SQ→SXx	4	Channel mask

24.2.4 *SQ to SP: Staging Register Data*

This is a broadcast bus that sends the VSISR information to the staging registers of the shader pipes.

Name	Direction	Bits	Description
SQ_SPx_vsr_data	SQ→SPx	96	Pointers of indexes or HOS surface information
SQ_SPx_vsr_double	SQ→SPx	1	0: Normal 96 bits per vert 1: double 192 bits per vert
SQ_SP0_vsr_valid	SQ→SP0	1	Data is valid
SQ_SP1_ vsr_ valid	SQ→SP1	1	Data is valid
SQ_SP2_ vsr_ valid	SQ→SP2	1	Data is valid
SQ_SP3_ vsr_ valid	SQ→SP3	1	Data is valid
SQ_SPx_vsr_read	SQ→SPx	1	Increment the read pointers

24.2.5 *VGT to SQ : Vertex interface*

24.2.5.1 Interface Signal Table

The area difference between the two methods is not sufficient to warrant complicating the interface or the state requirements of the VSISRs. **Therefore, the POR for this interface is that the VGT will transmit the data to the VSISRs (via the Shader Sequencer) in full, 32-bit floating-point format.** The VGT can transmit up to six 32-bit floating-point values to each VSISR where four or more values require two transmission clocks. The data bus is 96 bits wide.

Name	Bits	Description
VGT_SQ_vsisr_data	96	Pointers of indexes or HOS surface information
VGT_SQ_vsisr_double	1	0: Normal 96 bits per vert 1: double 192 bits per vert
VGT_SQ_end_of_vector	1	Indicates the last VSISR data set for the current process vector (for double vector data, "end_of_vector" is set on the first vector)
VGT_SQ_indx_valid	1	Vsisr data is valid
VGT_SQ_state	3	Render State (6*3+3 for constants). This signal is guaranteed to be correct when “VGT_SQ_vgt_end_of_vector” is high.
VGT_SQ_send	1	Data on the VGT_SQ is valid receive (see write-up for standard R400 SEND/RTR interface handshaking)
SQ_VGT_rtr	1	Ready to receive (see write-up for standard R400 SEND/RTR interface handshaking)

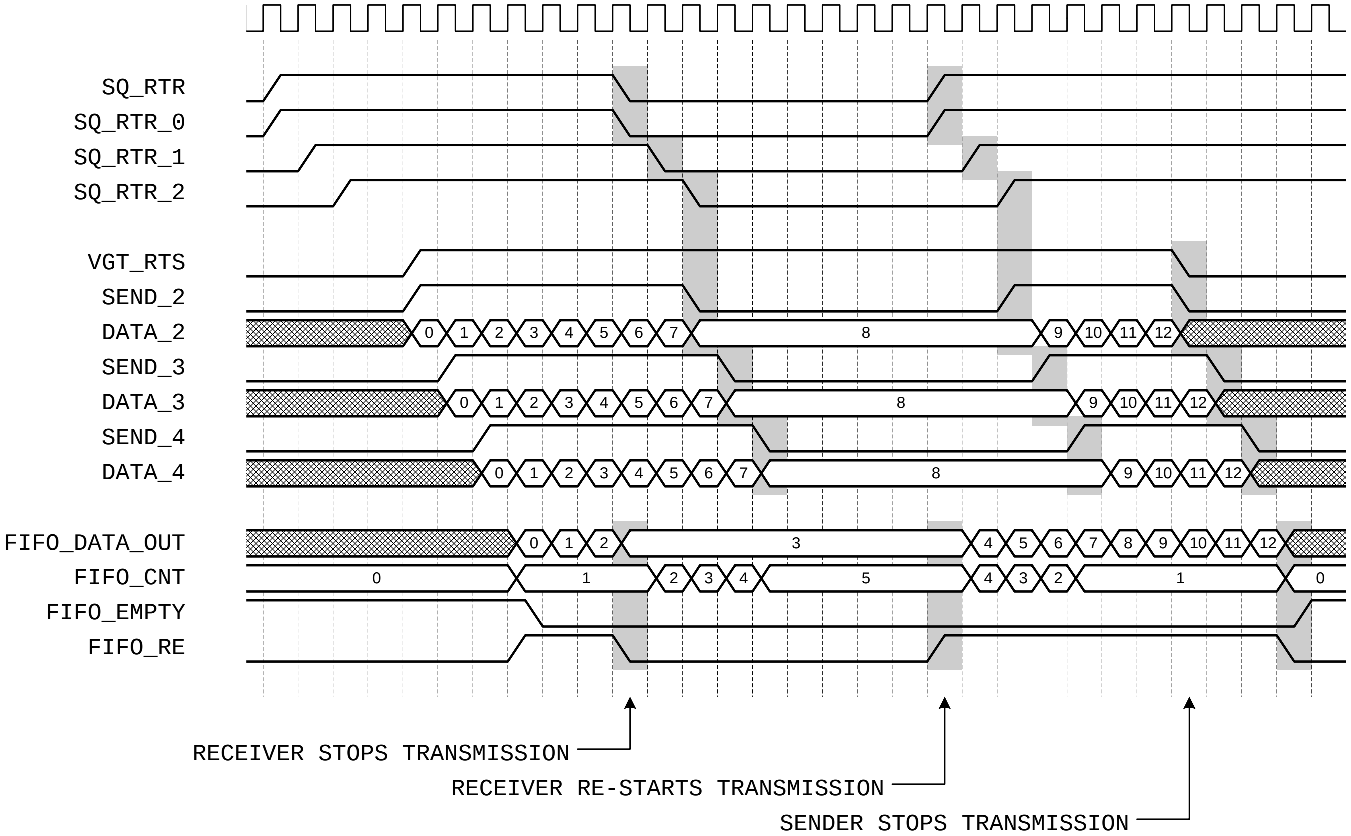

Figure 1. Detailed Logical Diagram for PA_SQ_vgt Interface.

24.2.6 *SQ to SX: Control bus*

Name	Direction	Bits	Description
SQ_SXx_exp_type	SQ→SXx	2	00: Pixel without z (1 to 4 buffers) 01: Pixel with z (1 to 4 buffers) 10: Position (1 or 2 results) 11: Pass thru (4,8 or 12 results aligned)
SQ_SXx_exp_number	SQ→SXx	2	Number of locations needed in the export buffer (encoding depends on the type see bellow).
SQ_SXx_exp_alu_id	SQ→SXx	1	ALU ID
SQ_SXx_exp_valid	SQ→SXx	1	Valid bit
SQ_SXx_exp_state	SQ→SXx	3	State Context
SQ_SXx_free_done	SQ→SXx	1	Pulse to indicate that the previous export is finished (this can be sent with or without the other fields of the interface)
SQ_SXx_free_alu_id	SQ→SXx	1	ALU ID

Depending on the type the number of export location changes:

- Type 00 : Pixels without Z
  - 00 = 1 buffer
  - 01 = 2 buffers
  - 10 = 3 buffers
  - 11 = 4 buffer
- Type 01: Pixels with Z
  - 00 = 2 Buffers (color + Z)
  - 01 = 3 buffers (2 color + Z)
  - 10 = 4 buffers (3 color + Z)
  - 11 = 5 buffers (4 color + Z)
- Type 10 : Position export
  - 00 = 1 position
  - 01 = 2 positions
  - 1X = Undefined
- Type 11: Pass Thru
  - 00 = 4 buffers
  - 01 = 8 buffers
  - 10 = 12 buffers
  - 11 = Undefined

Below the thick black line is the end of transfer packet that tells the SX that a given export is finished. The report packet **will always arrive either before or at the same time than the next export to the same ALU id**.

24.2.7 *SX to SQ : Output file control*

Name	Direction	Bits	Description
SXx_SQ_exp_count_rdy	SXx→SQ	1	Raised by SX0 to indicate that the following two fields reflect the result of the most recent export
SXx_SQ_exp_pos_avail	SXx→SQ	1	Specifies whether there is room for another position.
SXx_SQ_exp_buf_avail	SXx→SQ	7	Specifies the space available in the output buffers. 0: buffers are full 1: 2K-bits available (32-bits for each of the 64 pixels in a clause) ... 64: 128K-bits available (16 128-bit entries for each of 64 pixels) 65-127: RESERVED

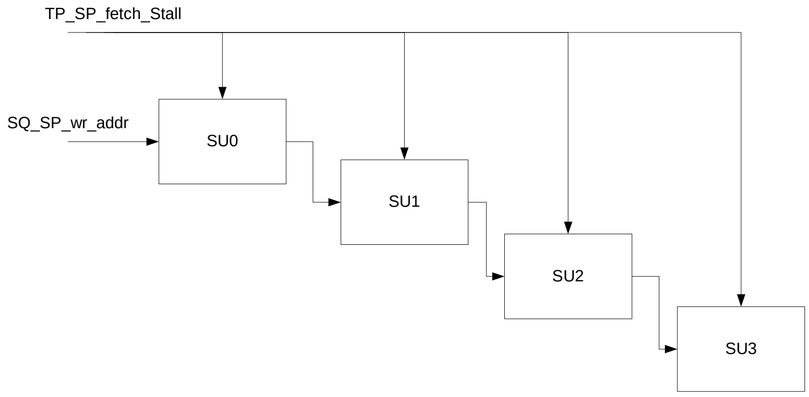
24.2.8 SQ to TP: Control bus

Once every clock, the fetch unit sends to the sequencer on which RS line it is now working and if the data in the GPRs is ready or not. This way the sequencer can update the fetch valid bits flags for the reservation station. The sequencer also provides the instruction and constants for the fetch to execute and the address in the register file where to write the fetch return data.

Name	Direction	Bits	Description
TPx_SQ_data_rdy	TPx→ SQ	1	Data ready
TPx_SQ_rs_line_num	TPx→ SQ	6	Line number in the Reservation station
TPx_SQ_type	TPx→ SQ	1	Type of data sent (0:PIXEL, 1:VERTEX)
SQ_TPx_send	SQ→TPx	1	Sending valid data
SQ_TPx_const	SQ→TPx	48	Fetch state sent over 4 clocks (192 bits total)
SQ_TPx_instr	SQ→TPx	24	Fetch instruction sent over 4 clocks
SQ_TPx_end_of_group	SQ→TPx	1	Last instruction of the group
SQ_TPx_Type	SQ→TPx	1	Type of data sent (0:PIXEL, 1:VERTEX)
SQ_TPx_gpr_phase	SQ→TPx	2	Write phase signal
SQ_TP0_lod_correct	SQ→TP0	6	LOD correct 3 bits per comp 2 components per quad
SQ_TP0_pix_mask	SQ→TP0	4	Pixel mask 1 bit per pixel
SQ_TP1_lod_correct	SQ→TP1	6	LOD correct 3 bits per comp 2 components per quad
SQ_TP1_pix_mask	SQ→TP1	4	Pixel mask 1 bit per pixel
SQ_TP2_lod_correct	SQ→TP2	6	LOD correct 3 bits per comp 2 components per quad
SQ_TP2_pix_mask	SQ→TP2	4	Pixel mask 1 bit per pixel
SQ_TP3_lod_correct	SQ→TP3	6	LOD correct 3 bits per comp 2 components per quad
SQ_TP3_pix_mask	SQ→TP3	4	Pixel mask 1 bit per pixel
SQ_TPx_rs_line_num	SQ→TPx	6	Line number in the Reservation station
SQ_TPx_write_gpr_index	SQ->TPx	7	Index into Register file for write of returned Fetch Data

24.2.9 TP to SQ: Texture stall

The TP sends this signal to the SQ and the SPs when its input buffer is full.



Name	Direction	Bits	Description
TP_SQ_fetch_stall	TP→ SQ	1	Do not send more texture request if asserted

24.2.10 *SQ to SP: Texture stall*

Name	Direction	Bits	Description
SQ_SPx_fetch_stall	SQ→SPx	1	Do not send more texture request if asserted

24.2.11 *SQ to SP: GPR and auto counter*

Name	Direction	Bits	Description
SQ_SPx_gpr_wr_addr	SQ→SPx	7	Write address
SQ_SPx_gpr_rd_addr	SQ→SPx	7	Read address
SQ_SPx_gpr_rd_en	SQ→SPx	1	Read Enable
SQ_SP0_gpr_wr_en	SQ→SPx	1	Write Enable for the GPRs of SP0
SQ_SP1_gpr_wr_en	SQ→SPx	1	Write Enable for the GPRs of SP1
SQ_SP2_gpr_wr_en	SQ→SPx	1	Write Enable for the GPRs of SP2
SQ_SP~~x~~3_gpr_wr_en	SQ→SPx	1	Write Enable for the GPRs of SP3
SQ_SPx_gpr_phase	SQ→SPx	2	The phase mux (arbitrates between inputs, ALU SRC reads and writes)
SQ_SPx_channel_mask	SQ→SPx	4	The channel mask
SQ_SPx_gpr_input_sel	SQ→SPx	2	When the phase mux selects the inputs this tells from which source to read from: Interpolated data, VTX0, VTX1, autogen counter.
SQ_SPx_auto_count	SQ→SPx	12?	Auto count generated by the SQ, common for all shader pipes

24.2.12 *SQ to SPx: Instructions*

Name	Direction	Bits	Description
SQ_SPx_instr_start	SQ→SPx	1	Instruction start
SQ_SP_instr	SQ→SPx	21	Transferred over 4 cycles 0: SRC A Select 2:0 SRC A Argument Modifier 3:3 SRC A swizzle 11:4 VectorDst 17:12 Unused 20:18 --- - 1: SRC B Select 2:0 SRC B Argument Modifier 3:3 SRC B swizzle 11:4 ScalarDst 17:12 Unused 20:18 --- - 2: SRC C Select 2:0 SRC C Argument Modifier 3:3 SRC C swizzle 11:4 Unused 20:12 --- - 3: Vector Opcode 4:0 Scalar Opcode 10:5 Vector Clamp 11:11 Scalar Clamp 12:12 Vector Write Mask 16:13 Scalar Write Mask 20:17
SQ_SPx_exp_alu_id	SQ→SPx	1	ALU ID
SQ_SPx_exporting	SQ→SPx	2	0: Not Exporting 1: Vector Exporting 2: Scalar Exporting
SQ_SPx_stall	SQ→SPx	1	Stall signal
SQ_SP0_write_mask	SQ→SP0	4	Result of pixel kill in the shader pipe, which must be output for all pixel exports (depth and all color buffers). 4x4 because 16 pixels are computed per clock
SQ_SP1_ write_mask	SQ→SP1	4	Result of pixel kill in the shader pipe, which must be output for all pixel exports (depth and all color buffers). 4x4 because 16 pixels are computed per clock
SQ_SP2_ write_mask	SQ→SP2	4	Result of pixel kill in the shader pipe, which must be output for all pixel exports (depth and all color buffers). 4x4 because 16 pixels are computed per clock
SQ_SP3_ write_mask	SQ→SP3	4	Result of pixel kill in the shader pipe, which must be output for all pixel exports (depth and all color buffers). 4x4 because 16 pixels are computed per clock

24.2.13 *SP to SQ: Constant address load/ Predicate Set*

Name	Direction	Bits	Description
SP0_SQ_const_addr	SP0→SQ	36	Constant address load / predicate vector load (4 bits only) to the sequencer
SP0_SQ_valid	SP0→SQ	1	Data valid
SP1_SQ_const_addr	SP1→SQ	36	Constant address load / predicate vector load (4 bits only) to the sequencer

SP1_SQ_valid	SP1→SQ	1	Data valid
SP2_SQ_const_addr	SP2→SQ	36	Constant address load / predicate vector load (4 bits only) to the sequencer
SP2_SQ_valid	SP2→SQ	1	Data valid
SP3_SQ_const_addr	SP3→SQ	36	Constant address load / predicate vector load (4 bits only) to the sequencer
SP3_SQ_valid	SP3→SQ	1	Data valid

24.2.14 *SQ to SPx: constant broadcast*

Name	Direction	Bits	Description
SQ_SPx_const	SQ→SPx	128	Constant broadcast

24.2.15 *SP0 to SQ: Kill vector load*

Name	Direction	Bits	Description
SP0_SQ_kill_vect	SP0→SQ	4	Kill vector load
SP1_SQ_kill_vect	SP1→SQ	4	Kill vector load
SP2_SQ_kill_vect	SP2→SQ	4	Kill vector load
SP3_SQ_kill_vect	SP3→SQ	4	Kill vector load

24.2.16 *SQ to CP: RBBM bus*

Name	Direction	Bits	Description
SQ_RBB_rs	SQ→CP	1	Read Strobe
SQ_RBB_rd	SQ→CP	32	Read Data
SQ_RBBM_nrtrtr	SQ→CP	1	Optional
SQ_RBBM_rtr	SQ→CP	1	Real-Time (Optional)

24.2.17 *CP to SQ: RBBM bus*

Name	Direction	Bits	Description
rbbm_we	CP→SQ	1	Write Enable
rbbm_a	CP→SQ	15	Address -- Upper Extent is TBD (16:2)
rbbm_wd	CP→SQ	32	Data
rbbm_be	CP→SQ	4	Byte Enables
rbbm_re	CP→SQ	1	Read Enable
rbb_rs0	CP→SQ	1	Read Return Strobe 0
rbb_rs1	CP→SQ	1	Read Return Strobe 1
rbb_rd0	CP→SQ	32	Read Data 0
rbb_rd1	CP→SQ	32	Read Data 0
RBBM_SQ_soft_reset	CP→SQ	1	Soft Reset

24.2.18 *SQ to CP: State report*

Name	Direction	Bits	Description
SQ_CP_vs_event	SQ→CP	1	Vertex Shader Event
SQ_CP_vs_eventid	SQ→CP	2	Vertex Shader Event ID
SQ_CP_ps_event	SQ→CP	1	Pixel Shader Event
SQ_CP_ps_eventid	SQ→CP	2	Pixel Shader Event ID

eventid = 0 => *sEndOfState (i.e. VsEndOfState)
eventid = 1 => *sDone (i.e. VsDone)

So, the CP will assume the Vs is done with a state whenever it gets a pulse on the SQ_CP_vs_event and the SQ_CP_vs_eventid = 0.

24.3 Example of control flow program execution

We now provide some examples of execution to better illustrate the new design.

Given the program:

Alu 0
Alu 1
Tex 0
Tex 1
Alu 3 Serial
Alu 4
Tex 2
Alu 5
Alu 6 Serial
Tex 3
Alu 7
Alloc Position 1 buffer
Alu 8 Export
Tex 4
Alloc Parameter 3 buffers
Alu 9 Export 0
Tex 5
Alu 10 Serial Export 2
Alu 11 Export 1 End

Would be converted into the following CF instructions:

```
Execute Alu 0 Alu 0 Tex 0 Tex 0 Alu 1 Alu 0 Tex 0 Alu 0 Alu 1 Tex 0
Execute Alu 0
Alloc Position 1
Execute Alu 0 Tex 0
Alloc Param 3
Execute Alu 0 Tex 0 Alu 1 Alu 0 End
```

And the execution of this program would look like this:

Put thread in Vertex RS:

Control Flow Instruction Pointer (12 bits), (CFP)
Execution Count Marker (3 or 4 bits), (ECM)
Loop Iterators (4x9 bits), (LI)
Call return pointers (4x12 bits), (CRP)
Predicate Bits(4x64 bits), (PB)
Export ID (1 bit), (EXID)
GPR Base Ptr (8 bits), (GPR)
Export Base Ptr (7 bits), (EB)
Context Ptr (3 bits).(CPTR)
LOD correction bits (16x6 bits) (LOD)

State Bits

CFP	ECM	LI	CRP	PB	EXID	GPR	EB	CPTR	LOD
0	0	0	0	0	0	0	0	0	0

Valid Thread (VALID)
Texture/ALU engine needed (TYPE)
Texture Reads are outstanding (PENDING)
Waiting on Texture Read to Complete (SERIAL)
Allocation Wait (2 bits) (ALLOC)

00 – No allocation needed
01 – Position export allocation needed (ordered export)
10 – Parameter or pixel export needed (ordered export)
11 – pass thru (out of order export)
Allocation Size (4 bits) (SIZE)
Position Allocated (POS_ALLOC)
First thread of a new context (FIRST)
Last (1 bit), (LAST)

Status Bits

VALID	TYPE	PENDING	SERIAL	ALLOC	SIZE	POS_ALLOC	FIRST	LAST
1	ALU	0	0	0	0	0	1	0

Then the thread is picked up for the execution of the first control flow instruction:

```
Execute Alu 0 Alu 0 Tex 0 Tex 0 Alu 1 Alu 0 Tex 0 Alu 0 Alu 1 Tex 0
```

It executes the first two ALU instructions and goes back to the RS for a resource request change. Here is the state returned to the RS:

State Bits

CFP	ECM	LI	CRP	PB	EXID	GPR	EB	CPTR	LOD
0	2	0	0	0	0	0	0	0	0

Status Bits

VALID	TYPE	PENDING	SERIAL	ALLOC	SIZE	POS_ALLOC	FIRST	LAST
1	TEX	0	0	0	0	0	1	0

Then when the texture pipe frees up, the arbiter picks up the thread to issue the texture reads. The thread comes back in this state:

State Bits

CFP	ECM	LI	CRP	PB	EXID	GPR	EB	CPTR	LOD
0	4	0	0	0	0	0	0	0	0

Status Bits

VALID	TYPE	PENDING	SERIAL	ALLOC	SIZE	POS_ALLOC	FIRST	LAST
1	ALU	1	1	0	0	0	1	0

Because of the serial bit the arbiter must wait for the texture to return and clear the PENDING bit before it can pick the thread up. Lets say that the texture reads are complete, then the arbiter picks up the thread and returns it in this state:

State Bits

CFP	ECM	LI	CRP	PB	EXID	GPR	EB	CPTR	LOD
0	6	0	0	0	0	0	0	0	0

Status Bits

VALID	TYPE	PENDING	SERIAL	ALLOC	SIZE	POS_ALLOC	FIRST	LAST
1	TEX	0	0	0	0	0	1	0

Again the TP frees up, the arbiter picks up the thread and executes. It returns in this state:

State Bits

CFP	ECM	LI	CRP	PB	EXID	GPR	EB	CPTR	LOD
0	7	0	0	0	0	0	0	0	0

Status Bits

VALID	TYPE	PENDING	SERIAL	ALLOC	SIZE	POS_ALLOC	FIRST	LAST
1	ALU	1	0	0	0	0	1	0

Now, even if the texture has not returned we can still pick up the thread for ALU execution because the serial bit is not set. The thread will however come back to the RS for the second ALU instruction because it has the serial bit set.

State Bits

CFP	ECM	LI	CRP	PB	EXID	GPR	EB	CPTR	LOD
0	8	0	0	0	0	0	0	0	0

Status Bits

VALID	TYPE	PENDING	SERIAL	ALLOC	SIZE	POS_ALLOC	FIRST	LAST
1	ALU	1	1	0	0	0	1	0

As soon as the TP clears the pending bit the thread is picked up and returns:

State Bits

CFP	ECM	LI	CRP	PB	EXID	GPR	EB	CPTR	LOD
0	9	0	0	0	0	0	0	0	0

Status Bits

VALID	TYPE	PENDING	SERIAL	ALLOC	SIZE	POS_ALLOC	FIRST	LAST
1	TEX	0	0	0	0	0	1	0

Picked up by the TP and returns:

```
Execute Alu 0
```

State Bits

CFP	ECM	LI	CRP	PB	EXID	GPR	EB	CPTR	LOD
1	0	0	0	0	0	0	0	0	0

Status Bits

VALID	TYPE	PENDING	SERIAL	ALLOC	SIZE	POS_ALLOC	FIRST	LAST
1	ALU	1	0	0	0	0	1	0

Picked up by the ALU and returns (lets say the TP has not returned yet):

```
Alloc Position 1
```

State Bits

CFP	ECM	LI	CRP	PB	EXID	GPR	EB	CPTR	LOD
2	0	0	0	0	0	0	0	0	0

Status Bits

VALID	TYPE	PENDING	SERIAL	ALLOC	SIZE	POS_ALLOC	FIRST	LAST
1	ALU	1	0	01	1	0	1	0

If the SX has the place for the export, the SQ is going to allocate and pick up the thread for execution. It returns to the RS in this state:

```
Execute Alu 0 Tex 0
```

State Bits

CFP	ECM	LI	CRP	PB	EXID	GPR	EB	CPTR	LOD
3	1	0	0	0	0	0	0	0	0

Status Bits

VALID	TYPE	PENDING	SERIAL	ALLOC	SIZE	POS_ALLOC	FIRST	LAST
1	TEX	1	0	0	0	1	1	0

Now, since the TP has not returned yet, we must wait for it to return because we cannot issue multiple texture requests. The TP returns, clears the PENDING bit and we proceed:

```
    Alloc Param 3
```

State Bits

CFP	ECM	LI	CRP	PB	EXID	GPR	EB	CPTR	LOD
4	0	0	0	0	1	0	0	0	0

Status Bits

VALID	TYPE	PENDING	SERIAL	ALLOC	SIZE	POS_ALLOC	FIRST	LAST
1	ALU	1	0	10	3	1	1	0

Once again the SQ makes sure the SX has enough room in the Parameter cache before it can pick up this thread.

```
    Execute Alu 0 Tex 0 Alu 1 Alu 0 End
```

State Bits

CFP	ECM	LI	CRP	PB	EXID	GPR	EB	CPTR	LOD
5	1	0	0	0	1	0	100	0	0

Status Bits

VALID	TYPE	PENDING	SERIAL	ALLOC	SIZE	POS_ALLOC	FIRST	LAST
1	TEX	1	0	0	0	1	1	0

This executes on the TP and then returns:

State Bits

CFP	ECM	LI	CRP	PB	EXID	GPR	EB	CPTR	LOD
5	2	0	0	0	1	0	100	0	0

Status Bits

VALID	TYPE	PENDING	SERIAL	ALLOC	SIZE	POS_ALLOC	FIRST	LAST
1	ALU	1	1	0	0	1	1	1

Waits for the TP to return because of the textures reads are pending (and SERIAL in this case). Then executes and does not return to the RS because the LAST bit is set. This is the end of this thread and before dropping it on the floor, the SQ notifies the SX of export completion.

25. Open issues

Need to do some testing on the size of the register file as well as on the register file allocation method (dynamic VS static).

Saving power?

R400 Sequencer Specification

SQ

Version 2.02~~1~~

Overview: This is an architectural specification for the R400 Sequencer block (SEQ). It provides an overview of the required capabilities and expected uses of the block. It also describes the block interfaces, internal sub-blocks, and provides internal state diagrams.

AUTOMATICALLY UPDATED FIELDS:

Revision Changes:

Rev 0.1 (Laurent Lefebvre) Date: May 7, 2001	First draft.
Rev 0.2 (Laurent Lefebvre) Date : July 9, 2001	Changed the interfaces to reflect the changes in the SP. Added some details in the arbitration section.
Rev 0.3 (Laurent Lefebvre) Date : August 6, 2001	Reviewed the Sequencer spec after the meeting on August 3, 2001.
Rev 0.4 (Laurent Lefebvre) Date : August 24, 2001	Added the dynamic allocation method for register file and an example (written in part by Vic) of the flow of pixels/vertices in the sequencer.
Rev 0.5 (Laurent Lefebvre) Date : September 7, 2001	Added timing diagrams (Vic)
Rev 0.6 (Laurent Lefebvre) Date : September 24, 2001	Changed the spec to reflect the new R400 architecture. Added interfaces.
Rev 0.7 (Laurent Lefebvre) Date : October 5, 2001	Added constant store management, instruction store management, control flow management and data dependant predication.
Rev 0.8 (Laurent Lefebvre) Date : October 8, 2001	Changed the control flow method to be more flexible. Also updated the external interfaces.
Rev 0.9 (Laurent Lefebvre) Date : October 17, 2001	Incorporated changes made in the 10/18/01 control flow meeting. Added a NOP instruction, removed the conditional_execute_or_jump. Added debug registers.
Rev 1.0 (Laurent Lefebvre) Date : October 19, 2001	Refined interfaces to RB. Added state registers.
Rev 1.1 (Laurent Lefebvre) Date : October 26, 2001	Added SEQ→SP0 interfaces. Changed delta precision. Changed VGT→SP0 interface. Debug Methods added.
Rev 1.2 (Laurent Lefebvre) Date : November 16, 2001	Interfaces greatly refined. Cleaned up the spec.
Rev 1.3 (Laurent Lefebvre) Date : November 26, 2001	Added the different interpolation modes.
Rev 1.4 (Laurent Lefebvre) Date : December 6, 2001	Added the auto incrementing counters. Changed the VGT→SQ interface. Added content on constant management. Updated GPRs.
Rev 1.5 (Laurent Lefebvre) Date : December 11, 2001	Removed from the spec all interfaces that weren't directly tied to the SQ. Added explanations on constant management. Added PA→SQ synchronization fields and explanation.
Rev 1.6 (Laurent Lefebvre) Date : January 7, 2002	Added more details on the staging register. Added detail about the parameter caches. Changed the call instruction to a Conditionnal_call instruction. Added details on constant management and updated the diagram.
Rev 1.7 (Laurent Lefebvre) Date : February 4, 2002	Added Real Time parameter control in the SX interface. Updated the control flow section.
Rev 1.8 (Laurent Lefebvre) Date : March 4, 2002	New interfaces to the SX block. Added the end of clause modifier, removed the end of clause instructions.
Rev 1.9 (Laurent Lefebvre) Date : March 18, 2002	Rearangement of the CF instruction bits in order to ensure byte alignement.
Rev 1.10 (Laurent Lefebvre) Date : March 25, 2002	Updated the interfaces and added a section on exporting rules.
Rev 1.11 (Laurent Lefebvre) Date : April 19, 2002	Added CP state report interface. Last version of the spec with the old control flow scheme
Rev 2.0 (Laurent Lefebvre) Date : April 19, 2002	New control flow scheme

Rev 2.01 (Laurent Lefebvre) Date : May 2, 2002	Changed slightly the control flow instructions to allow force jumps and calls.
Rev 2.02 (Laurent Lefebvre) Date : May 13, 2002	Updated the Opcodes. Added type field to the constant/pred interface. Added Last field to the SQ→SP instruction load interface.

1. Overview

The sequencer chooses two ALU threads and a fetch hread to execute, and executes all of the instructions in a block before looking for a new clause of the same type. Two ALU threads are executed interleaved to hide the ALU latency. The arbitrator will give priority to older threads. There are two separate reservation stations, one for pixel vectors and one for vertices vectors. This way a pixel can pass a vertex and a vertex can pass a pixel.

To support the shader pipe the sequencer also contains the shader instruction cache, constant store, control flow constants and texture state. The four shader pipes also execute the same instruction thus there is only one sequencer for the whole chip.

The sequencer first arbitrates between vectors of 64 vertices that arrive directly from primitive assembly and vectors of 16 quads (64 pixels) that are generated in the scan converter.

The vertex or pixel program specifies how many GPRs it needs to execute. The sequencer will not start the next vector until the needed space is available in the GPRs.

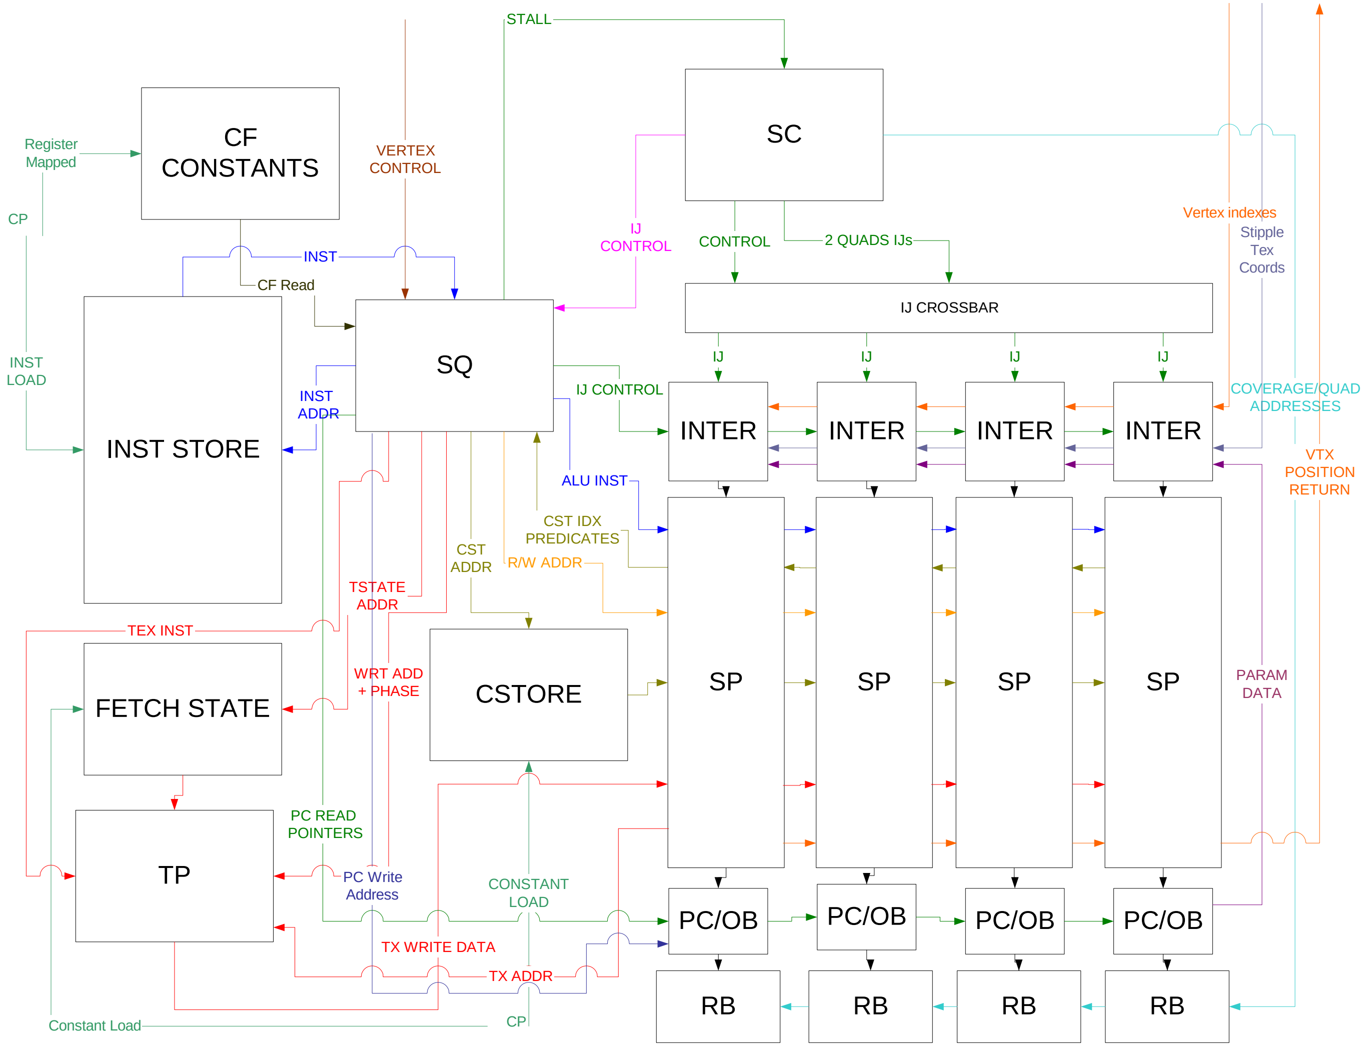

Figure 1: General Sequencer overview

1.1 Top Level Block Diagram

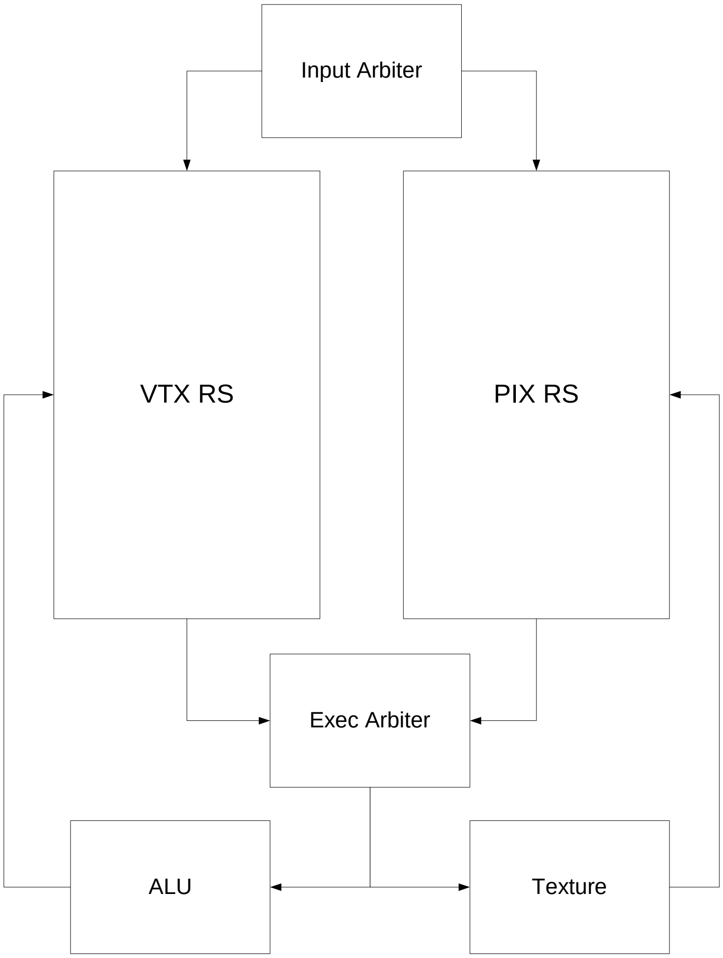

Figure 2: Reservation stations and arbiters

Under this new scheme, the sequencer (SQ) will only use one global state management machine per vector type (pixel, vertex) that we call the reservation station (RS).

1.2 Data Flow graph (SP)

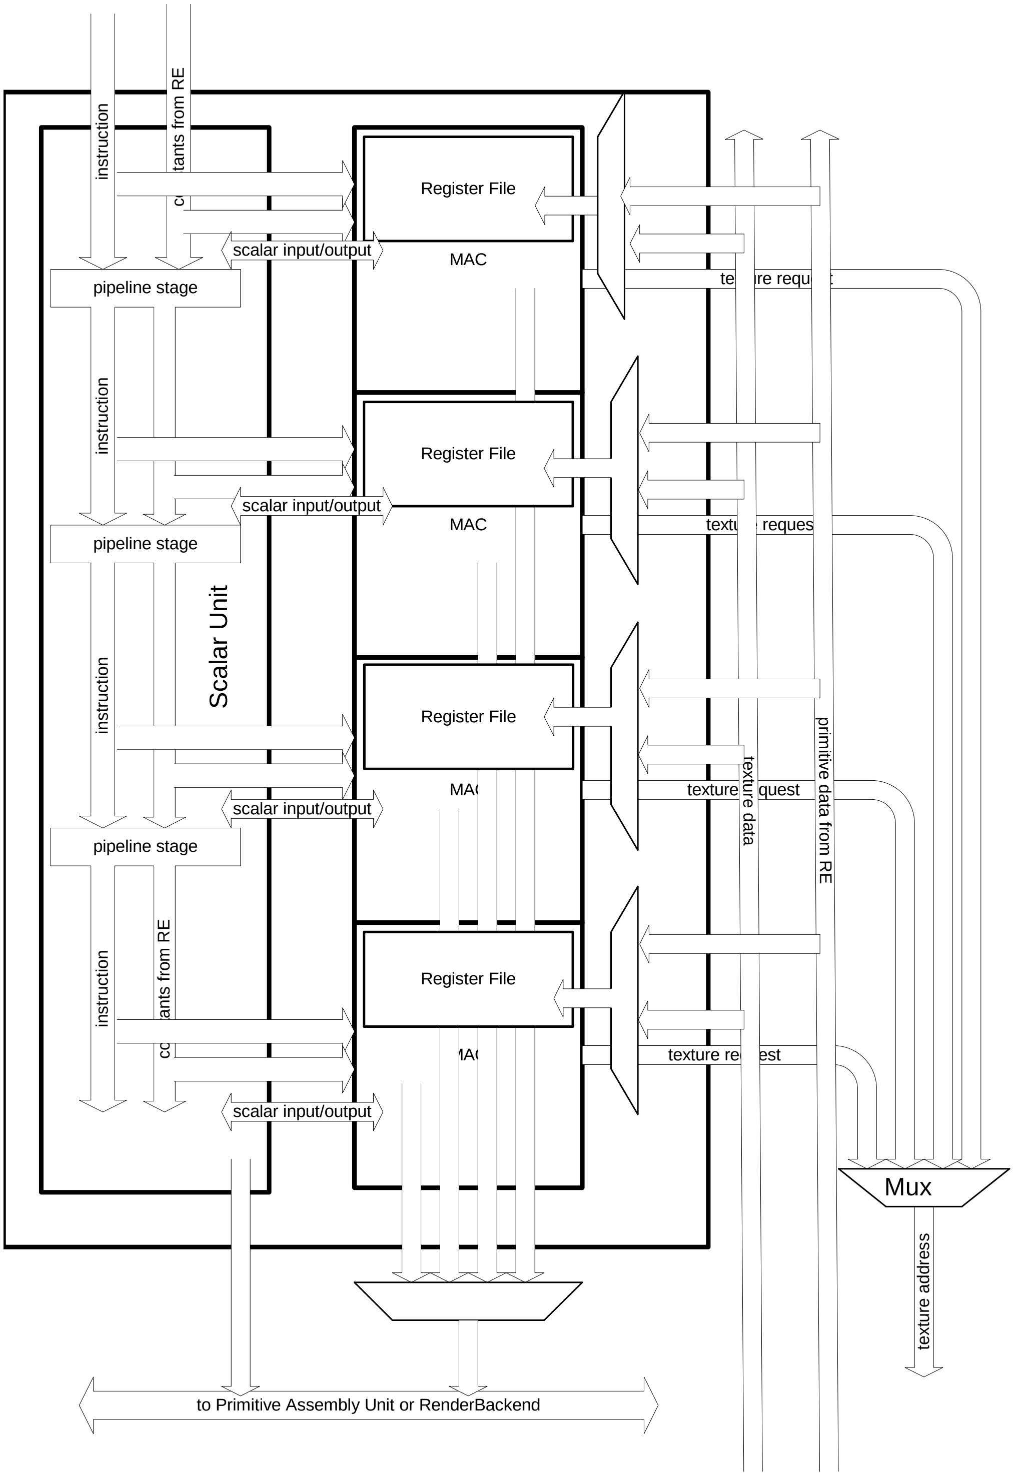

Figure 3: The shader Pipe

The gray area represents blocks that are replicated 4 times per shader pipe (16 times on the overall chip).

1.3 Control Graph

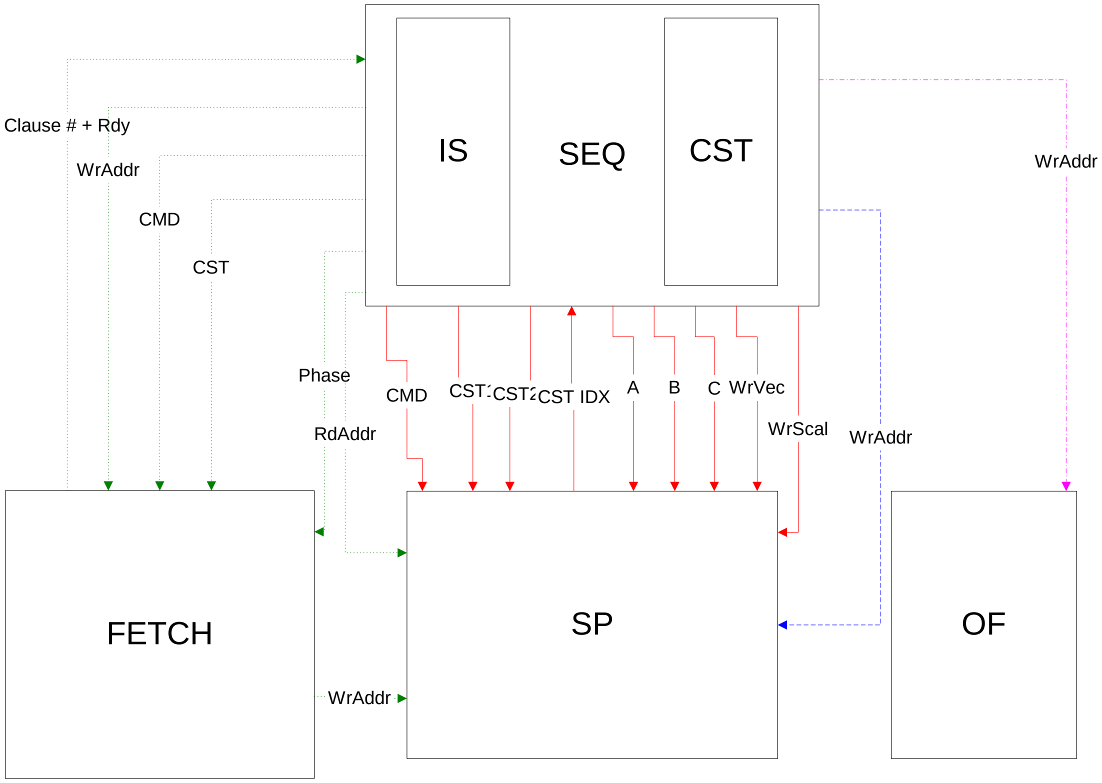

Figure 4: Sequencer Control interfaces

In green is represented the Fetch control interface, in red the ALU control interface, in blue the Interpolated/Vector control interface and in purple is the output file control interface.

2. Interpolated data bus

The interpolators contain an IJ buffer to pack the information as much as possible before writing it to the register file.

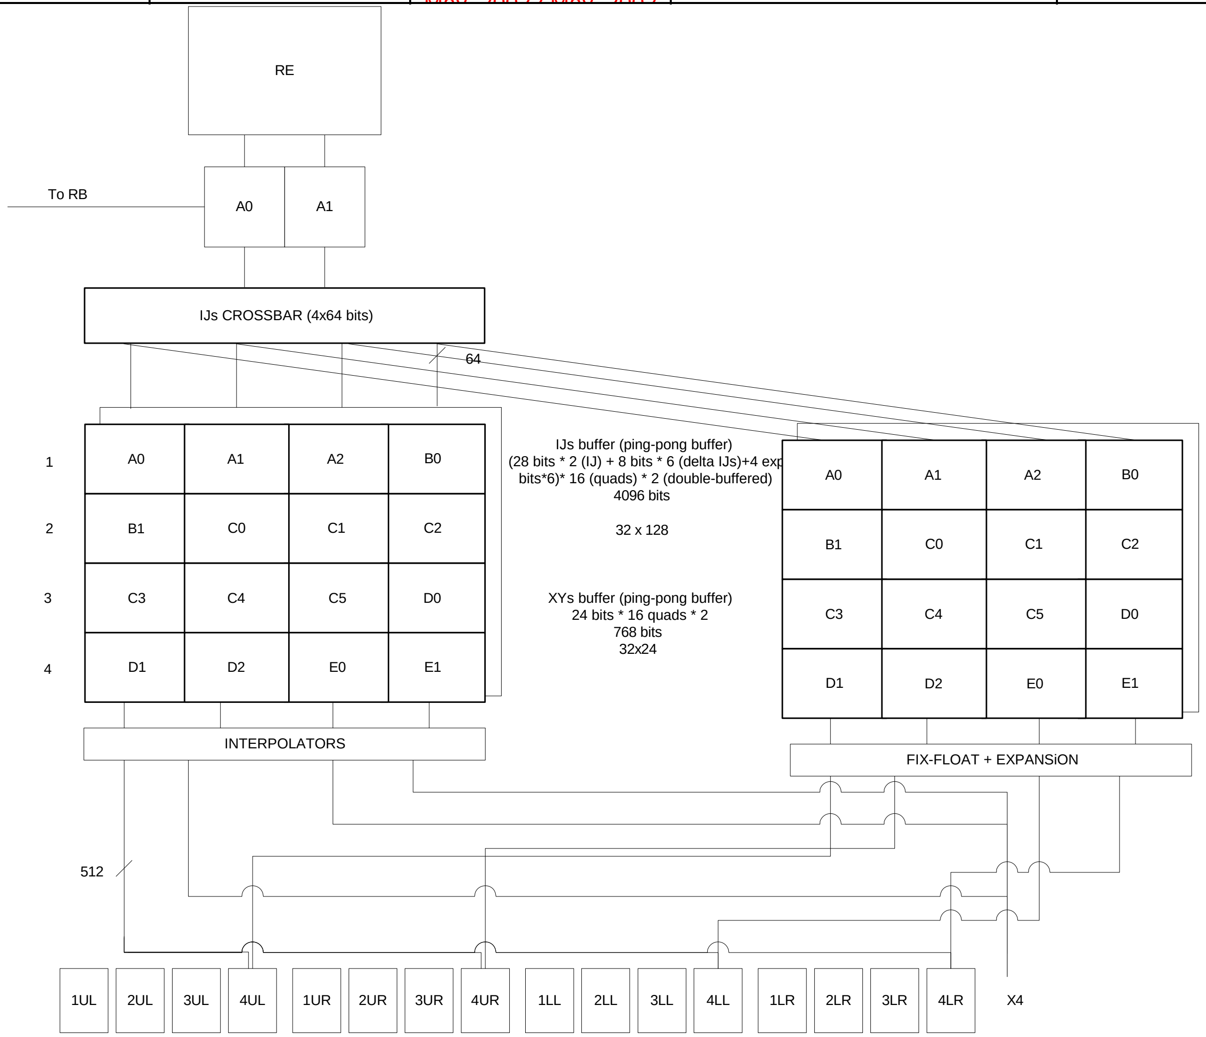

Figure 5: Interpolation buffers

		XY						P1									P2					VTX		

Figure 6: Interpolation timing diagram

Above is an example of a tile the sequencer might receive from the SC. The write side is how the data get stacked into the XY and IJ buffers, the read side is how the data is passed to the GPRs. The IJ information is packed in the IJ buffer 4 quads at a time or two clocks. The sequencer allows at any given time as many as four quads to interpolate a parameter. They all have to come from the same primitive. Then the sequencer controls the write mask to the GPRs to write the valid data in.

3. Instruction Store

There is going to be only one instruction store for the whole chip. It will contain 4096 instructions of 96 bits each.

It is likely to be a 1 port memory; we use 1 clock to load the ALU instruction, 1 clocks to load the Fetch instruction, 1 clock to load 2 control flow instructions and 1 clock to write instructions.

The instruction store is loaded by the CP thru the register mapped registers.

The VS_BASE and PS_BASE context registers are used to specify for each context where its shader is in the instruction memory.

For the Real time commands the story is quite the same but for some small differences. There are no wrap-around points for real time so the driver must be careful not to overwrite regular shader data. The shared code (shared subroutines) uses the same path as real time.

4. Sequencer Instructions

All control flow instructions and move instructions are handled by the sequencer only. The ALUs will perform NOPs during this time (MOV PV,PV, PS,PS) if they have nothing else to do.

5. Constant Stores

5.1 Memory organizations

A likely size for the ALU constant store is 1024x128 bits. The read BW from the ALU constant store is 128 bits/clock and the write bandwidth is 32 bits/clock (directed by the CP bus size not by memory ports).

The maximum logical size of the constant store for a given shader is 256 constants. Or 512 for the pixel/vertex shader pair. The size of the re-mapping table is 128 lines (each line addresses 4 constants). The write granularity is 4 constants or 512 bits. It takes 16 clocks to write the four constants. Real time requires 256 lines in the physical memory (this is physically register mapped).

The texture state is also kept in a similar memory. The size of this memory is 320x96 bits (128 texture states for regular mode, 32 states for RT). The memory thus holds 128 texture states (192 bits per state). The logical size exposes 32 different states total, which are going to be shared between the pixel and the vertex shader. The size of the re-mapping table to for the texture state memory is 32 lines (each line addresses 1 texture state lines in the real memory). The CP write granularity is 1 texture state lines (or 192 bits). The driver sends 512 bits but the CP ignores the top 320 bits. It thus takes 6 clocks to write the texture state. Real time requires 32 lines in the physical memory (this is physically register mapped).

The control flow constant memory doesn't sit behind a renaming table. It is register mapped and thus the driver must reload its content each time there is a change in the control flow constants. Its size is 320*32 because it must hold 8 copies of the 32 dwords of control flow constants and the loop construct constants must be aligned.

The constant re-mapping tables for texture state and ALU constants are logically register mapped for regular mode and physically register mapped for RT operation.

5.2 Management of the Control Flow Constants

The control flow constants are register mapped, thus the CP writes to the according register to set the constant, the SQ decodes the address and writes to the block pointed by its current base pointer (CF_WR_BASE). On the read side, one level of indirection is used. A register (SQ_CONTEXT_MISC.CF_RD_BASE) keeps the current base pointer to the control flow block. This register is copied whenever there is a state change. Should the CP write to CF after the state change, the base register is updated with the (current pointer number +1)% number of states. This way, if the CP doesn't write to CF the state is going to use the previous CF constants.

5.3 Management of the re-mapping tables

5.3.1 *R400 Constant management*

The sequencer is responsible to manage two re-mapping tables (one for the constant store and one for the texture state). On a state change (by the driver), the sequencer will broadside copy the contents of its re-mapping tables to a new one. We have 8 different re-mapping tables we can use concurrently.

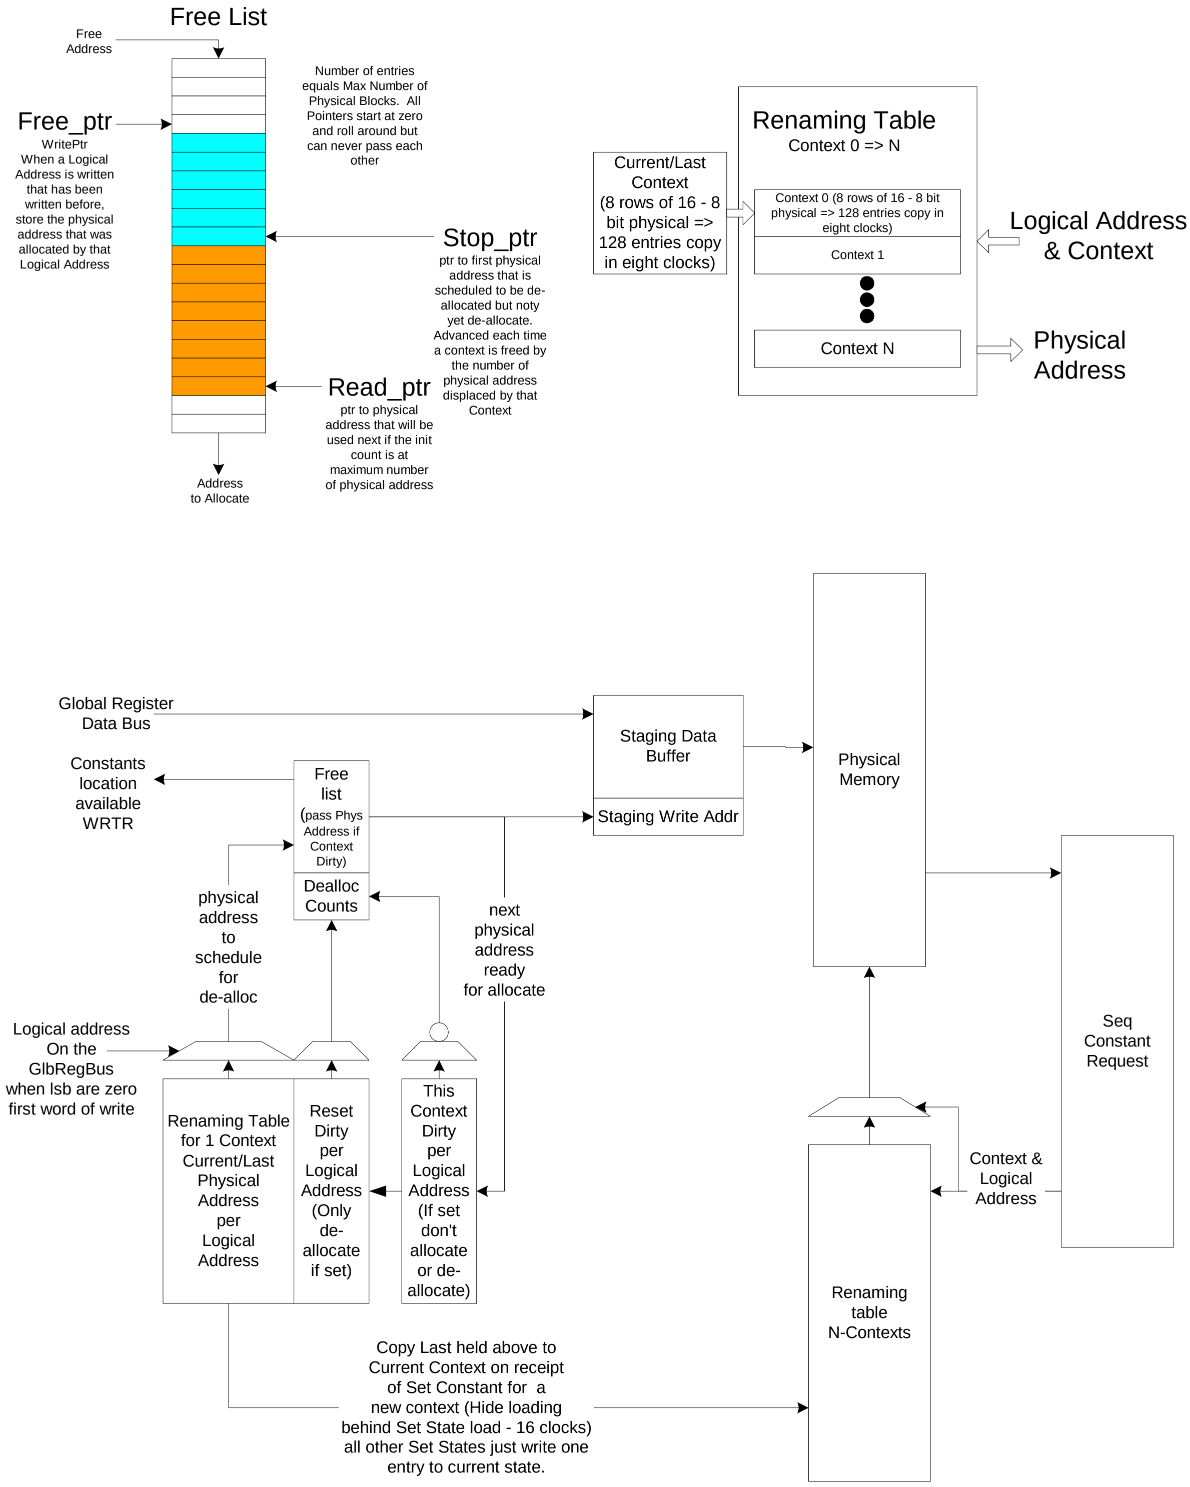
The constant memory update will be incremental, the driver only need to update the constants that actually changed between the two state changes.

For this model to work in its simplest form, the requirement is that the physical memory MUST be at least twice as large as the logical address space + the space allocated for Real Time. In our case, since the logical address space is 512 and the reserved RT space can be up to 256 entries, the memory must be of sizes 1280 and above. Similarly the size of the texture store must be of 32*2+32 = 96 entries and above.

5.3.2 *Proposal for R400LE constant management*

To make this scheme work with only 512+256 = 768 entries, upon reception of a CONTROL packet of state + 1, the sequencer would check for SQ_IDLE and PA_IDLE and if both are idle will erase the content of state to replace it with the new state (this is depicted in Figure 8: De-allocation mechanism~~Figure 8: De-allocation mechanism~~~~Figure 8: De-allocation mechanism~~). Note that in the case a state is cleared a value of 0 is written to the corresponding de-allocation counter location so that when the SQ is going to report a state change, nothing will be de-allocated upon the first report.

The second path sets all context dirty bits that were used in the current state to 1 (thus allowing the new state to reuse these physical addresses if needed).



Free List
Free Address
Free_ptr
WritePtr
When a Logical Address is written that has been written before, store the physical address that was allocated by that Logical Address
Number of entries equals Max Number of Physical Blocks. All Pointers start at zero and roll around but can never pass each other
Stop_ptr
ptr to first physical address that is scheduled to be de-allocated but noty yet de-allocate. Advanced each time a context is freed by the number of physical address displaced by that Context
Read_ptr
ptr to physical address that will be used next if the init count is at maximum number of physical address

Context & Logical Address
Renaming table N-Contexts
Copy Last held above to Current Context on receipt of Set Constant for a new context (Hide loading behind Set State load - 16 clocks) all other Set States just write one entry to current state.

Figure 7: Constant management

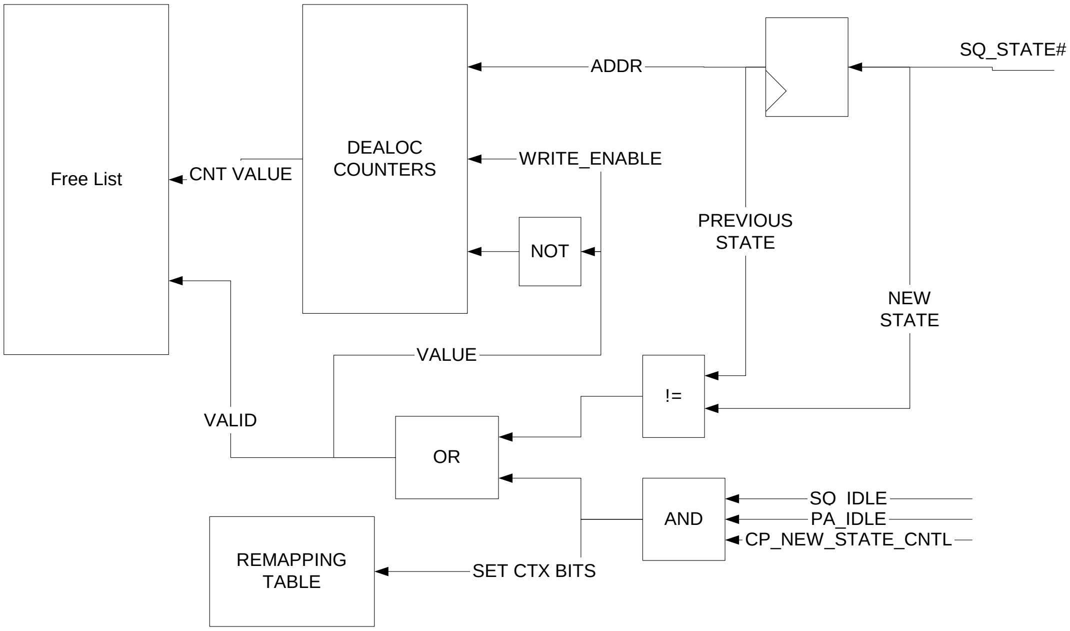

Figure 8: De-allocation mechanism for R400LE

5.3.3 *Dirty bits*

Two sets of dirty bits will be maintained per logical address. The first one will be set to zero on reset and set when the logical address is addressed. The second one will be set to zero whenever a new context is written and set for each address written while in this context. The reset dirty is not set, then writing to that logical address will not require de-allocation of whatever address stored in the renaming table. If it is set and the context dirty is not set, then the physical address store needs to be de-allocated and a new physical address is necessary to store the incoming data. If they are both set, then the data will be written into the physical address held in the renaming for the current logical address. No de-allocation or allocation takes place. This will happen when the driver does a set constant twice to the same logical address between context changes. NOTE: It is important to detect and prevent this, failure to do it will allow multiple writes to allocate all physical memory and thus hang because a context will not fit for rendering to start and thus free up space.

5.3.4 *Free List Block*

A free list block that would consist of a counter (called the IFC or Initial Free Counter) that would reset to zero and incremented every time a chunk of physical memory is used until they have all been used once. This counter would be checked each time a physical block is needed, and if the original ones have not been used up, us a new one, else check the free list for an available physical block address. The count is the physical address for when getting a chunk from the counter.

Storage of a free list big enough to store all physical block addresses.

Maintain three pointers for the free list that are reset to zero. The first one we will call write_ptr. This pointer will identify the next location to write the physical address of a block to be de-allocated. Note: we can never free more physical memory locations than we have. Once recording address the pointer will be incremented to walk the free list like a ring.

The second pointer will be called stop_ptr. The stop_ptr pointer will be advanced by the number of address chunks de-allocates when a context finishes. The address between the stop_ptr and write_ptr cannot be reused because they are still in use. But as soon as the context using then is dismissed the stop_ptr will be advanced.

The third pointer will be called read_ptr. This pointer will point will point to the next address that can be used for allocation as long as the read_ptr does not equal the stop_ptr and the IFC is at its maximum count.

5.3.5 *De-allocate Block*

This block will maintain a free physical address block count for each context. While in current context, a count shall be maintained specifying how many blocks were written into the free list at the write_ptr pointer. This count will be reset upon reset or when this context is active on the back and different than the previous context. It is actually a count of blocks in the previous context that will no longer be used. This count will be used to advance the write_ptr pointer to make available the set of physical blocks freed when the previous context was done. This allows the discard or de-allocation of any number of blocks in one clock.

5.3.6 *Operation of Incremental model*

The basic operation of the model would start with the write_ptr, stop_ptr, read_ptr pointers in the free list set to zero and the free list counter is set to zero. Also all the dirty bits and the previous context will be initialized to zero. When the first set constants happen, the reset dirty bit will not be set, so we will allocate a physical location from the free list counter because its not at the max value. The data will be written into physical address zero. Both the additional copy of the renaming table and the context zeros of the big renaming table will be updated for the logical address that was written by set start with physical address of 0. This process will be repeated for any logical address that are not dirty until the context changes. If a logical address is hit that has its dirty bits set while in the same context, both dirty bits would be set, so the new data will be over-written to the last physical address assigned for this logical address. When the first draw command of the context is detected, the previous context stored in the additional renaming table will be copied to the larger renaming table in the current (new) context location. Then the set constant logical address with be loaded with a new physical address during the copy and if the reset dirty was set, the physical address it replaced in the renaming table would be entered at the write_ptr pointer location on the free list and the write_ptr will be incremented. The de-allocation counter for the previous context (eight) will be incremented. This as set states come in for this context one of the following will happen:

1.) No dirty bits are set for the logical address being updated. A line will be allocated of the free-list counter or the free list at read_ptr pointer if read_ptr != to stop_ptr .
2.) Reset dirty set and Context dirty not set. A new physical address is allocated, the physical address in the renaming table is put on the free list at write_ptr and it is incremented along with the de-allocate counter for the last context.
3.) Context dirty is set then the data will be written into the physical address specified by the logical address.

This process will continue as long as set states arrive. This block will provide backpressure to the CP whenever he has not free list entries available (counter at max and stop_ptr == read_ptr). The command stream will keep a count of contexts of constants in use and prevent more than max constants contexts from being sent.

Whenever a draw packet arrives, the content of the re-mapping table is written to the correct re-mapping table for the context number. Also if the next context uses less constants than the current one all exceeding lines are moved to the free list to be de-allocated later. This happens in parallel with the writing of the re-mapping table to the correct memory.

Now preferable when the constant context leaves the last ALU clause it will be sent to this block and compared with the previous context that left. (Init to zero) If they differ than the older context will no longer be referenced and thus can be de-allocated in the physical memory. This is accomplished by adding the number of blocks freed this context to the stop_ptr pointer. This will make all the physical addresses used by this context available to the read_ptr allocate pointer for future allocation.

This device allows representation of multiple contexts of constants data with N copies of the logical address space. It also allows the second context to be represented as the first set plus some new additional data by just storing the delta's. It allows memory to be efficiently used and when the constants updates are small it can store multiple context. However, if the updates are large, less contexts will be stored and potentially performance will be degraded. Although it will still perform as well as a ring could in this case.

5.4 Constant Store Indexing

In order to do constant store indexing, the sequencer must be loaded first with the indexes (that come from the GPRs). There are 144 wires from the exit of the SP to the sequencer (9 bits pointers x 16 vertexes/clock). Since the data must pass thru the Shader pipe for the float to fixed conversion, there is a latency of 4 clocks (1 instruction)

between the time the sequencer is loaded and the time one can index into the constant store. The assembly will look like this

```
MOVA  R1.X,R2.X      // Loads the sequencer with the content of R2.X, also copies the content of R2.X into R1.X
NOP                  // latency of the float to fixed conversion
ADD   R3,R4,C0[R2.X]// Uses the state from the sequencer to add R4 to C0[R2.X] into R3
```

Note that we don't really care about what is in the brackets because we use the state from the MOVA instruction. R2.X is just written again for the sake of simplicity and coherency.

The storage needed in the sequencer in order to support this feature is 2*64*9 bits = 1152 bits.

5.5 Real Time Commands

The real time commands constants are written by the CP using the register mapped registers allocated for RT. It works is the same way than when dealing with regular constant loads BUT in this case the CP is not sending a logical address but rather a physical address and the reads are not passing thru the re-mapping table but are directly read from the memory. The boundary between the two zones is defined by the CONST_EO_RT control register. Similarly, for the fetch state, the boundary between the two zones is defined by the TSTATE_EO_RT control register.

5.6 Constant Waterfalling

In order to have a reasonable performance in the case of constant store indexing using the address register, we are going to have the possibility of using the physical memory port for read only. This way we can read 1 constant per clock and thus have a worst-case waterfall mode of 1 vertex per clock. There is a small synchronization issue related with this as we need for the SQ to make sure that the constants where actually written to memory (not only sent to the sequencer) before it can allow the first vector of pixels or vertices of the state to go thru the ALUs. To do so, the sequencer keeps 8 bits (one per render state) and sets the bits whenever the last render state is written to memory and clears the bit whenever a state is freed.

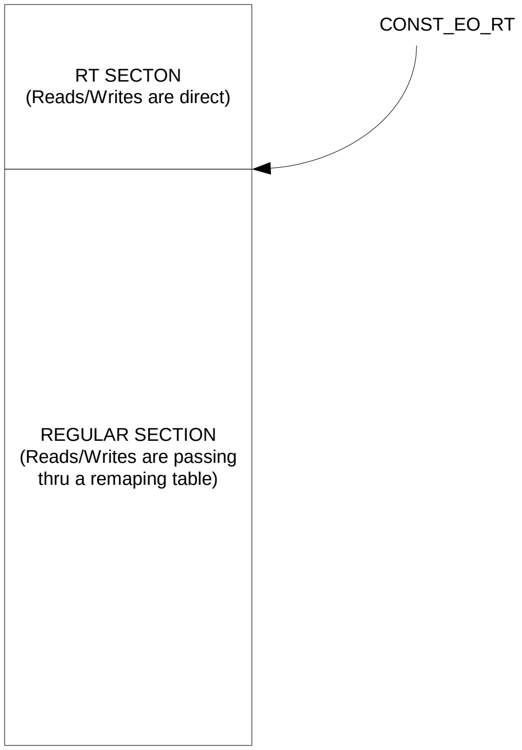

Figure 9: The instruction store

6. Looping and Branches

Loops and branches are planned to be supported and will have to be dealt with at the sequencer level. We plan on supporting constant loops and branches using a control program.

6.1 The controlling state.

The R400 controling state consists of:

Boolean[256:0]
Loop_count[7:0][31:0]
Loop_Start[7:0][31:0]
Loop_Step[7:0][31:0]

That is 256 Booleans and 32 loops.

We have a stack of 4 elements for nested calls of subroutines and 4 loop counters to allow for nested loops.

This state is available on a per shader program basis.

6.2 The Control Flow Program

We'd like to be able to code up a program of the form:

```
1:      Loop
2:      Exec    TexFetch
3:              TexFetch
4:              ALU
5:              ALU
6:              TexFetch
7:      End Loop
8:      ALU Export
```

But realize that 3: may be dependent on 2: and 4: is almost certainly dependent on 2: and 3:. Without clausing, these dependencies need to be expressed in the Control Flow instructions. Additionally, without separate 'texture clauses' and 'ALU clauses' we need to know which instructions to dispatch to the Texture Unit and which to the ALU unit. This information will be encapsulated in the flow control instructions.

Each control flow instruction will contain 2 bits of information for each (non-control flow) instruction:

a) ALU or Texture
b) Serialize Execution

(b) would force the thread to stop execution at this point (before the instruction is executed) and wait until all textures have been fetched. Given the allocation of reserved bits, this would mean that the count of an 'Exec' instruction would be limited to about 8 (non-control-flow) instructions. If more than this were needed, a second Exec (with the same conditions) would be issued.

Another function that relies upon 'clauses' is allocation and order of execution. We need to assure that pixels and vertices are exported in the correct order (even if not all execution is ordered) and that space in the output buffers are allocated in order. Additionally data can't be exported until space is allocated. A new control flow instruction:

Alloc <buffer select -- position,parameter, pixel or vertex memory. And the size required>.

would be created to mark where such allocation needs to be done. To assure allocation is done in order, the actual allocation for a given thread can not be performed unless the equivalent allocation for all previous threads is already completed. The implementation would also assure that execution of instruction(s) following the serialization due to the Alloc will occur in order -- at least until the next serialization or change from ALU to Texture. In most cases this will allow the exports to occur without any further synchronization. Only 'final' allocations or position allocations are

guaranteed to be ordered. Because strict ordering is required for pixels, parameters and positions, this implies only a single alloc for these structures. Vertex exports to memory do not require ordering during allocation and so multiple 'allocs' may be done.

6.2.1 *Control flow instructions table*

Here is the revised control flow instruction set.

Note that whenever a field is marked as RESERVED, it is assumed that all the bits of the field are cleared (0).

NOP		
47 … 44	43	42 … 0
0000	Addressing	RESERVED

This is a regular NOP.

Execute					
47 … 44~~47~~	43~~46… 43~~	40 … 34	33 …16	15…12	11 … 0
0001~~Addressing~~	Addressing~~0001~~	RESERVED	Instructions type + serialize (9 instructions)	Count	Exec Address

Execute_End					
47 … 44	43	40 … 34	33 …16	15…12	11 … 0
0010	Addressing	RESERVED	Instructions type + serialize (9 instructions)	Count	Exec Address

Execute up to 9 instructions at the specified address in the instruction memory. The Instruction type field tells the sequencer the type of the instruction (LSB) (1 = Texture, 0 = ALU and whether to serialize or not the execution (MSB) (1 = Serialize, 0 = Non-Serialized). If Execute_End this is the last execution block of the shader program.

~~This is a regular NOP.~~

Conditional_Execute						
47 … 44~~47~~	43~~46 … 43~~	42	41 … 34	33…16	15 …12	11 … 0
0011~~Addressing~~	Addressing~~0011~~	Condition	Boolean address	Instructions type + serialize (9 instructions)	Count	Exec Address

Conditional_Execute_End						
47 … 44	43	42	41 … 34	33…16	15 …12	11 … 0
0100	Addressing	Condition	Boolean address	Instructions type + serialize (9 instructions)	Count	Exec Address

If the specified Boolean (8 bits can address 256 Booleans) meets the specified condition then execute the specified instructions (up to 9 instructions). If the condition is not met, we go on to the next control flow instruction. If Conditional_Execute_End and the condition is met, this is the last execution block of the shader program.

Conditional_Execute_Predicates							
47 … 44~~47~~	43~~46 … 43~~	42	41 … 36	35 … 34	33…16	15…12	11 … 0
0101~~Addressing~~	Addressing~~0010~~	Condition	RESERVED	Predicate vector	Instructions type + serialize (9 instructions)	Count	Exec Address

Conditional_Execute_Predicates_End							
47 … 44	43	42	41 … 36	35 … 34	33…16	15…12	11 … 0
0110	Addressing	Condition	RESERVED	Predicate vector	Instructions type + serialize (9 instructions)	Count	Exec Address

Check the AND/OR of all current predicate bits. If AND/OR matches the condition execute the specified number of instructions. We need to AND/OR this with the kill mask in order not to consider the pixels that aren't valid. If the condition is not met, we go on to the next control flow instruction. If Conditional_Execute_Predicates_End and the condition is met, this is the last execution block of the shader program.

Loop_Start					
47 … 44~~47~~	43~~46 … 43~~	42 … 17	20 … 16	15…12	11 … 0
0111~~Addressing~~	Addressing~~0101~~	RESERVED	loop ID	RESERVED	Jump address

Loop Start. Compares the loop iterator with the end value. If loop condition not met jump to the address. Forward jump only. Also computes the index value. The loop id must match between the start to end, and also indicates which control flow constants should be used with the loop.

Loop_End						
47 … 44~~47~~	43~~46 … 43~~	42 … 24	23… 21	20 … 16	15…12	11 … 0
1000~~Addressing~~	Addressing~~0011~~	RESERVED	Predicate break	loop ID	RESERVED	start address

Loop end. Increments the counter by one, compares the loop count with the end value. If loop condition met, continue, else, jump BACK to the start of the loop. If predicate break != 0, then compares predicate vector n (specified by predicate break number). If all bits cleared then break the loop.

The way this is described does not prevent nested loops, and the inclusion of the loop id make this easy to do.

Conditionnal_Call						
47 … 44~~47~~	43~~46 … 43~~	42	41 … 34	33 … 13	12	11 … 0
1001~~Addressing~~	Addressing~~0111~~	Condition	Boolean address	RESERVED	Force Call	Jump address

If the condition is met, jumps to the specified address and pushes the control flow program counter on the stack. If force call is set the condition is ignored and the call is made always.

Return		
47 … 44~~47~~	43~~46 … 43~~	42 … 0
1010~~Addressing~~	Addressing~~1000~~	RESERVED

Pops the topmost address from the stack and jumps to that address. If nothing is on the stack, the program will just continue to the next instruction.

Conditionnal_Jump							
47 … 44~~47~~	43~~46 … 43~~	42	41… 34	33	32 … 13	12	11 … 0
1011~~Addressing~~	Addressing~~1001~~	Condition	Boolean address	FW only	RESERVED	Force Jump	Jump address

If force jump is set the condition is ignored and the jump is made always. If FW only is set then only forward jumps are allowed.

Allocate				
47 … 44~~47~~	43~~46 … 43~~	42…41	40 … 4	3 …0
1100~~Debug~~	Debug~~10 10~~	Buffer Select	RESERVED	Allocation size

Buffer Select takes a value of the following:
01 – position export (ordered export)
10 – parameter cache or pixel export (ordered export)
11 – pass thru (out of order exports).

If debug is set this is a debug alloc (ignore if debug DB_ON register is set to off).

~~Marks the end of the program.~~

6.3 Implementation

The envisioned implementation has a buffer that maintains the state of each thread. A thread lives in a given location in the buffer during its entire life, but the buffer has FIFO qualities in that threads leave in the order that they enter. Actually two buffers are maintained -- one for Vertices and one for Pixels. The intended implementation would allow for:

16 entries for vertices
48 entries for pixels.

From each buffer, arbitration logic attempts to select 1 thread for the texture unit and 1 (interleaved) thread for the ALU unit. Once a thread is selected it is read out of the buffer, marked as invalid, and submitted to appropriate execution unit. It is returned to the buffer (at the same place) with its status updated once all possible sequential instructions have been executed. A switch from ALU to TEX or visa-versa or a Serialize_Execution modifier forces the thread to be returned to the buffer.

Each entry in the buffer will be stored across two physical pieces of memory - most bits will be stored in a 1 read port device. Only bits needed for thread arbitration will be stored in a highly multi-ported structure. The bits kept in the 1 read port device will be termed 'state'. The bits kept in the multi-read ported device will be termed 'status'.

'State Bits' needed include:

1. Control Flow Instruction Pointer (13 bits),
2. Execution Count Marker 4 bits),
3. Loop Iterators (4x9 bits),
4. Call return pointers (4x12 bits),
5. Predicate Bits (64 bits),
6. Export ID (1 bit),
7. Parameter Cache base Ptr (7 bits),
8. GPR Base Ptr (8 bits),
9. Context Ptr (3 bits).
10. LOD corrections (6x16 bits)
11. Valid bits (64 bits)

Absent from this list are 'Index' pointers. These are costly enough that I'm presuming that they are instead stored in the GPRs. The first seven fields above (Control Flow Ptr, Execution Count, Loop Counts, call return ptrs, Predicate bits, PC base ptr and export ID) are updated every time the thread is returned to the buffer based on how much progress has been mode on thread execution. GPR Base Ptr, Context Ptr and LOD corrections are unchanged throughout execution of the thread.

'Status Bits' needed include:

- Valid Thread
- Texture/ALU engine needed
- Texture Reads are outstanding
- Waiting on Texture Read to Complete
- Allocation Wait (2 bits)
- 00 – No allocation needed
- 01 – Position export allocation needed (ordered export)
- 10 – Parameter or pixel export needed (ordered export)
- 11 – pass thru (out of order export)
- Allocation Size (4 bits)
- Position Allocated
- First thread of a new context
- Event thread (NULL thread that needs to trickle down the pipe)
- Last (1 bit)
- Pulse SX (1 bit)

All of the above fields from all of the entries go into the arbitration circuitry. The arbitration circuitry will select a winner for both the Texture Engine and for the ALU engine. There are actually two sets of arbitration -- one for pixels and one for vertices. A final selection is then done between the two. But the rest of this implementation summary only considers the 'first' level selection which is similar for both pixels and vertices.

Texture arbitration requires no allocation or ordering so it is purely based on selecting the 'oldest' thread that requires the Texture Engine.

ALU arbitration is a little more complicated. First, only threads where either of Texture_Reads_outstanding or Waiting_on_Texture_Read_to_Complete are '0' are considered. Then if Allocation_Wait is active, these threads are further filtered based on whether space is available. If the allocation is position allocation, then the thread is only considered if all 'older' threads have already done their position allocation (position allocated bits set). If the allocation is parameter or pixel allocation, then the thread is only considered if it is the oldest thread. Also a thread is not considered if it is a parameter or pixel or position allocation, has its First_thread_of_a_new_context bit set and would cause ALU interleaving with another thread performing the same parameter or pixel or position allocation. Finally the 'oldest' of the threads that pass through the above filters is selected. If the thread needed to allocate, then at this time the allocation is done, based on Allocation_Size. If a thread has its “last” bit set, then it is also removed from the buffer, never to return.

If I now redefine 'clauses' to mean 'how many times the thread is removed from the thread buffer for the purpose of exection by either the ALU or Texture engine', then the minimum number of clauses needed is 2 -- one to perform the allocation for exports (execution automatically halts after an 'Alloc' instruction) (but doesn't performs the actual allocation) and one for the actual ALU/export instructions. As the 'Alloc' instruction could be part of a texture clause (presumably the final instruction in such a clause), a thread could still execute in this minimal number of 2 clauses, even if it involved texture fetching.

The Texture_Reads_Outstanding bit must be updated by the sequencer, based on keeping track of how many Texture Clauses have been executed by a given thread that have not yet had there data returned. Any number above 0 results in this bit being set. We could consider forcing synchronization such that two texture clauses for a given thread may not be outstanding at any time (that would be my preference for simplicity reasons and because it would require only very little change in the texture pipe interface). This would allow the sequencer to set the bit on execution of the texture clause, and allow the texture unit to return a pointer to the thread buffer on completion that clears the bit.

6.4 Data dependant predicate instructions

Data dependant conditionals will be supported in the R400. The only way we plan to support those is by supporting three vector/scalar predicate operations of the form:

PRED_SETE_# - similar to SETE except that the result is 'exported' to the sequencer.
PRED_SETNE_# - similar to SETNE except that the result is 'exported' to the sequencer.
PRED_SETGT_# - similar to SETGT except that the result is 'exported' to the sequencer
PRED_SETGTE_# - similar to SETGTE except that the result is 'exported' to the sequencer

For the scalar operations only we will also support the two following instructions:
PRED_SETE0_# – SETE0
PRED_SETE1_# – SETE1

The export is a single bit - 1 or 0 that is sent using the same data path as the MOVA instruction. The sequencer will maintain 4 sets of 64 bit predicate vectors (in fact 8 sets because we interleave two programs but only 4 will be exposed) and use it to control the write masking. This predicate is not maintained across clause boundaries. The # sign is used to specify which predicate set you want to use 0 thru 3.

Then we have two conditional execute bits. The first bit is a conditional execute “on” bit and the second bit tells us if we execute on 1 or 0. For example, the instruction:

P0_ADD_# R0,R1,R2

Is only going to write the result of the ADD into those GPRs whose predicate bit is 0. Alternatively, P1_ADD_# would only write the results to the GPRs whose predicate bit is set. The use of the P0 or P1 without precharging the sequencer with a PRED instruction is undefined.

{Issue: do we have to have a NOP between PRED and the first instruction that uses a predicate?}

6.5 HW Detection of PV,PS

Because of the control program, the compiler cannot detect statically dependant instructions. In the case of non-masked writes and subsequent reads the sequencer will insert uses of PV,PS as needed. This will be done by comparing the read address and the write address of consecutive instructions. For masked writes, the sequencer will insert NOPs wherever there is a dependant read/write.

The sequencer will also have to insert NOPs between PRED_SET and MOVA instructions and their uses.

6.6 Register file indexing

Because we can have loops in fetch clause, we need to be able to index into the register file in order to retrieve the data created in a fetch clause loop and use it into an ALU clause. The instruction will include the base address for register indexing and the instruction will contain these controls:

Bit7	Bit 6	
0	0	'absolute register'
0	1	'relative register'
1	0	'previous vector'
1	1	'previous scalar'

In the case of an absolute register we just take the address as is. In the case of a relative register read we take the base address and we add to it the loop_index and this becomes our new address that we give to the shader pipe.

The sequencer is going to keep a loop index computed as such:

Index = Loop_iterator*Loop_step + Loop_start.

We loop until loop_iterator = loop_count. Loop_step is a signed value [-128…127]. The computed index value is a 10 bit counter that is also signed. Its real range is [-256,256]. The tenth bit is only there so that we can provide an out of range value to the “indexing logic” so that it knows when the provided index is out of range and thus can make the necessary arrangements.

6.7 Debugging the Shaders

In order to be able to debug the pixel/vertex shaders efficiently, we provide 2 methods.

6.7.1 *Method 1: Debugging registers*

Current plans are to expose 2 debugging, or error notification, registers:
1. address register where the first error occurred
2. count of the number of errors

The sequencer will detect the following groups of errors:
- count overflow
- constant indexing overflow
- register indexing overflow

Compiler recognizable errors:
  - jump errors
    relative jump address > size of the control flow program
  - call stack
    call with stack full
    return with stack empty

A jump error will always cause the program to break. In this case, a break means that a clause will halt execution, but allowing further clauses to be executed.

With all the other errors, program can continue to run, potentially to worst-case limits. The program will only break if the DB_PROB_BREAK register is set.

If indexing outside of the constant or the register range, causing an overflow error, the hardware is specified to return the value with an index of 0. This could be exploited to generate error tokens, by reserving and initializing the 0th register (or constant) for errors.

{ISSUE : Interrupt to the driver or not?}

6.7.2 *Method 2: Exporting the values in the GPRs*

1) The sequencer will have a debug active, count register and an address register for this mode.

Under the normal mode execution follows the normal course.

Under the debug mode it is assumed that the program is always exporting n debug vectors and that all other exports to the SX block (position, color, z, ect) will been turned off (changed into NOPs) by the sequencer (even if they occur before the address stated by the ADDR debug register).

7. Pixel Kill Mask

A vector of 64 bits is kept by the sequencer per group of pixels/vertices. Its purpose is to optimize the texture fetch requests and allow the shader pipe to kill pixels using the following instructions:

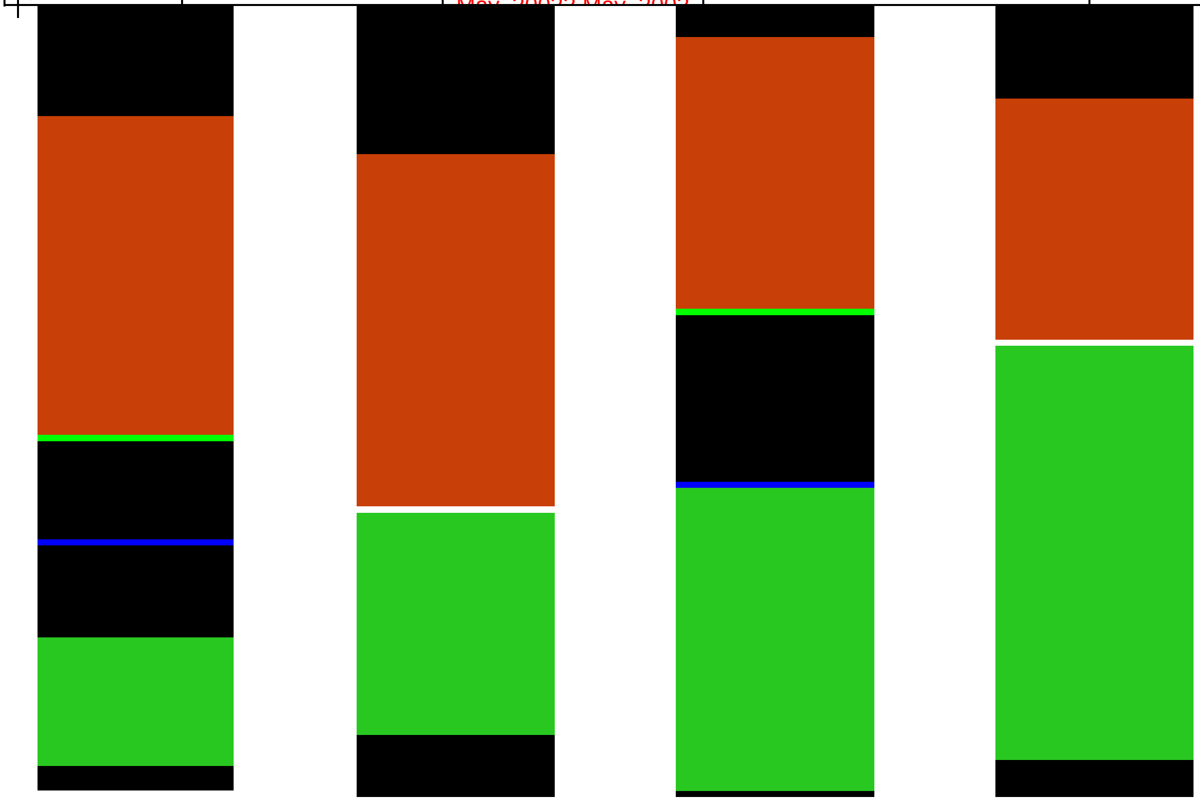
MASK_SETE
MASK_SETNE
MASK_SETGT
MASK_SETGTE

8. Multipass vertex shaders (HOS)

Multipass vertex shaders are able to export from the 6 last clauses but to memory ONLY.

9. Register file allocation

The register file allocation for vertices and pixels can either be static or dynamic. In both cases, the register file in managed using two round robins (one for pixels and one for vertices). In the dynamic case the boundary between pixels and vertices is allowed to move, in the static case it is fixed to 128-VERTEX_REG_SIZE for vertices and PIXEL_REG_SIZE for pixels.



Above is an example of how the algorithm works. Vertices come in from top to bottom; pixels come in from bottom to top. Vertices are in orange and pixels in green. The blue line is the tail of the vertices and the green line is the tail of the pixels. Thus anything between the two lines is shared. When pixels meets vertices the line turns white and the boundary is static until both vertices and pixels share the same “unallocated bubble”. Then the boundary is allowed to move again. The numbering of the GPRs starts from the bottom of the picture at index 0 and goes up to the top at index 127.

10. Fetch Arbitration

The fetch arbitration logic chooses one of the 8 potentially pending fetch clauses to be executed. The choice is made by looking at the fifos from 7 to 0 and picking the first one ready to execute. Once chosen, the clause state machine will send one 2x2 fetch per clock (or 4 fetches in one clock every 4 clocks) until all the fetch instructions of the clause are sent. This means that there cannot be any dependencies between two fetches of the same clause.

The arbitrator will not wait for the fetches to return prior to selecting another clause for execution. The fetch pipe will be able to handle up to X(?) in flight fetches and thus there can be a fair number of active clauses waiting for their fetch return data.

11. ALU Arbitration

ALU arbitration proceeds in almost the same way than fetch arbitration. The ALU arbitration logic chooses one of the 8 potentially pending ALU clauses to be executed. The choice is made by looking at the fifos from 7 to 0 and picking the first one ready to execute. There are two ALU arbiters, one for the even clocks and one for the odd clocks. For example, here is the sequencing of two interleaved ALU clauses (E and O stands for Even and Odd sets of 4 clocks):

Einst0 Oinst0 Einst1 Oinst1 Einst2 Oinst2 Einst0 Oinst3 Einst1 Oinst4 Einst2 Oinst0…
Proceeding this way hides the latency of 8 clocks of the ALUs. Also note that the interleaving also occurs across clause boundaries.

12. Handling Stalls

When the output file is full, the sequencer prevents the ALU arbitration logic from selecting the last clause (this way nothing can exit the shader pipe until there is place in the output file. If the packet is a vertex packet and the position buffer is full (POS_FULL) then the sequencer also prevents a thread from entering the exporting clause (3?). The sequencer will set the OUT_FILE_FULL signal n clocks before the output file is actually full and thus the ALU arbiter will be able read this signal and act accordingly by not preventing exporting clauses to proceed.

13. Content of the reservation station FIFOs

The reservation FIFOs contain the state of the vector of pixels and vertices. We have two sets of those: one for pixels, and one for vertices. They contain 3 bits of Render State 7 bits for the base address of the GPRs, some bits for LOD correction and coverage mask information in order to fetch fetch for only valid pixels, the quad address.

14. The Output File

The output file is where pixels are put before they go to the RBs. The write BW to this store is 256 bits/clock. Just before this output file are staging registers with write BW 512 bits/clock and read BW 256 bits/clock. The staging registers are 4x128 (and there are 16 of those on the whole chip).

15. IJ Format

The IJ information sent by the PA is of this format on a per quad basis:

We have a vector of IJ's (one IJ per pixel at the centroid of the fragment or at the center of the pixel depending on the mode bit). The interpolation is done at a different precision across the 2x2. The upper left pixel's parameters are always interpolated at full 20x24 mantissa precision. Then the result of the interpolation along with the difference in IJ in reduced precision is used to interpolate the parameter for the other three pixels of the 2x2. Here is how we do it:

Assuming P0 is the interpolated parameter at Pixel 0 having the barycentric coordinates I(0), J(0) and so on for P1,P2 and P3. Also assuming that A is the parameter value at V0 (interpolated with I), B is the parameter value at V1 (interpolated with J) and C is the parameter value at V2 (interpolated with (1-I-J).

$$\Delta 01I = I(1) - I(0)$$
$$\Delta 01J = J(1) - J(0)$$
$$\Delta 02I = I(2) - I(0)$$
$$\Delta 02J = J(2) - J(0)$$
$$\Delta 03I = I(3) - I(0)$$
$$\Delta 03J = J(3) - J(0)$$

P0	P1
P2	P3

$$P0 = C + I(0) * (A - C) + J(0) * (B - C)$$
$$P1 = P0 + \Delta 01I * (A - C) + \Delta 01J * (B - C)$$
$$P2 = P0 + \Delta 02I * (A - C) + \Delta 02J * (B - C)$$
$$P3 = P0 + \Delta 03I * (A - C) + \Delta 03J * (B - C)$$

P0 is computed at 20x24 mantissa precision and P1 to P3 are computed at 8X24 mantissa precision. So far no visual degradation of the image was seen using this scheme.

Multiplies (Full Precision): 2
Multiplies (Reduced precision): 6
Subtracts 19x24 (Parameters): 2

Adds: 8

FORMAT OF P0's IJ : Mantissa 20 Exp 4 for I + Sign
Mantissa 20 Exp 4 for J + Sign

FORMAT of Deltas (x3):Mantissa 8 Exp 4 for I + Sign
Mantissa 8 Exp 4 for J + Sign

Total number of bits : 20*2 + 8*6 + 4*8 + 4*2 = 128

All numbers are kept using the un-normalized floating point convention: if exponent is different than 0 the number is normalized if not, then the number is un-normalized. The maximum range for the IJs (Full precision) is +/- 63 and the range for the Deltas is +/- 127.

15.1 Interpolation of constant attributes

Because of the floating point imprecision, we need to take special provisions if all the interpolated terms are the same or if two of the barycentric coordinates are the same.

We start with the premise that if A = B and B = C and C = A, then P0,1,2,3 = A. Since one or more of the IJ terms may be zero, so we extend this to:

```
if (A=B and B=C and C=A)
   P0,1,2,3 = A;
else if ((I = 0) or (J = 0)) and
          ((J = 0) or (1-I-J = 0)) and
          ((1-J-I = 0) or (I = 0))) {
                if(I != 0) {
                    P0 = A;
               } else if(J != 0) {
                    P0 = B;
               } else {
                    P0 = C;
              }
             //rest of the quad interpolated normally
}
else
{
             normal interpolation
}
```

16. Staging Registers

In order for the reuse of the vertices to be 14, the sequencer will have to re-order the data sent IN ORDER by the VGT for it to be aligned with the parameter cache memory arrangement. Given the following group of vertices sent by the VGT:

0 1 2 3 4 5 6 7 8 9 10 11 12 13 14 15 || 16 17 18 19 20 21 22 23 24 25 26 27 28 29 30 31 || 32 33 34 35 36 37 38 39 40 41 42 43 44 45 46 47 || 48 49 50 51 52 53 54 55 56 57 58 59 60 61 62 63

The sequencer will re-arrange them in this fashion:

0 1 2 3 16 17 18 19 32 33 34 35 48 49 50 51 || 4 5 6 7 20 21 22 23 36 37 38 39 52 53 54 55 || 8 9 10 11 24 25 26 27 40 41 42 43 56 57 58 59 || 12 13 14 15 28 29 30 31 44 45 46 47 60 61 62 63

The || markers show the SP divisions. In the event a shader pipe is broken, the VGT will send padding to account for the missing pipe. For example, if SP1 is broken, vertices 4 5 6 7 20 21 22 23 36 37 38 39 52 53 54 55 will still be sent by the VGT to the SQ **BUT** will not be processed by the SP and thus should be considered invalid (by the SU and VGT).

The most straightforward, *non-compressed* interface method would be to convert, in the VGT, the data to 32-bit floating point prior to transmission to the VSISRs. In this scenario, the data would be transmitted to (and stored in) the VSISRs in full 32-bit floating point. This method requires three 24-bit fixed-to-float converters in the VGT. Unfortunately, it also requires and additional 3,072 bits of storage across the VSISRs. This interface is illustrated in Figure 11~~Figure 11Figure 11~~. The area of the fixed-to-float converters and the VSISRs for this method is roughly estimated as 0.759sqmm using the R300 process. The gate count estimate is shown in Figure 10~~Figure 10Figure 10~~.

Basis for 8-deep Latch Memory (from R300)			
8x24-bit	11631 μ^2		60.57813 μ^2 per bit
Area of 96x8-deep Latch Memory	46524 μ^2		
Area of 24-bit Fix-to-float Converter	4712 μ^2 per converter		
Method 1	Block	Quantity	Area
	F2F	3	14136
	8x96 Latch	16	744384
			758520 μ^2

Figure 10:Area Estimate for VGT to Shader Interface

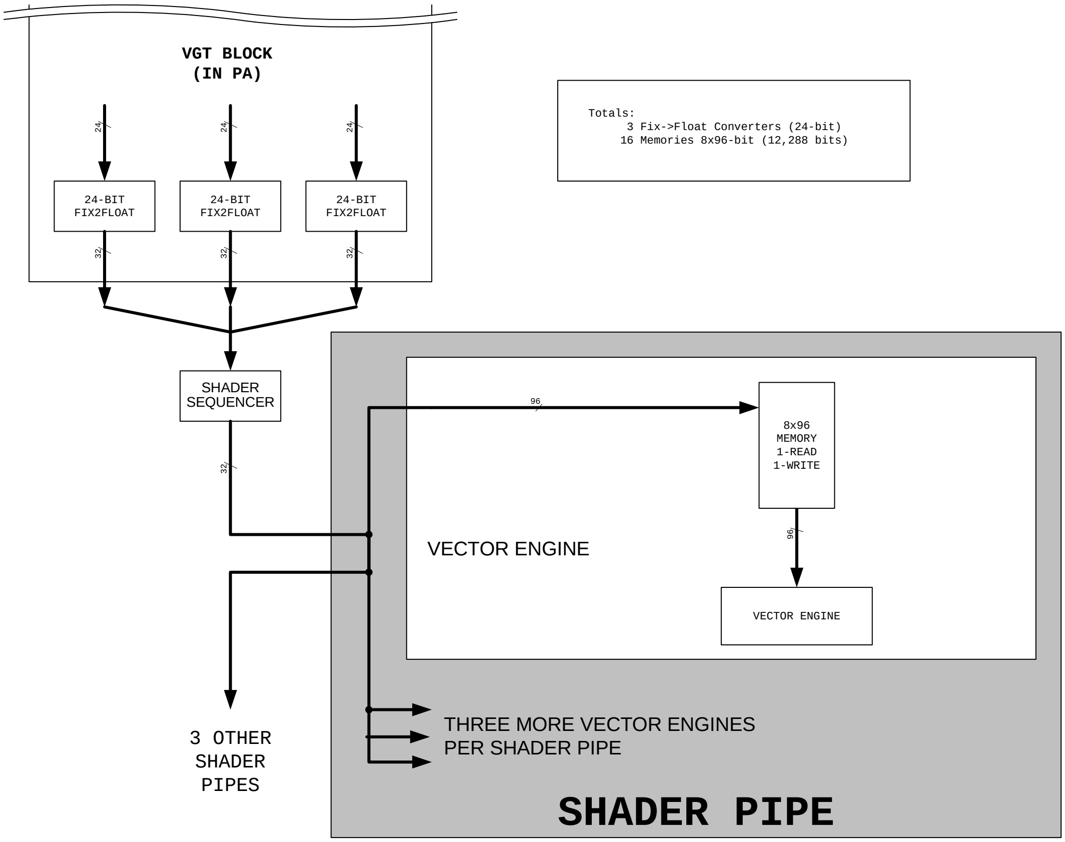


Figure 11:VGT to Shader Interface

17. The parameter cache

The parameter cache is where the vertex shaders export their data. It consists of 16 128x128 memories (1R/1W). The reuse engine will make it so that all vertexes of a given primitive will hit different memories. The allocation method for these memories is a simple round robin. The parameter cache pointers are mapped in the following way: 4MSBs are the memory number and the 7 LSBs are the address within this memory.

MEMORY NUMBER 4 bits	ADDRESS 7 bits

The PA generates the parameter cache addresses as the positions come from the SQ. All it needs to do is keep a Current_Location pointer (7 bits only) and as the positions comes increment the memory number. When the memory number field wraps around, the PA increments the Current_Location by VS_EXPORT_COUNT (a snooped register from the SQ). As an example, say the memories are all empty to begin with and the vertex shader is exporting 8 parameters per vertex (VS_EXPORT_COUNT = 8). The first position received is going to have the PC address 00000000000 the second one 00010000000, third one 00100000000 and so on up to 11110000000. Then the next position received (the 17th) is going to have the address 00000001000, the 18th 00010001000, the 19th 00100001000 and so on. The Current_location is NEVER reset BUT on chip resets. The only thing to be careful about is that if the SX doesn't send you a full group of positions (<64) then you need to fill the address space so that the next group starts correctly aligned (for example if you receive only 33 positions then you need to add 2*VS_EXPORT_COUNT to Current_Location and reset the memory count to 0 before the next vector begins).

17.1 Export restrictions

17.1.1 *Pixel exports:*

Pixels can export 1,2,3 or 4 color buffers to the SX(+z). The exports will be done in order. The PRED_OPTIMIZE function has to be turned of if the exports are done using interleaved predicated instructions. The exports will always be ordered to the SX.

17.1.2 *Vertex exports:*

Position or parameter caches can be exported in any order in the shader program. It is always better to export posistion as soon as possible. Position has to be exported in a single export block (no texture instructions can be placed between the exports). Parameter cache exports can be done in any order with texture instructions interleaved. The PRED_OPTIMIZE function has to be turned of if the exports are done using interleaved predicated instructions to the Parameter cache (see Arbitration restrictions for details). The exports will always be allocated in order to the SX.

17.1.3 *Pass thru exports:*

Pass thru exports have to be done in groups of the form:

```
Alloc 4 (8 or 12)
Execute ALU(ADDR) ALU(DATA) ALU(DATA) ALU(DATA)…
```

They cannot have texture instructions interleaved in the export block. These exports **are not guaranteed to be ordered**.

Also, when doing a pass thru export, Position MUST be exported AFTER all pass thru exports. This position export is used to synchronize the chip when doing a transition from pass thru shader to regular shader and vice versa.

17.2 Arbitration restrictions

Here are the Sequencer arbitration restrictions:

1) Cannot execute a serialized thread if the corresponding texture pending bit is set
2) Cannot allocate position if any older thread has not allocated position
3) If last thread is marked as not valid AND marked as last and we are about to execute the second to oldest thread also marked last then:
    a. Both threads must be from the same context (cannot allow a first thread)
    b. Must turn off the predicate optimization for the second thread
4) Cannot execute a texture clause if texture reads are pending
5) Cannot execute last if texture pending (even if not serial)

18. Export Types

The export type (or the location where the data should be put) is specified using the destination address field in the ALU instruction. Here is a list of all possible export modes:

18.1 Vertex Shading

0:15	- 16 parameter cache
16:31	- Empty (Reserved?)
32	- Export Address
33:40	- 8 vertex exports to the frame buffer and index
41:47	- Empty
48:55	- 8 debug export (interpret as normal vertex export)
60	- export addressing mode
61	- Empty
62	- position

63	- sprite size export that goes with position export (point_h,point_w,edgeflag,misc)

18.2 Pixel Shading

0	- Color for buffer 0 (primary)
1	- Color for buffer 1
2	- Color for buffer 2
3	- Color for buffer 3
4:7	- Empty
8	- Buffer 0 Color/Fog (primary)
9	- Buffer 1 Color/Fog
10	- Buffer 2 Color/Fog
11	- Buffer 3 Color/Fog
12:15	- Empty
16:31	- Empty (Reserved?)
32	- Export Address
33:40	- 8 exports for multipass pixel shaders.
41:47	- Empty
48:55	- 8 debug exports (interpret as normal pixel export)
60	- export addressing mode
61:62	- Empty
63	- Z for primary buffer (Z exported to 'alpha' component)

19. Special Interpolation modes

19.1 Real time commands

We are unable to use the parameter memory since there is no way for a command stream to write into it. Instead we need to add three 16x128 memories (one for each of three vertices x 16 interpolants). These will be mapped onto the register bus and written by type 0 packets, and output to the the parameter busses (the sequencer and/or PA need to be able to address the realtime parameter memory as well as the regular parameter store. For higher performance we should be able able to view them as two banks of 16 and do double buffering allowing one to be loaded, while the other is rasterized with. Most overlay shaders will need 2 or 4 scalar coordinates, one option might be to restrict the memory to 16x64 or 32x64 allowing only two interpolated scalars per cycle, the only problem I see with this is, if we view support for 16 vector-4 interpolants important (true only if we map Microsoft's high priority stream to the realtime stream), then the PA/sequencer need to support a realtime-specific mode where we need to address 32 vectors of parameters instead of 16. This mode is triggered by the primitive type: REAL TIME. The actual memories are in the in the SX blocks. The parameter data memories are hooked on the RBBM bus and are loaded by the CP using register mapped memory.

19.2 Sprites/ XY screen coordinates/ FB information

When working with sprites, one may want to overwrite the parameter 0 with SC generated data. Also, XY screen coordinates may be needed in the shader program. This functionality is controlled by the gen_I0 register (in SQ) in conjunction with the SND_XY register (in SC). Also it is possible to send the faceness information (for OGL front/back special operations) to the shader using the same control register. Here is a list of all the modes and how they interact together:

Gen_st is a bit taken from the interface between the SC and the SQ. This is the MSB of the primitive type. If the bit is set, it means we are dealing with Point AA, Line AA or sprite and in this case the vertex values are going to generated between 0 and 1.

Param_Gen_I0 disable, snd_xy disable, no gen_st – I0 = No modification
Param_Gen_I0 disable, snd_xy disable, gen_st – I0 = No modification
Param_Gen_I0 disable, snd_xy enable, no gen_st – I0 = No modification
Param_Gen_I0 disable, snd_xy enable, gen_st – I0 = No modification
Param_Gen_I0 enable, snd_xy disable, no gen_st – I0 = garbage, garbage, garbage, faceness

Param_Gen_I0 enable, snd_xy disable, gen_st – I0 = garbage, garbage, s, t
Param_Gen_I0 enable, snd_xy enable, no gen_st – I0 = screen x, screen y, garbage, faceness
Param_Gen_I0 enable, snd_xy enable, gen_st – I0 = screen x, screen y, s, t

19.3 Auto generated counters

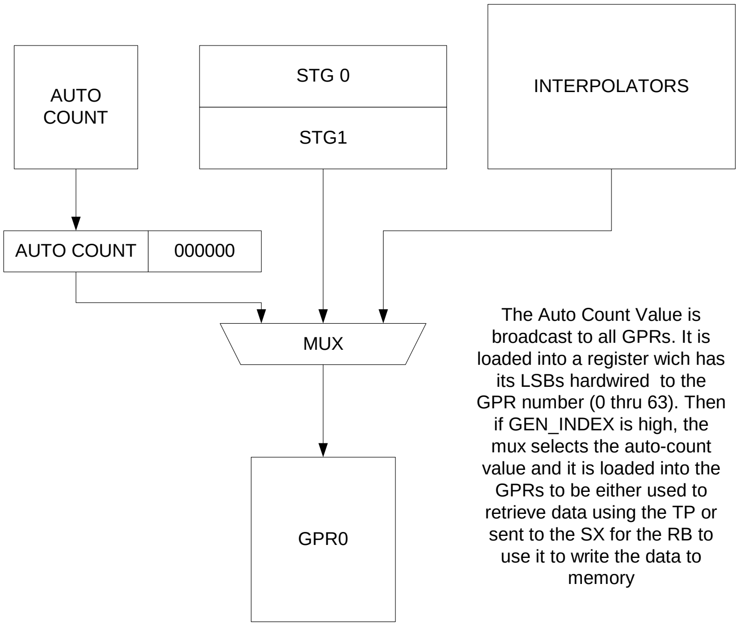
In the cases we are dealing with multipass shaders, the sequencer is going to generate a vector count to be able to both use this count to write the 1st pass data to memory and then use the count to retrieve the data on the 2nd pass. The count is always generated in the same way but it is passed to the shader in a slightly different way depending on the shader type (pixel or vertex). This is toggled on and off using the GEN_INDEX register. The sequencer is going to keep two counters, one for pixels and one for vertices. Every time a full vector of vertices or pixels is written to the GPRs the counter is incremented. Every time a state change is detected, the corresponding counter is reset. While there is only one count broadcast to the GPRs, the LSB are hardwired to specific values making the index different for all elements in the vector.

19.3.1 *Vertex shaders*

In the case of vertex shaders, if GEN_INDEX is set, the data will be put into the x field of the third register (it means that the compiler must allocate 3 GPRs in all multipass vertex shader modes).

19.3.2 *Pixel shaders*

In the case of pixel shaders, if GEN_INDEX is set and Param_Gen_I0 is enabled, the data will be put in the x field of the 2nd register (R1.x), else if GEN_INDEX is set the data will be put into the x field of the 1st register (R0.x).



The Auto Count Value is broadcast to all GPRs. It is loaded into a register wich has its LSBs hardwired to the GPR number (0 thru 63). Then if GEN_INDEX is high, the mux selects the auto-count value and it is loaded into the GPRs to be either used to retrieve data using the TP or sent to the SX for the RB to use it to write the data to memory

Figure 12: GPR input mux Control

20. State management

Every clock, the sequencer will report to the CP the oldest states still in the pipe. These are the states of the programs as they enter the last ALU clause.

20.1 Parameter cache synchronization

In order for the sequencer not to begin a group of pixels before the associated group of vertices has finished, the sequencer will keep a 6 bit count per state (for a total of 8 counters). These counters are initialized to 0 and every time a vertex shader exports its data TO THE PARAMETER CACHE, the corresponding pointer is incremented. When the SC sends a new vector of pixels with the SC_SQ_new_vector bit asserted, the sequencer will first check if the count is greater than 0 before accepting the transmission (it will in fact accept the transmission but then lower its ready to receive). Then the sequencer waits for the count to go to one and decrements it. The sequencer can then issue the group of pixels to the interpolators. Every time the state changes, the new state counter is initialized to 0.

21. XY Address imports

The SC will be able to send the XY addresses to the GPRs. It does so by interleaving the writes of the IJs (to the IJ buffer) with XY writes (to the XY buffer). Then when writing the data to the GPRs, the sequencer is going to interpolate the IJ data or pass the XY data thru a Fix→float converter and expander and write the converted values to the GPRs. The Xys are currently SCREEN SPACE COORDINATES. The values in the XY buffers will wrap. See section 19.2 for details on how to control the interpolation in this mode.

21.1 Vertex indexes imports

In order to import vertex indexes, we have 16 8x96 staging registers. These are loaded one line at a time by the VGT block (96 bits). They are loaded in floating point format and can be transferred in 4 or 8 clocks to the GPRs.

22. Registers

22.1 Control

REG_DYNAMIC	Dynamic allocation (pixel/vertex) of the register file on or off.
REG_SIZE_PIX	Size of the register file's pixel portion (minimal size when dynamic allocation turned on)
REG_SIZE_VTX	Size of the register file's vertex portion (minimal size when dynamic allocation turned on)
ARBITRATION_POLICY	policy of the arbitration between vertexes and pixels
INST_BASE_VTX	start point for the vertex instruction store (RT always ends at vertex_base and Begins at 0)
INST_BASE_PIX	start point for the pixel shader instruction store
ONE_THREAD	debug state register. Only allows one program at a time into the GPRs
ONE_ALU	debug state register. Only allows one ALU program at a time to be executed (instead of 2)
INSTRUCTION	This is where the CP puts the base address of the instruction writes and type (auto-incremented on reads/writes) Register mapped
CONSTANTS	512*4 ALU constants + 32*6 Texture state 32 bits registers (logically mapped)
CONSTANTS_RT	256*4 ALU constants + 32*6 texture states? (physically mapped)
CONSTANT_EO_RT	This is the size of the space reserved for real time in the constant store (from 0 to CONSTANT_EO_RT). The re-mapping table operates on the rest of the memory

TSTATE_EO_RT This is the size of the space reserved for real time in the fetch state store (from 0 to TSTATE_EO_RT). The re-mapping table operates on the rest of the memory

22.2 Context

PS_BASE	base pointer for the pixel shader in the instruction store
VS_BASE	base pointer for the vertex shader in the instruction store
VS_CF_SIZE	size of the vertex shader (# of instructions in control program/2)
PS_CF_SIZE	size of the pixel shader (# of instructions in control program/2)
PS_SIZE	size of the pixel shader (cntl+instructions)
VS_SIZE	size of the vertex shader (cntl+instructions)
PS_NUM_REG	number of GPRs to allocate for pixel shader programs
VS_NUM_REG	number of GPRs to allocate for vertex shader programs
PARAM_SHADE	One 16 bit register specifying which parameters are to be gouraud shaded (0 = flat, 1 = gouraud)
PARAM_WRAP	64 bits: for which parameters (and channels (xyzw)) do we do the cyl wrapping (0=linear, 1=cylindrical).
PS_EXPORT_MODE	0xxxx : Normal mode

	1xxxx : Multipass mode If normal, bbbz where bbb is how many colors (0-4) and z is export z or not If multipass 1-12 exports for color.
VS_EXPORT_MODE	0: position (1 vector), 1: position (2 vectors), 3:multipass
VS_EXPORT_COUNT	Number of locations exported by the VS (and thus number of interpolated parameters)
PARAM_GEN_I0	Do we overwrite or not the parameter 0 with XY data and generated T and S values
GEN_INDEX	Auto generates an address from 0 to XX. Puts the results into R0-1 for pixel shaders and R2 for vertex shaders
CONST_BASE_VTX (9 bits)	Logical Base address for the constants of the Vertex shader
CONST_BASE_PIX (9 bits)	Logical Base address for the constants of the Pixel shader
CONST_SIZE_PIX (8 bits)	Size of the logical constant store for pixel shaders
CONST_SIZE_VTX (8 bits)	Size of the logical constant store for vertex shaders
INST_PRED_OPTIMIZE	Turns on the predicate bit optimization (if of, conditional_execute_predicates is always executed).
CF_BOOLEANS	256 boolean bits
CF_LOOP_COUNT	32x8 bit counters (number of times we traverse the loop)
CF_LOOP_START	32x8 bit counters (init value used in index computation)
CF_LOOP_STEP	32x8 bit counters (step value used in index computation)

23. DEBUG Registers

23.1 Context

DB_PROB_ADDR	instruction address where the first problem occurred
DB_PROB_COUNT	number of problems encountered during the execution of the program
DB_PROB_BREAK	break the clause if an error is found.
DB_ON	turns on an off debug method 2
DB_INST_COUNT	instruction counter for debug method 2
DB_BREAK_ADDR	break address for method number 2

23.2 Control

DB_ALUCST_MEMSIZE	Size of the physical ALU constant memory
DB_TSTATE_MEMSIZE	Size of the physical texture state memory

24. Interfaces

24.1 External Interfaces

Whenever an x is used, it means that the bus is broadcast to all units of the same name. For example, if a bus is named SQ→SPx it means that SQ is going to broadcast the same information to all SP instances.

24.2 SC to SP Interfaces

24.2.1 *SC_SP#*

There is one of these interfaces at front of each of the SP (buffer to stage pixel interpolators). This interface transmits the I,J data for pixel interpolation. For the entire system, two quads per clock are transferred to the 4 SPs, so each of these 4 interfaces transmits one half of a quad per clock. The interface below describes a half of a quad worth of data.
The actual data which is transferred per quad is
Ref Pix I => S4.20 Floating Point I value
Ref Pix J => S4.20 Floating Point J value

Delta Pix I (x3) => S4.8 Floating Point Delta I value
Delta Pix J (x3) => S4.8 Floating Point Delta J value
This equates to a total of 128 bits which transferred over 2 clocks
and therefor needs an interface 64 bits wide

Additionally, X,Y data (12-bit unsigned fixed) is conditionally sent across this data bus over the same wires in an additional clock. The X,Y data is sent on the lower 24 bits of the data bus with faceness in the msb.
Transfers across these interfaces are synchronized with the SC_SQ IJ Control Bus transfers.

The data transfer across each of these busses is controlled by a IJ_BUF_INUSE_COUNT in the SC. Each time the SC has sent a pixel vector's worth of data to the SPs, he will increment the IJ_BUF_INUSE_COUNT count. Prior to sending the next pixel vectors data, he will check to make sure the count is less than MAX_BUFER_MINUS_2, if not the SC will stall until the SQ returns a pipelined pulse to decrement the count when he has scheduled a buffer free. Note: We could/may optimize for the case of only sending only IJ to use all the buffers to pre-load more. Currently it is planned for the SP to hold 2 double buffers of I,J data and two buffers of X,Y data, so if either X,Y or Centers and Centroids are on, then the SC can send two Buffers.

In at least the initial version, the SC shall send 16 quads per pixel vector even if the vector is not full. This will increment buffer write address pointers correctly all the time. (We may revisit this for both the SX,SP,SQ and add a EndOfVector signal on all interfaces to quit early. We opted for the simple mode first with a belief that only the end of packet and multiple new vector signals should cause a partial vector and that this would not really be significant performance hit.)

Name	**Bits**	**Description**
SC_SP#_data	64	IJ information sent over 2 clocks (or X,Y in 24 LSBs with faceness in upper bit) **Type 0 or 1**, First clock I, second clk J Field ULC URC LLC LRC Bits [63:39] [38:26] [25:13] [12:0] Format SE4M20 SE4M8 SE4M8 SE4M8 **Type 2** Field Face X Y Bits [63] [23:12] [11:0] Format Bit Unsigned Unsigned
SC_SP#_valid	1	Valid
SC_SP#_last_quad_data	1	This bit will be set on the last transfer of data per quad.
SC_SP#_type	2	0 -> Indicates centroids 1 -> Indicates centers 2 -> Indicates X,Y Data and faceness on data bus The SC shall look at state data to determine how many types to send for the interpolation process.

The # is included for clarity in the spec and will be replaced with a prefix of u#_ in the verilog module statement for the SC and the SP block will have neither because the instantiation will insert the prefix.

24.2.2 *SC_SQ*

This is the control information sent to the sequencer in order to synchronize and control the interpolation and/or loading data into the GPRs needed to execute a shader program on the sent pixels. This data will be sent over two clocks per transfer with 1 to 16 transfers. Therefore the bus (approx ~~92~~ 94 bits) could be folded in half to approx ~~47~~ 49 bits.

Name	**Bits**	**Description**
SC_SQ_data	46	Control Data sent to the SQ 1 clk transfers Event – valid data consist of event_id and state_id. Instruct SQ to post an event vector to send state id and event_id through request fifo

		and onto the reservation stations making sure state id and/or event_id gets back to the CP. Events only follow end of packets so no pixel vectors will be in progress. Empty Quad Mask – Transfer Control data consisting of pc_dealloc or new_vector. Receipt of this is to transfer pc_dealloc or new_vector without any valid quad data. New vector will always be posted to request fifo and pc_dealloc will be attached to any pixel vector outstanding or posted in request fifo if no valid quad outstanding. 2 clk transfers Quad Data Valid – Sending quad data with or without new_vector or pc_dealloc. New vector will be posted to request fifo with or without a pixel vector and pc_dealloc will be posted with a pixel vector unless none is in progress. In this case the pc_dealloc will be posted in the request queue. Filler quads will be transferred with The Quad mask set but the pixel corresponding pixel mask set to zero.
SC_SQ_valid	1	SC sending valid data, 2nd clk could be all zeroes

SC_SQ_data – first clock and second clock transfers are shown in the table below.

Name	**BitField**	**Bits**	**Description**
1st Clock Transfer			
SC_SQ_event	0	1	This transfer is a 1 clock event vector Force quad_mask = new_vector=pc_dealloc=0
SC_SQ_event_id	[4:1]	4	This field identifies the event 0 => denotes an End Of State Event 1 => TBD
SC_SQ_pc_dealloc	[7:5]	3	Deallocation token for the Parameter Cache
SC_SQ_new_vector	8	1	The SQ must wait for Vertex shader done count > 0 and after dispatching the Pixel Vector the SQ will decrement the count.
SC_SQ_quad_mask	[12:9]	4	Quad Write mask left to right SP0 => SP3
SC_SQ_end_of_prim	13	1	End Of the primitive
SC_SQ_state_id	[16:14]	3	State/constant pointer (6*3+3)
SC_SQ_pix_mask	[32:17]	16	Valid bits for all pixels SP0=>SP3 (UL,UR,LL,LR)
SC_SQ_provok_vtx	[37:36]	2	Provoking vertex for flat shading
SC_SQ_pc_ptr0	[48:38]	11	Parameter Cache pointer for vertex 0
2nd Clock Transfer			
SC_SQ_pc_ptr1	[10:0]	11	Parameter Cache pointer for vertex 1
SC_SQ_pc_ptr2	[21:11]	11	Parameter Cache pointer for vertex 2
SC_SQ_lod_correct	[45:22]	24	LOD correction per quad (6 bits per quad)
SC_SQ_prim_type	[48:46]	3	Stippled line and Real time command need to load tex cords from alternate buffer 000: Normal 100: Realtime 101: Line AA 110: Point AA (Sprite)

Name	Bits	Description
SQ_SC_free_buff	1	Pipelined bit that instructs SC to decrement count of buffers in use.
SQ_SC_dec_cntr_cnt	1	Pipelined bit that instructs SC to decrement count of new vector and/or event sent to prevent SC from overflowing SQ interpolator/Reservation request fifo.

The scan converter will submit a partial vector whenever:

1.) He gets a primitive marked with an end of packet signal.
2.) A current pixel vector is being assembled with at least one or more valid quads and the vector has been marked for deallocate when a primitive marked new_vector arrives. The Scan Converter will submit a partial vector (up to 16quads with zero pixel mask to fill out the vector) prior to submitting the new_vector marker\primitive.

(This will prevent a hang which can be demonstrated when all primitives in a packet three vectors are culled except for a one quad primitive that gets marked pc_dealloc (vertices maximum size). In this case two new_vectors are submitted and processed, but then one valid quad with the pc_dealloc creates a vector and then the new would wait for another vertex vector to be processed, but the one being waited for could never export until the pc_dealloc signal made it through and thus the hang.)

24.2.3 *SQ to SX: Interpolator bus*

Name	Direction	Bits	Description
SQ_SXx_interp_flat_vtx	SQ→SPx	2	Provoking vertex for flat shading
SQ_SXx_interp_flat_gouraud	SQ→SPx	1	Flat or gouraud shading
SQ_SXx_interp_cyl_wrap	SQ→SPx	4	Wich channel needs to be cylindrical wrapped
SQ_SXx_pc_ptr0	SQ→SXx	11	Parameter Cache Pointer
SQ_SXx_pc_ptr1	SQ→SXx	11	Parameter Cache Pointer
SQ_SXx_pc_ptr2	SQ→SXx	11	Parameter Cache Pointer
SQ_SXx_rt_sel	SQ→SXx	1	Selects between RT and Normal data
SQ_SXx_pc_wr_en	SQ→SXx	1	Write enable for the PC memories
SQ_SXx_pc_wr_addr	SQ→SXx	7	Write address for the PCs
SQ_SXx_pc_channel_mask	SQ→SXx	4	Channel mask

24.2.4 *SQ to SP: Staging Register Data*

This is a broadcast bus that sends the VSISR information to the staging registers of the shader pipes.

Name	Direction	Bits	Description
SQ_SPx_vsr_data	SQ→SPx	96	Pointers of indexes or HOS surface information
SQ_SPx_vsr_double	SQ→SPx	1	0: Normal 96 bits per vert 1: double 192 bits per vert
SQ_SP0_ vsr_ valid	SQ→SP0	1	Data is valid
SQ_SP1_ vsr_ valid	SQ→SP1	1	Data is valid
SQ_SP2_ vsr_ valid	SQ→SP2	1	Data is valid
SQ_SP3_ vsr_ valid	SQ→SP3	1	Data is valid
SQ_SPx_vsr_read	SQ→SPx	1	Increment the read pointers

24.2.5 *VGT to SQ : Vertex interface*

24.2.5.1 Interface Signal Table

The area difference between the two methods is not sufficient to warrant complicating the interface or the state requirements of the VSISRs. **Therefore, the POR for this interface is that the VGT will transmit the data to the VSISRs (via the Shader Sequencer) in full, 32-bit floating-point format.** The VGT can transmit up to six 32-bit floating-point values to each VSISR where four or more values require two transmission clocks. The data bus is 96 bits wide.

Name	Bits	Description
VGT_SQ_vsisr_data	96	Pointers of indexes or HOS surface information
VGT_SQ_vsisr_double	1	0: Normal 96 bits per vert 1: double 192 bits per vert
VGT_SQ_end_of_vector	1	Indicates the last VSISR data set for the current process vector (for double vector data, "end_of_vector" is set on the first vector)
VGT_SQ_indx_valid	1	Vsisr data is valid
VGT_SQ_state	3	Render State (6*3+3 for constants). This signal is guaranteed to be correct when “VGT_SQ_vgt_end_of_vector” is high.
VGT_SQ_send	1	Data on the VGT_SQ is valid receive (see write-up for standard R400 SEND/RTR interface handshaking)
SQ_VGT_rtr	1	Ready to receive (see write-up for standard R400 SEND/RTR interface handshaking)

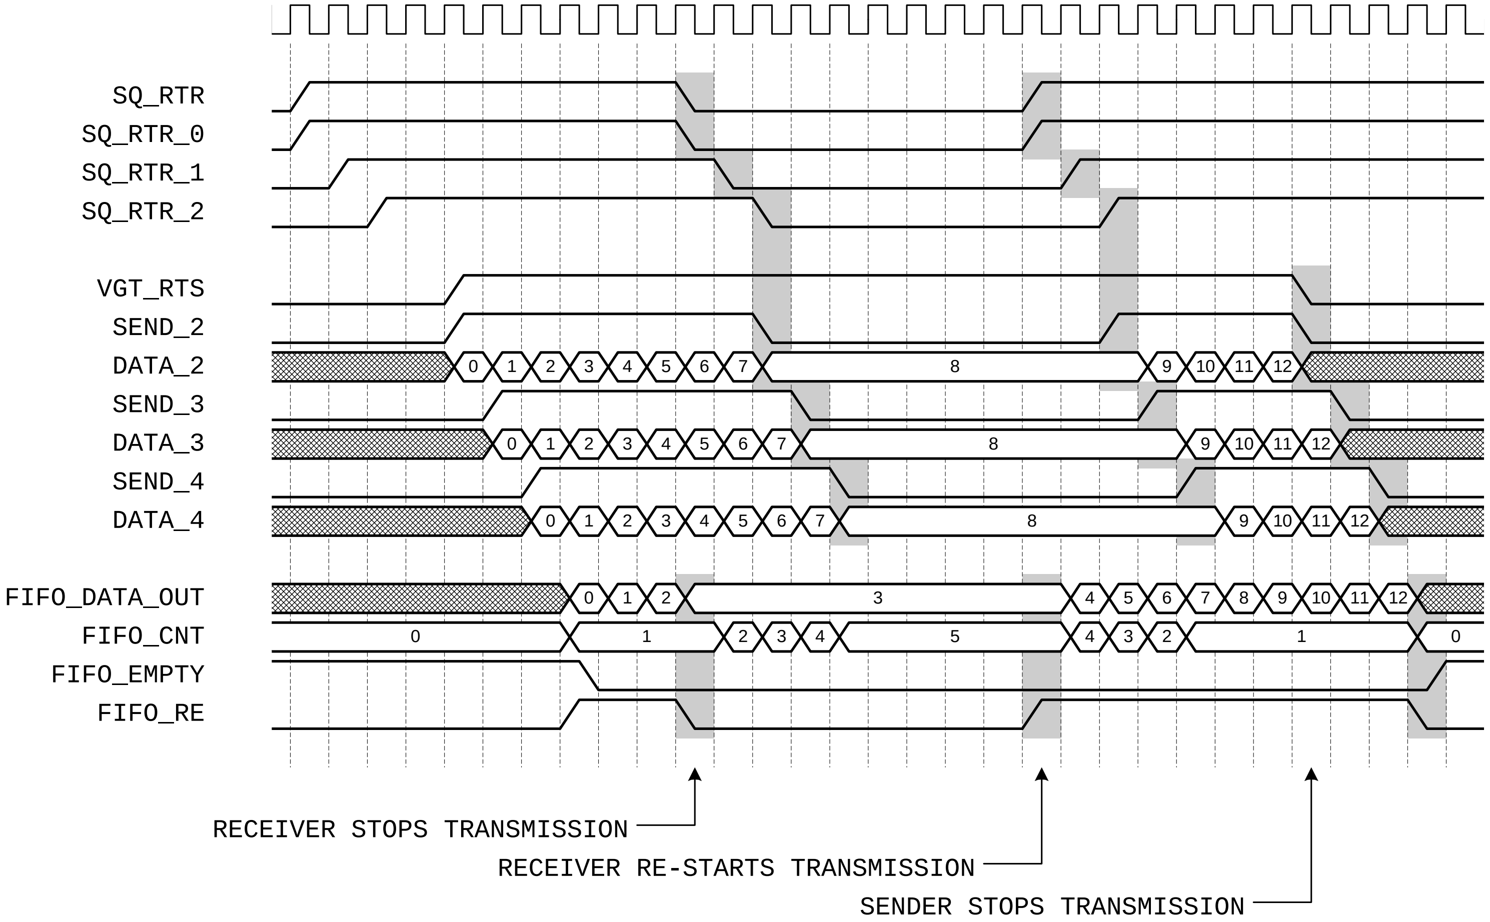

Figure 1. Detailed Logical Diagram for PA_SQ_vgt Interface.

24.2.6 *SQ to SX: Control bus*

Name	Direction	Bits	Description
SQ_SXx_exp_type	SQ→SXx	2	00: Pixel without z (1 to 4 buffers) 01: Pixel with z (1 to 4 buffers) 10: Position (1 or 2 results) 11: Pass thru (4,8 or 12 results aligned)
SQ_SXx_exp_number	SQ→SXx	2	Number of locations needed in the export buffer (encoding depends on the type see bellow).
SQ_SXx_exp_alu_id	SQ→SXx	1	ALU ID
SQ_SXx_exp_valid	SQ→SXx	1	Valid bit
SQ_SXx_exp_state	SQ→SXx	3	State Context
SQ_SXx_free_done	SQ→SXx	1	Pulse to indicate that the previous export is finished (this can be sent with or without the other fields of the interface)
SQ_SXx_free_alu_id	SQ→SXx	1	ALU ID

Depending on the type the number of export location changes:

- Type 00 : Pixels without Z
  - 00 = 1 buffer
  - 01 = 2 buffers
  - 10 = 3 buffers
  - 11 = 4 buffer
- Type 01: Pixels with Z
  - 00 = 2 Buffers (color + Z)
  - 01 = 3 buffers (2 color + Z)
  - 10 = 4 buffers (3 color + Z)
  - 11 = 5 buffers (4 color + Z)
- Type 10 : Position export
  - 00 = 1 position
  - 01 = 2 positions
  - 1X = Undefined
- Type 11: Pass Thru
  - 00 = 4 buffers
  - 01 = 8 buffers
  - 10 = 12 buffers
  - 11 = Undefined

Below the thick black line is the end of transfer packet that tells the SX that a given export is finished. The report packet **will always arrive either before or at the same time than the next export to the same ALU id**.

24.2.7 *SX to SQ : Output file control*

Name	Direction	Bits	Description
SXx_SQ_exp_count_rdy	SXx→SQ	1	Raised by SX0 to indicate that the following two fields reflect the result of the most recent export
SXx_SQ_exp_pos_avail	SXx→SQ	1	Specifies whether there is room for another position.
SXx_SQ_exp_buf_avail	SXx→SQ	7	Specifies the space available in the output buffers. 0: buffers are full 1: 2K-bits available (32-bits for each of the 64 pixels in a clause) ... 64: 128K-bits available (16 128-bit entries for each of 64 pixels) 65-127: RESERVED

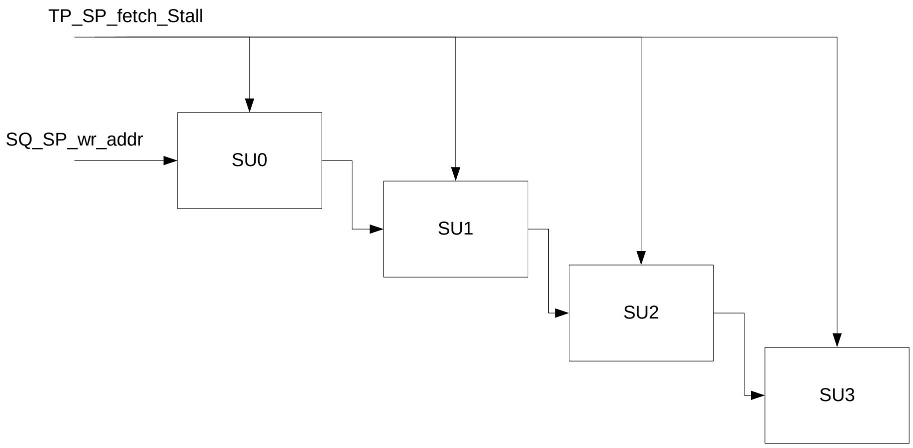
24.2.8 *SQ to TP: Control bus*

Once every clock, the fetch unit sends to the sequencer on which RS line it is now working and if the data in the GPRs is ready or not. This way the sequencer can update the fetch valid bits flags for the reservation station. The sequencer also provides the instruction and constants for the fetch to execute and the address in the register file where to write the fetch return data.

Name	Direction	Bits	Description
TPx_SQ_data_rdy	TPx→ SQ	1	Data ready
TPx_SQ_rs_line_num	TPx→ SQ	6	Line number in the Reservation station
TPx_SQ_type	TPx→ SQ	1	Type of data sent (0:PIXEL, 1:VERTEX)
SQ_TPx_send	SQ→TPx	1	Sending valid data
SQ_TPx_const	SQ→TPx	48	Fetch state sent over 4 clocks (192 bits total)
SQ_TPx_instr	SQ→TPx	24	Fetch instruction sent over 4 clocks
SQ_TPx_end_of_group	SQ→TPx	1	Last instruction of the group
SQ_TPx_Type	SQ→TPx	1	Type of data sent (0:PIXEL, 1:VERTEX)
SQ_TPx_gpr_phase	SQ→TPx	2	Write phase signal
SQ_TP0_lod_correct	SQ→TP0	6	LOD correct 3 bits per comp 2 components per quad
SQ_TP0_pix_mask	SQ→TP0	4	Pixel mask 1 bit per pixel
SQ_TP1_lod_correct	SQ→TP1	6	LOD correct 3 bits per comp 2 components per quad
SQ_TP1_pix_mask	SQ→TP1	4	Pixel mask 1 bit per pixel
SQ_TP2_lod_correct	SQ→TP2	6	LOD correct 3 bits per comp 2 components per quad
SQ_TP2_pix_mask	SQ→TP2	4	Pixel mask 1 bit per pixel
SQ_TP3_lod_correct	SQ→TP3	6	LOD correct 3 bits per comp 2 components per quad
SQ_TP3_pix_mask	SQ→TP3	4	Pixel mask 1 bit per pixel
SQ_TPx_rs_line_num	SQ→TPx	6	Line number in the Reservation station
SQ_TPx_write_gpr_index	SQ->TPx	7	Index into Register file for write of returned Fetch Data

24.2.9 *TP to SQ: Texture stall*

The TP sends this signal to the SQ and the SPs when its input buffer is full.



Name	Direction	Bits	Description
TP_SQ_fetch_stall	TP→ SQ	1	Do not send more texture request if asserted

24.2.10 SQ to SP: Texture stall

Name	Direction	Bits	Description
SQ_SPx_fetch_stall	SQ→SPx	1	Do not send more texture request if asserted

24.2.11 SQ to SP: GPR and auto counter

Name	Direction	Bits	Description
SQ_SPx_gpr_wr_addr	SQ→SPx	7	Write address
SQ_SPx_gpr_rd_addr	SQ→SPx	7	Read address
SQ_SPx_gpr_rd_en	SQ→SPx	1	Read Enable
SQ_SP0_gpr_wr_en	SQ→SPx	1	Write Enable for the GPRs of SP0
SQ_SP1_gpr_wr_en	SQ→SPx	1	Write Enable for the GPRs of SP1
SQ_SP2_gpr_wr_en	SQ→SPx	1	Write Enable for the GPRs of SP2
SQ_SP3_gpr_wr_en	SQ→SPx	1	Write Enable for the GPRs of SP3
SQ_SPx_gpr_phase	SQ→SPx	2	The phase mux (arbitrates between inputs, ALU SRC reads and writes)
SQ_SPx_channel_mask	SQ→SPx	4	The channel mask
SQ_SPx_gpr_input_sel	SQ→SPx	2	When the phase mux selects the inputs this tells from which source to read from: Interpolated data, VTX0, VTX1, autogen counter.
SQ_SPx_auto_count	SQ→SPx	12?	Auto count generated by the SQ, common for all shader pipes

24.2.12 *SQ to SPx: Instructions*

Name	Direction	Bits	Description
SQ_SPx_instr_start	SQ→SPx	1	Instruction start
SQ_SP_instr	SQ→SPx	21	Transferred over 4 cycles 0: SRC A Select 2:0 SRC A Argument Modifier 3:3 SRC A swizzle 11:4 VectorDst 17:12 Unused 20:18 --- - 1: SRC B Select 2:0 SRC B Argument Modifier 3:3 SRC B swizzle 11:4 ScalarDst 17:12 Unused 20:18 --- - 2: SRC C Select 2:0 SRC C Argument Modifier 3:3 SRC C swizzle 11:4 Unused 20:12 --- - 3: Vector Opcode 4:0 Scalar Opcode 10:5 Vector Clamp 11:11 Scalar Clamp 12:12 Vector Write Mask 16:13 Scalar Write Mask 20:17
SQ_SPx_exp_alu_id	SQ→SPx	1	ALU ID
SQ_SPx_exporting	SQ→SPx	2	0: Not Exporting 1: Vector Exporting 2: Scalar Exporting
SQ_SPx_stall	SQ→SPx	1	Stall signal
SQ_SP0_write_mask	SQ→SP0	4	Result of pixel kill in the shader pipe, which must be output for all pixel exports (depth and all color buffers). 4x4 because 16 pixels are computed per clock
SQ_SP1_ write_mask	SQ→SP1	4	Result of pixel kill in the shader pipe, which must be output for all pixel exports (depth and all color buffers). 4x4 because 16 pixels are computed per clock
SQ_SP2_ write_mask	SQ→SP2	4	Result of pixel kill in the shader pipe, which must be output for all pixel exports (depth and all color buffers). 4x4 because 16 pixels are computed per clock
SQ_SP3_ write_mask	SQ→SP3	4	Result of pixel kill in the shader pipe, which must be output for all pixel exports (depth and all color buffers). 4x4 because 16 pixels are computed per clock
SQ_SPx_last	SQ→SPx	1	Last instruction of the block

24.2.13 *SP to SQ: Constant address load/ Predicate Set*

Name	Direction	Bits	Description
SP0_SQ_const_addr	SP0→SQ	36	Constant address load / predicate vector load (4 bits only) to the sequencer
SP0_SQ_valid	SP0→SQ	1	Data valid
SP1_SQ_const_addr	SP1→SQ	36	Constant address load / predicate vector load (4 bits only)

			to the sequencer
SP1_SQ_valid	SP1→SQ	1	Data valid
SP2_SQ_const_addr	SP2→SQ	36	Constant address load / predicate vector load (4 bits only) to the sequencer
SP2_SQ_valid	SP2→SQ	1	Data valid
SP3_SQ_const_addr	SP3→SQ	36	Constant address load / predicate vector load (4 bits only) to the sequencer
SP3_SQ_valid	SP3→SQ	1	Data valid
SP0_SQ_data_type	SP→SQ	1	Data Type 0: Constant Load 1: Predicate Set

24.2.14 *SQ to SPx: constant broadcast*

Name	**Direction**	**Bits**	**Description**
SQ_SPx_const	SQ→SPx	128	Constant broadcast

24.2.15 *SP0 to SQ: Kill vector load*

Name	**Direction**	**Bits**	**Description**
SP0_SQ_kill_vect	SP0→SQ	4	Kill vector load
SP1_SQ_kill_vect	SP1→SQ	4	Kill vector load
SP2_SQ_kill_vect	SP2→SQ	4	Kill vector load
SP3_SQ_kill_vect	SP3→SQ	4	Kill vector load

24.2.16 *SQ to CP: RBBM bus*

Name	**Direction**	**Bits**	**Description**
SQ_RBB_rs	SQ→CP	1	Read Strobe
SQ_RBB_rd	SQ→CP	32	Read Data
SQ_RBBM_nrtrtr	SQ→CP	1	Optional
SQ_RBBM_rtr	SQ→CP	1	Real-Time (Optional)

24.2.17 *CP to SQ: RBBM bus*

Name	**Direction**	**Bits**	**Description**
rbbm_we	CP→SQ	1	Write Enable
rbbm_a	CP→SQ	15	Address -- Upper Extent is TBD (16:2)
rbbm_wd	CP→SQ	32	Data
rbbm_be	CP→SQ	4	Byte Enables
rbbm_re	CP→SQ	1	Read Enable
rbb_rs0	CP→SQ	1	Read Return Strobe 0
rbb_rs1	CP→SQ	1	Read Return Strobe 1
rbb_rd0	CP→SQ	32	Read Data 0
rbb_rd1	CP→SQ	32	Read Data 0
RBBM_SQ_soft_reset	CP→SQ	1	Soft Reset

24.2.18 *SQ to CP: State report*

Name	**Direction**	**Bits**	**Description**
SQ_CP_vs_event	SQ→CP	1	Vertex Shader Event
SQ_CP_vs_eventid	SQ→CP	2	Vertex Shader Event ID
SQ_CP_ps_event	SQ→CP	1	Pixel Shader Event
SQ_CP_ps_eventid	SQ→CP	2	Pixel Shader Event ID

eventid = 0 => *sEndOfState (i.e. VsEndOfState)
eventid = 1 => *sDone (i.e. VsDone)

So, the CP will assume the Vs is done with a state whenever it gets a pulse on the SQ_CP_vs_event and the SQ_CP_vs_eventid = 0.

24.3 Example of control flow program execution

We now provide some examples of execution to better illustrate the new design.

Given the program:

Alu 0
Alu 1
Tex 0
Tex 1
Alu 3 Serial
Alu 4
Tex 2
Alu 5
Alu 6 Serial
Tex 3
Alu 7
Alloc Position 1 buffer
Alu 8 Export
Tex 4
Alloc Parameter 3 buffers
Alu 9 Export 0
Tex 5
Alu 10 Serial Export 2
Alu 11 Export 1 End

Would be converted into the following CF instructions:

```
Execute Alu 0 Alu 0 Tex 0 Tex 0 Alu 1 Alu 0 Tex 0 Alu 0 Alu 1 Tex 0
Execute Alu 0
Alloc Position 1
Execute Alu 0 Tex 0
Alloc Param 3
Execute Alu 0 Tex 0 Alu 1 Alu 0 End
```

And the execution of this program would look like this:

Put thread in Vertex RS:

Control Flow Instruction Pointer (12 bits), (CFP)
Execution Count Marker (3 or 4 bits), (ECM)
Loop Iterators (4x9 bits), (LI)
Call return pointers (4x12 bits), (CRP)
Predicate Bits(4x64 bits), (PB)
Export ID (1 bit), (EXID)
GPR Base Ptr (8 bits), (GPR)
Export Base Ptr (7 bits), (EB)
Context Ptr (3 bits).(CPTR)
LOD correction bits (16x6 bits) (LOD)

State Bits									
CFP	ECM	LI	CRP	PB	EXID	GPR	EB	CPTR	LOD
0	0	0	0	0	0	0	0	0	0

Valid Thread (VALID)
Texture/ALU engine needed (TYPE)
Texture Reads are outstanding (PENDING)

Waiting on Texture Read to Complete (SERIAL)
Allocation Wait (2 bits) (ALLOC)
00 – No allocation needed
01 – Position export allocation needed (ordered export)
10 – Parameter or pixel export needed (ordered export)
11 – pass thru (out of order export)
Allocation Size (4 bits) (SIZE)
Position Allocated (POS_ALLOC)
First thread of a new context (FIRST)
Last (1 bit), (LAST)

Status Bits								
VALID	TYPE	PENDING	SERIAL	ALLOC	SIZE	POS_ALLOC	FIRST	LAST
1	ALU	0	0	0	0	0	1	0

Then the thread is picked up for the execution of the first control flow instruction:

```
Execute Alu 0 Alu 0 Tex 0 Tex 0 Alu 1 Alu 0 Tex 0 Alu 0 Alu 1 Tex 0
```

It executes the first two ALU instructions and goes back to the RS for a resource request change. Here is the state returned to the RS:

State Bits									
CFP	ECM	LI	CRP	PB	EXID	GPR	EB	CPTR	LOD
0	2	0	0	0	0	0	0	0	0

Status Bits								
VALID	TYPE	PENDING	SERIAL	ALLOC	SIZE	POS_ALLOC	FIRST	LAST
1	TEX	0	0	0	0	0	1	0

Then when the texture pipe frees up, the arbiter picks up the thread to issue the texture reads. The thread comes back in this state:

State Bits									
CFP	ECM	LI	CRP	PB	EXID	GPR	EB	CPTR	LOD
0	4	0	0	0	0	0	0	0	0

Status Bits								
VALID	TYPE	PENDING	SERIAL	ALLOC	SIZE	POS_ALLOC	FIRST	LAST
1	ALU	1	1	0	0	0	1	0

Because of the serial bit the arbiter must wait for the texture to return and clear the PENDING bit before it can pick the thread up. Lets say that the texture reads are complete, then the arbiter picks up the thread and returns it in this state:

State Bits									
CFP	ECM	LI	CRP	PB	EXID	GPR	EB	CPTR	LOD
0	6	0	0	0	0	0	0	0	0

Status Bits								
VALID	TYPE	PENDING	SERIAL	ALLOC	SIZE	POS_ALLOC	FIRST	LAST
1	TEX	0	0	0	0	0	1	0

Again the TP frees up, the arbiter picks up the thread and executes. It returns in this state:

State Bits									
CFP	ECM	LI	CRP	PB	EXID	GPR	EB	CPTR	LOD
0	7	0	0	0	0	0	0	0	0

Status Bits								
VALID	TYPE	PENDING	SERIAL	ALLOC	SIZE	POS_ALLOC	FIRST	LAST
1	ALU	1	0	0	0	0	1	0

Now, even if the texture has not returned we can still pick up the thread for ALU execution because the serial bit is not set. The thread will however come back to the RS for the second ALU instruction because it has the serial bit set.

State Bits									
CFP	ECM	LI	CRP	PB	EXID	GPR	EB	CPTR	LOD
0	8	0	0	0	0	0	0	0	0

Status Bits								
VALID	TYPE	PENDING	SERIAL	ALLOC	SIZE	POS_ALLOC	FIRST	LAST
1	ALU	1	1	0	0	0	1	0

As soon as the TP clears the pending bit the thread is picked up and returns:

State Bits									
CFP	ECM	LI	CRP	PB	EXID	GPR	EB	CPTR	LOD
0	9	0	0	0	0	0	0	0	0

Status Bits								
VALID	TYPE	PENDING	SERIAL	ALLOC	SIZE	POS_ALLOC	FIRST	LAST
1	TEX	0	0	0	0	0	1	0

Picked up by the TP and returns:

```
Execute Alu 0
```

State Bits									
CFP	ECM	LI	CRP	PB	EXID	GPR	EB	CPTR	LOD
1	0	0	0	0	0	0	0	0	0

Status Bits								
VALID	TYPE	PENDING	SERIAL	ALLOC	SIZE	POS_ALLOC	FIRST	LAST
1	ALU	1	0	0	0	0	1	0

Picked up by the ALU and returns (lets say the TP has not returned yet):

```
Alloc Position 1
```

State Bits									
CFP	ECM	LI	CRP	PB	EXID	GPR	EB	CPTR	LOD
2	0	0	0	0	0	0	0	0	0

Status Bits

VALID	TYPE	PENDING	SERIAL	ALLOC	SIZE	POS_ALLOC	FIRST	LAST
1	ALU	1	0	01	1	0	1	0

If the SX has the place for the export, the SQ is going to allocate and pick up the thread for execution. It returns to the RS in this state:

```
Execute Alu 0 Tex 0
```

State Bits

CFP	ECM	LI	CRP	PB	EXID	GPR	EB	CPTR	LOD
3	1	0	0	0	0	0	0	0	0

Status Bits

VALID	TYPE	PENDING	SERIAL	ALLOC	SIZE	POS_ALLOC	FIRST	LAST
1	TEX	1	0	0	0	1	1	0

Now, since the TP has not returned yet, we must wait for it to return because we cannot issue multiple texture requests. The TP returns, clears the PENDING bit and we proceed:

```
    Alloc Param 3
```

State Bits

CFP	ECM	LI	CRP	PB	EXID	GPR	EB	CPTR	LOD
4	0	0	0	0	1	0	0	0	0

Status Bits

VALID	TYPE	PENDING	SERIAL	ALLOC	SIZE	POS_ALLOC	FIRST	LAST
1	ALU	1	0	10	3	1	1	0

Once again the SQ makes sure the SX has enough room in the Parameter cache before it can pick up this thread.

```
    Execute Alu 0 Tex 0 Alu 1 Alu 0 End
```

State Bits

CFP	ECM	LI	CRP	PB	EXID	GPR	EB	CPTR	LOD
5	1	0	0	0	1	0	100	0	0

Status Bits

VALID	TYPE	PENDING	SERIAL	ALLOC	SIZE	POS_ALLOC	FIRST	LAST
1	TEX	1	0	0	0	1	1	0

This executes on the TP and then returns:

State Bits

CFP	ECM	LI	CRP	PB	EXID	GPR	EB	CPTR	LOD
5	2	0	0	0	1	0	100	0	0

Status Bits

VALID	TYPE	PENDING	SERIAL	ALLOC	SIZE	POS_ALLOC	FIRST	LAST
1	ALU	1	1	0	0	1	1	1

Waits for the TP to return because of the textures reads are pending (and SERIAL in this case). Then executes and does not return to the RS because the LAST bit is set. This is the end of this thread and before dropping it on the floor, the SQ notifies the SX of export completion.

25. Open issues

Need to do some testing on the size of the register file as well as on the register file allocation method (dynamic VS static).

Saving power?

R400 Sequencer Specification

SQ

Version 2.03~~2~~

Overview: This is an architectural specification for the R400 Sequencer block (SEQ). It provides an overview of the required capabilities and expected uses of the block. It also describes the block interfaces, internal sub-blocks, and provides internal state diagrams.

Revision Changes:

Rev 0.1 (Laurent Lefebvre) Date: May 7, 2001	First draft.
Rev 0.2 (Laurent Lefebvre) Date : July 9, 2001	Changed the interfaces to reflect the changes in the SP. Added some details in the arbitration section.
Rev 0.3 (Laurent Lefebvre) Date : August 6, 2001	Reviewed the Sequencer spec after the meeting on August 3, 2001.
Rev 0.4 (Laurent Lefebvre) Date : August 24, 2001	Added the dynamic allocation method for register file and an example (written in part by Vic) of the flow of pixels/vertices in the sequencer.
Rev 0.5 (Laurent Lefebvre) Date : September 7, 2001	Added timing diagrams (Vic)
Rev 0.6 (Laurent Lefebvre) Date : September 24, 2001	Changed the spec to reflect the new R400 architecture. Added interfaces.
Rev 0.7 (Laurent Lefebvre) Date : October 5, 2001	Added constant store management, instruction store management, control flow management and data dependant predication.
Rev 0.8 (Laurent Lefebvre) Date : October 8, 2001	Changed the control flow method to be more flexible. Also updated the external interfaces.
Rev 0.9 (Laurent Lefebvre) Date : October 17, 2001	Incorporated changes made in the 10/18/01 control flow meeting. Added a NOP instruction, removed the conditional_execute_or_jump. Added debug registers.
Rev 1.0 (Laurent Lefebvre) Date : October 19, 2001	Refined interfaces to RB. Added state registers.
Rev 1.1 (Laurent Lefebvre) Date : October 26, 2001	Added SEQ→SP0 interfaces. Changed delta precision. Changed VGT→SP0 interface. Debug Methods added.
Rev 1.2 (Laurent Lefebvre) Date : November 16, 2001	Interfaces greatly refined. Cleaned up the spec.
Rev 1.3 (Laurent Lefebvre) Date : November 26, 2001	Added the different interpolation modes.
Rev 1.4 (Laurent Lefebvre) Date : December 6, 2001	Added the auto incrementing counters. Changed the VGT→SQ interface. Added content on constant management. Updated GPRs.
Rev 1.5 (Laurent Lefebvre) Date : December 11, 2001	Removed from the spec all interfaces that weren't directly tied to the SQ. Added explanations on constant management. Added PA→SQ synchronization fields and explanation.
Rev 1.6 (Laurent Lefebvre) Date : January 7, 2002	Added more details on the staging register. Added detail about the parameter caches. Changed the call instruction to a Conditionnal_call instruction. Added details on constant management and updated the diagram.
Rev 1.7 (Laurent Lefebvre) Date : February 4, 2002	Added Real Time parameter control in the SX interface. Updated the control flow section.
Rev 1.8 (Laurent Lefebvre) Date : March 4, 2002	New interfaces to the SX block. Added the end of clause modifier, removed the end of clause instructions.
Rev 1.9 (Laurent Lefebvre) Date : March 18, 2002	Rearangement of the CF instruction bits in order to ensure byte alignement.
Rev 1.10 (Laurent Lefebvre) Date : March 25, 2002	Updated the interfaces and added a section on exporting rules.
Rev 1.11 (Laurent Lefebvre) Date : April 19, 2002	Added CP state report interface. Last version of the spec with the old control flow scheme
Rev 2.0 (Laurent Lefebvre) Date : April 19, 2002	New control flow scheme

Rev 2.01 (Laurent Lefebvre) Date : May 2, 2002	Changed slightly the control flow instructions to allow force jumps and calls.
Rev 2.02 (Laurent Lefebvre) Date : May 13, 2002	Updated the Opcodes. Added type field to the constant/pred interface. Added Last field to the SQ→SP instruction load interface.
Rev 2.03 (Laurent Lefebvre) Date : July 15, 2002	SP interface updated to include predication optimizations. Added the predicate no stall instructions,

1. Overview

The sequencer chooses two ALU threads and a fetch hread to execute, and executes all of the instructions in a block before looking for a new clause of the same type. Two ALU threads are executed interleaved to hide the ALU latency. The arbitrator will give priority to older threads. There are two separate reservation stations, one for pixel vectors and one for vertices vectors. This way a pixel can pass a vertex and a vertex can pass a pixel.

To support the shader pipe the sequencer also contains the shader instruction cache, constant store, control flow constants and texture state. The four shader pipes also execute the same instruction thus there is only one sequencer for the whole chip.

The sequencer first arbitrates between vectors of 64 vertices that arrive directly from primitive assembly and vectors of 16 quads (64 pixels) that are generated in the scan converter.

The vertex or pixel program specifies how many GPRs it needs to execute. The sequencer will not start the next vector until the needed space is available in the GPRs.

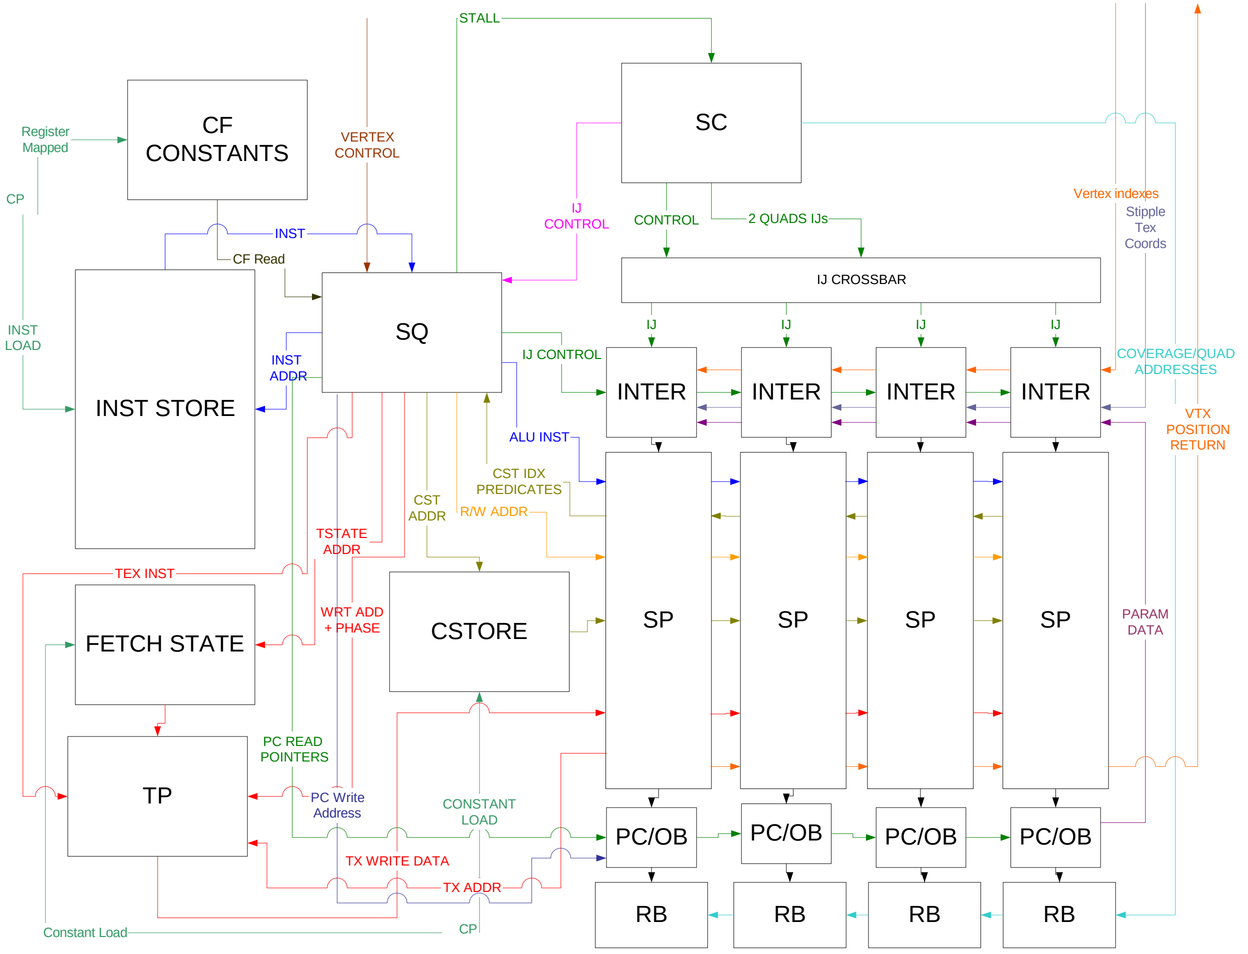

Figure 1: General Sequencer overview

1.1 Top Level Block Diagram

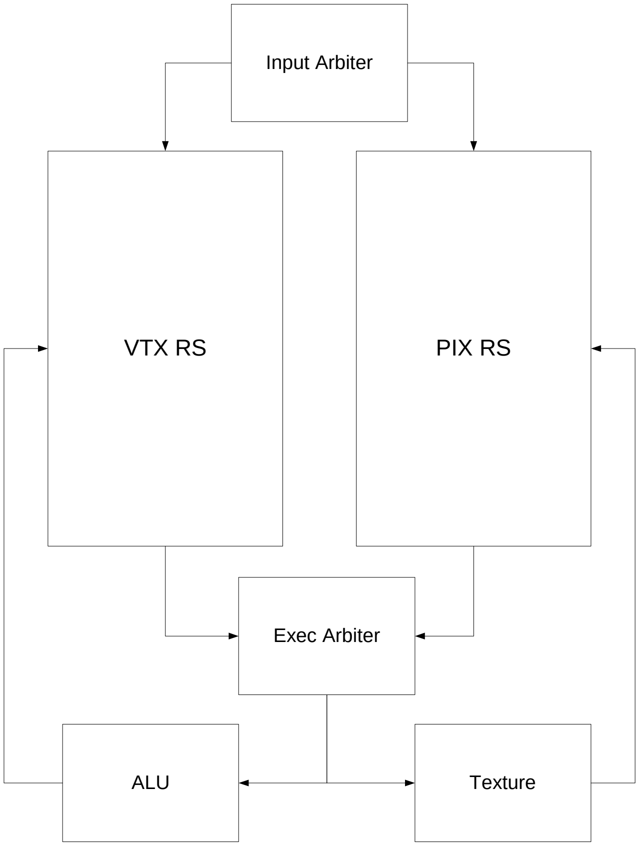

Figure 2: Reservation stations and arbiters

Under this new scheme, the sequencer (SQ) will only use one global state management machine per vector type (pixel, vertex) that we call the reservation station (RS).

1.2 Data Flow graph (SP)

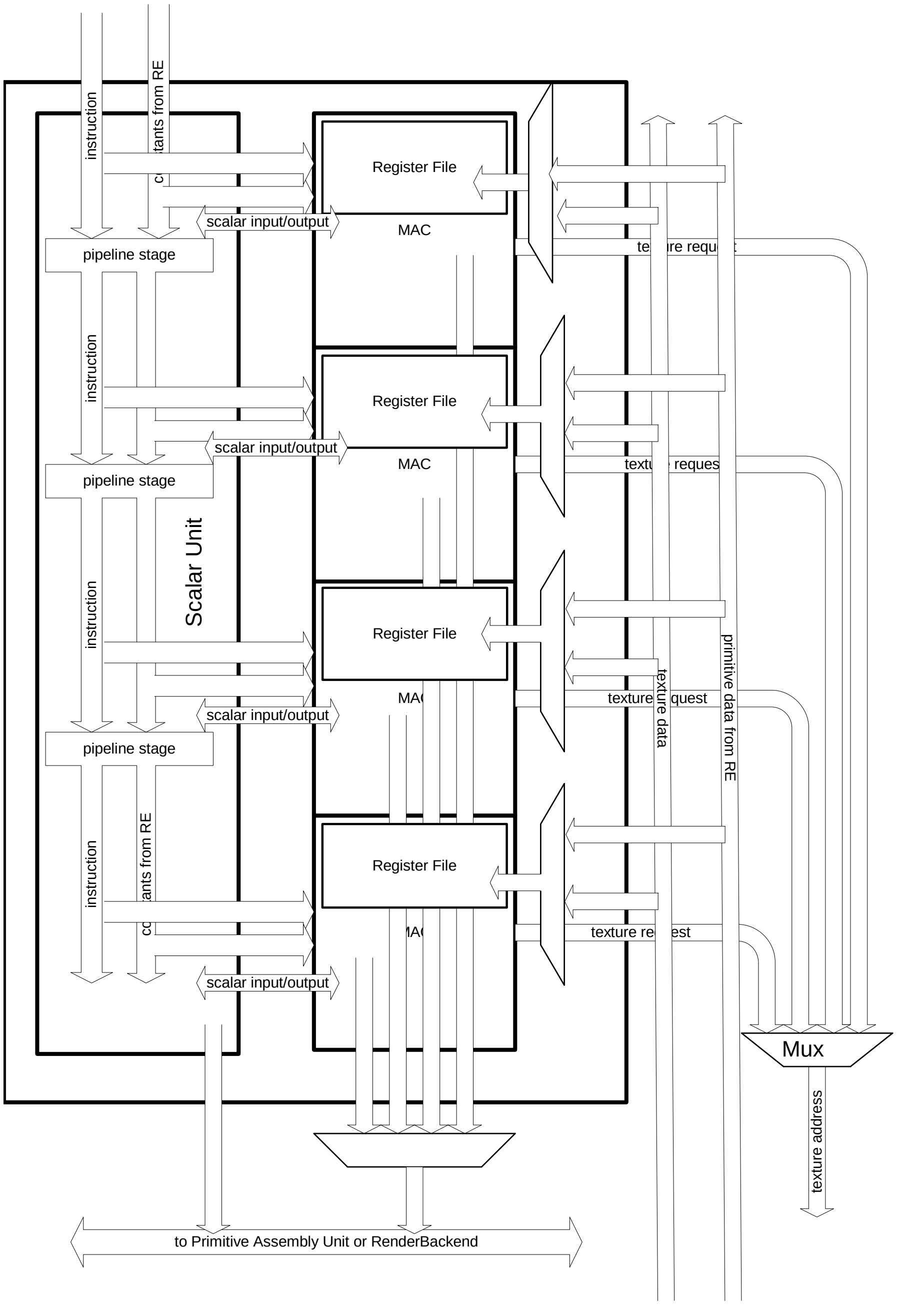

Figure 3: The shader Pipe

The gray area represents blocks that are replicated 4 times per shader pipe (16 times on the overall chip).

1.3 Control Graph

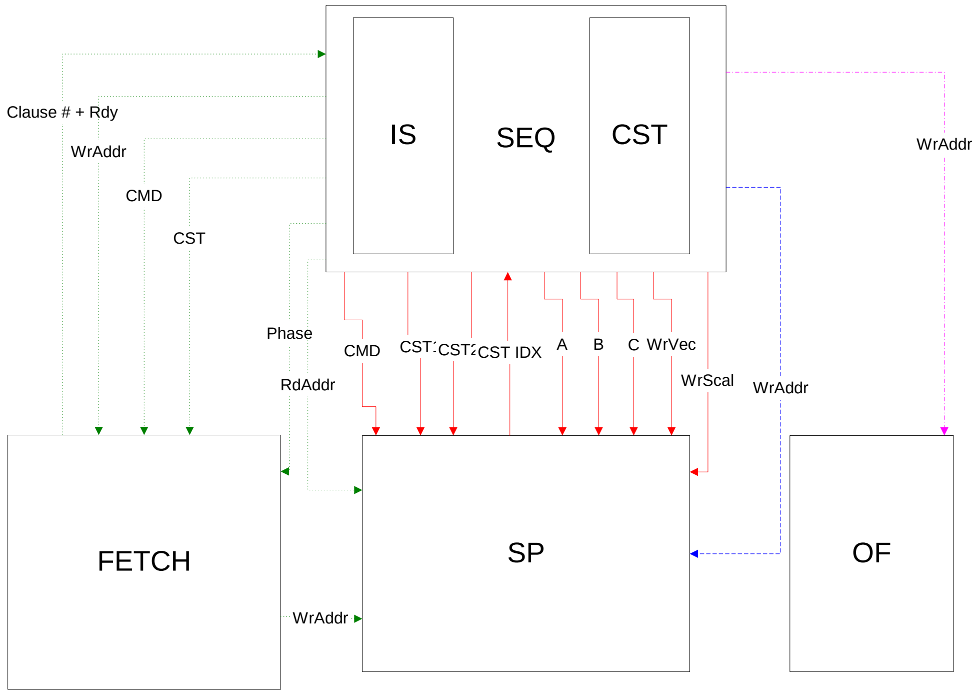

Figure 4: Sequencer Control interfaces

In green is represented the Fetch control interface, in red the ALU control interface, in blue the Interpolated/Vector control interface and in purple is the output file control interface.

2. Interpolated data bus

The interpolators contain an IJ buffer to pack the information as much as possible before writing it to the register file.

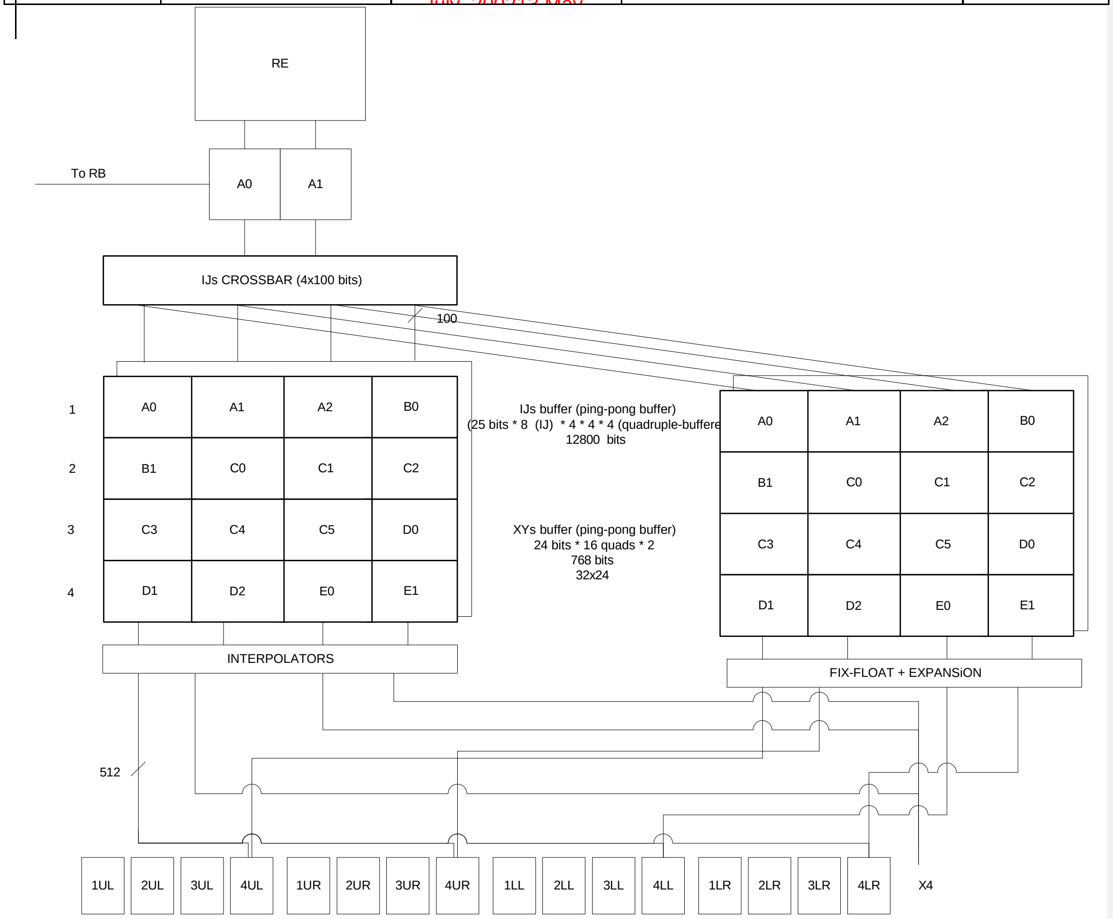

Figure 5: Interpolation buffers

Figure 6: Interpolation timing diagram

Above is an example of a tile the sequencer might receive from the SC. The write side is how the data get stacked into the XY and IJ buffers, the read side is how the data is passed to the GPRs. The IJ information is packed in the IJ buffer 4 quads at a time or two clocks. The sequencer allows at any given time as many as four quads to interpolate a parameter. They all have to come from the same primitive. Then the sequencer controls the write mask to the GPRs to write the valid data in.

3. Instruction Store

There is going to be only one instruction store for the whole chip. It will contain 4096 instructions of 96 bits each.

It is likely to be a 1 port memory; we use 1 clock to load the ALU instruction, 1 clocks to load the Fetch instruction, 1 clock to load 2 control flow instructions and 1 clock to write instructions.

The instruction store is loaded by the CP thru the register mapped registers.

The VS_BASE and PS_BASE context registers are used to specify for each context where its shader is in the instruction memory.

For the Real time commands the story is quite the same but for some small differences. There are no wrap-around points for real time so the driver must be careful not to overwrite regular shader data. The shared code (shared subroutines) uses the same path as real time.

4. Sequencer Instructions

All control flow instructions and move instructions are handled by the sequencer only. The ALUs will perform NOPs during this time (MOV PV,PV, PS,PS) if they have nothing else to do.

5. Constant Stores

5.1 Memory organizations

A likely size for the ALU constant store is 1024x128 bits. The read BW from the ALU constant store is 128 bits/clock and the write bandwidth is 32 bits/clock (directed by the CP bus size not by memory ports).

The maximum logical size of the constant store for a given shader is 256 constants. Or 512 for the pixel/vertex shader pair. The size of the re-mapping table is 128 lines (each line addresses 4 constants). The write granularity is 4 constants or 512 bits. It takes 16 clocks to write the four constants. Real time requires 256 lines in the physical memory (this is physically register mapped).

The texture state is also kept in a similar memory. The size of this memory is 320x96 bits (128 texture states for regular mode, 32 states for RT). The memory thus holds 128 texture states (192 bits per state). The logical size exposes 32 different states total, which are going to be shared between the pixel and the vertex shader. The size of the re-mapping table to for the texture state memory is 32 lines (each line addresses 1 texture state lines in the real memory). The CP write granularity is 1 texture state lines (or 192 bits). The driver sends 512 bits but the CP ignores the top 320 bits. It thus takes 6 clocks to write the texture state. Real time requires 32 lines in the physical memory (this is physically register mapped).

The control flow constant memory doesn't sit behind a renaming table. It is register mapped and thus the driver must reload its content each time there is a change in the control flow constants. Its size is 320*32 because it must hold 8 copies of the 32 dwords of control flow constants and the loop construct constants must be aligned.

The constant re-mapping tables for texture state and ALU constants are logically register mapped for regular mode and physically register mapped for RT operation.

5.2 Management of the Control Flow Constants

The control flow constants are register mapped, thus the CP writes to the according register to set the constant, the SQ decodes the address and writes to the block pointed by its current base pointer (CF_WR_BASE). On the read side, one level of indirection is used. A register (SQ_CONTEXT_MISC.CF_RD_BASE) keeps the current base pointer to the control flow block. This register is copied whenever there is a state change. Should the CP write to CF after the state change, the base register is updated with the (current pointer number +1)% number of states. This way, if the CP doesn't write to CF the state is going to use the previous CF constants.

5.3 Management of the re-mapping tables

5.3.1 *R400 Constant management*

The sequencer is responsible to manage two re-mapping tables (one for the constant store and one for the texture state). On a state change (by the driver), the sequencer will broadside copy the contents of its re-mapping tables to a new one. We have 8 different re-mapping tables we can use concurrently.

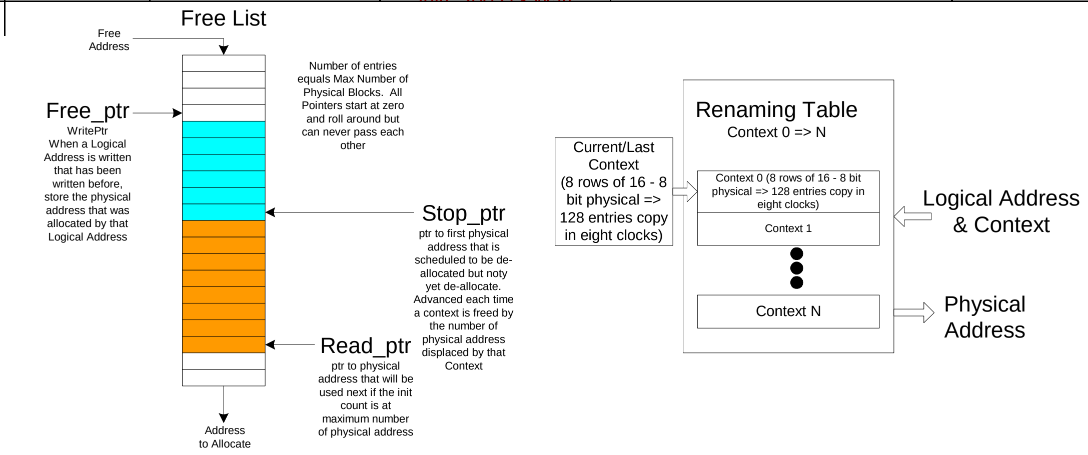
The constant memory update will be incremental, the driver only need to update the constants that actually changed between the two state changes.

For this model to work in its simplest form, the requirement is that the physical memory MUST be at least twice as large as the logical address space + the space allocated for Real Time. In our case, since the logical address space is 512 and the reserved RT space can be up to 256 entries, the memory must be of sizes 1280 and above. Similarly the size of the texture store must be of 32*2+32 = 96 entries and above.

5.3.2 *Proposal for R400LE constant management*

To make this scheme work with only 512+256 = 768 entries, upon reception of a CONTROL packet of state + 1, the sequencer would check for SQ_IDLE and PA_IDLE and if both are idle will erase the content of state to replace it with the new state (this is depicted in Figure 8: De-allocation mechanism~~Figure 8: De-allocation mechanismFigure 8: De-allocation mechanism~~). Note that in the case a state is cleared a value of 0 is written to the corresponding de-allocation counter location so that when the SQ is going to report a state change, nothing will be de-allocated upon the first report.

The second path sets all context dirty bits that were used in the current state to 1 (thus allowing the new state to reuse these physical addresses if needed).



Free List
Free Address
Free_ptr
WritePtr
When a Logical Address is written that has been written before, store the physical address that was allocated by that Logical Address
Number of entries equals Max Number of Physical Blocks. All Pointers start at zero and roll around but can never pass each other
Stop_ptr
ptr to first physical address that is scheduled to be de-allocated but noty yet de-allocate. Advanced each time a context is freed by the number of physical address displaced by that Context
Read_ptr
ptr to physical address that will be used next if the init count is at maximum number of physical address
Address to Allocate
Current/Last Context (8 rows of 16 - 8 bit physical => 128 entries copy in eight clocks)

This Context Dirty per Logical Address (If set don't allocate or de-allocate)
Context & Logical Address
Renaming table N-Contexts
Copy Last held above to Current Context on receipt of Set Constant for a new context (Hide loading behind Set State load - 16 clocks) all other Set States just write one entry to current state.

Figure 7: Constant management

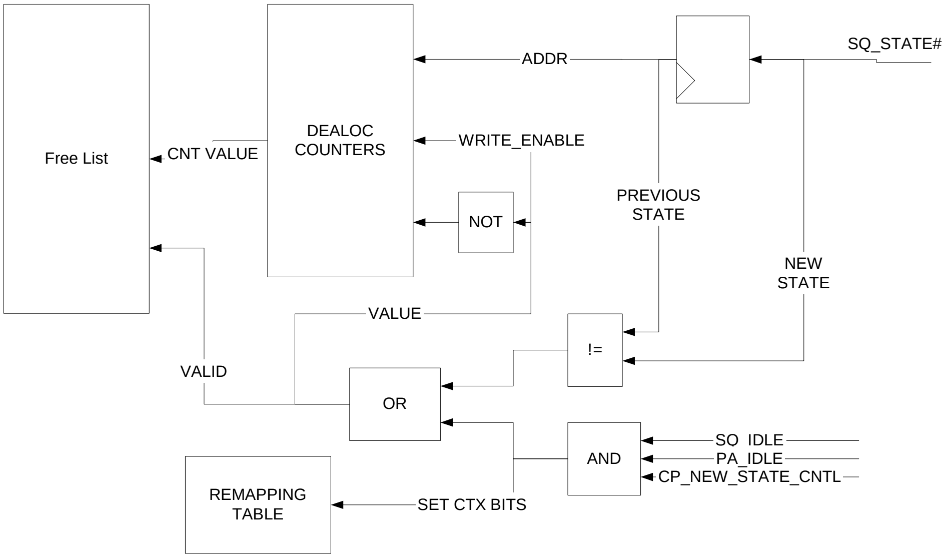

Figure 8: De-allocation mechanism for R400LE

5.3.3 *Dirty bits*

Two sets of dirty bits will be maintained per logical address. The first one will be set to zero on reset and set when the logical address is addressed. The second one will be set to zero whenever a new context is written and set for each address written while in this context. The reset dirty is not set, then writing to that logical address will not require de-allocation of whatever address stored in the renaming table. If it is set and the context dirty is not set, then the physical address store needs to be de-allocated and a new physical address is necessary to store the incoming data. If they are both set, then the data will be written into the physical address held in the renaming for the current logical address. No de-allocation or allocation takes place. This will happen when the driver does a set constant twice to the same logical address between context changes. NOTE: It is important to detect and prevent this, failure to do it will allow multiple writes to allocate all physical memory and thus hang because a context will not fit for rendering to start and thus free up space.

5.3.4 *Free List Block*

A free list block that would consist of a counter (called the IFC or Initial Free Counter) that would reset to zero and incremented every time a chunk of physical memory is used until they have all been used once. This counter would be checked each time a physical block is needed, and if the original ones have not been used up, us a new one, else check the free list for an available physical block address. The count is the physical address for when getting a chunk from the counter.

Storage of a free list big enough to store all physical block addresses.

Maintain three pointers for the free list that are reset to zero. The first one we will call write_ptr. This pointer will identify the next location to write the physical address of a block to be de-allocated. Note: we can never free more physical memory locations than we have. Once recording address the pointer will be incremented to walk the free list like a ring.

The second pointer will be called stop_ptr. The stop_ptr pointer will be advanced by the number of address chunks de-allocates when a context finishes. The address between the stop_ptr and write_ptr cannot be reused because they are still in use. But as soon as the context using then is dismissed the stop_ptr will be advanced.

The third pointer will be called read_ptr. This pointer will point will point to the next address that can be used for allocation as long as the read_ptr does not equal the stop_ptr and the IFC is at its maximum count.

5.3.5 *De-allocate Block*

This block will maintain a free physical address block count for each context. While in current context, a count shall be maintained specifying how many blocks were written into the free list at the write_ptr pointer. This count will be reset upon reset or when this context is active on the back and different than the previous context. It is actually a count of blocks in the previous context that will no longer be used. This count will be used to advance the write_ptr pointer to make available the set of physical blocks freed when the previous context was done. This allows the discard or de-allocation of any number of blocks in one clock.

5.3.6 *Operation of Incremental model*

The basic operation of the model would start with the write_ptr, stop_ptr, read_ptr pointers in the free list set to zero and the free list counter is set to zero. Also all the dirty bits and the previous context will be initialized to zero. When the first set constants happen, the reset dirty bit will not be set, so we will allocate a physical location from the free list counter because its not at the max value. The data will be written into physical address zero. Both the additional copy of the renaming table and the context zeros of the big renaming table will be updated for the logical address that was written by set start with physical address of 0. This process will be repeated for any logical address that are not dirty until the context changes. If a logical address is hit that has its dirty bits set while in the same context, both dirty bits would be set, so the new data will be over-written to the last physical address assigned for this logical address. When the first draw command of the context is detected, the previous context stored in the additional renaming table will be copied to the larger renaming table in the current (new) context location. Then the set constant logical address with be loaded with a new physical address during the copy and if the reset dirty was set, the physical address it replaced in the renaming table would be entered at the write_ptr pointer location on the free list and the write_ptr will be incremented. The de-allocation counter for the previous context (eight) will be incremented. This as set states come in for this context one of the following will happen:

1.) No dirty bits are set for the logical address being updated. A line will be allocated of the free-list counter or the free list at read_ptr pointer if read_ptr != to stop_ptr .
2.) Reset dirty set and Context dirty not set. A new physical address is allocated, the physical address in the renaming table is put on the free list at write_ptr and it is incremented along with the de-allocate counter for the last context.
3.) Context dirty is set then the data will be written into the physical address specified by the logical address.

This process will continue as long as set states arrive. This block will provide backpressure to the CP whenever he has not free list entries available (counter at max and stop_ptr == read_ptr). The command stream will keep a count of contexts of constants in use and prevent more than max constants contexts from being sent.

Whenever a draw packet arrives, the content of the re-mapping table is written to the correct re-mapping table for the context number. Also if the next context uses less constants than the current one all exceeding lines are moved to the free list to be de-allocated later. This happens in parallel with the writing of the re-mapping table to the correct memory.

Now preferable when the constant context leaves the last ALU clause it will be sent to this block and compared with the previous context that left. (Init to zero) If they differ than the older context will no longer be referenced and thus can be de-allocated in the physical memory. This is accomplished by adding the number of blocks freed this context to the stop_ptr pointer. This will make all the physical addresses used by this context available to the read_ptr allocate pointer for future allocation.

This device allows representation of multiple contexts of constants data with N copies of the logical address space. It also allows the second context to be represented as the first set plus some new additional data by just storing the delta's. It allows memory to be efficiently used and when the constants updates are small it can store multiple context. However, if the updates are large, less contexts will be stored and potentially performance will be degraded. Although it will still perform as well as a ring could in this case.

5.4 Constant Store Indexing

In order to do constant store indexing, the sequencer must be loaded first with the indexes (that come from the GPRs). There are 144 wires from the exit of the SP to the sequencer (9 bits pointers x 16 vertexes/clock). Since the data must pass thru the Shader pipe for the float to fixed conversion, there is a latency of 4 clocks (1 instruction)

between the time the sequencer is loaded and the time one can index into the constant store. The assembly will look like this

```
MOVA  R1.X,R2.X       // Loads the sequencer with the content of R2.X, also copies the content of R2.X into R1.X
NOP                   // latency of the float to fixed conversion
ADD   R3,R4,C0[R2.X]// Uses the state from the sequencer to add R4 to C0[R2.X] into R3
```

Note that we don't really care about what is in the brackets because we use the state from the MOVA instruction. R2.X is just written again for the sake of simplicity and coherency.

The storage needed in the sequencer in order to support this feature is 2*64*9 bits = 1152 bits.

5.5 Real Time Commands

The real time commands constants are written by the CP using the register mapped registers allocated for RT. It works is the same way than when dealing with regular constant loads BUT in this case the CP is not sending a logical address but rather a physical address and the reads are not passing thru the re-mapping table but are directly read from the memory. The boundary between the two zones is defined by the CONST_EO_RT control register. Similarly, for the fetch state, the boundary between the two zones is defined by the TSTATE_EO_RT control register.

5.6 Constant Waterfalling

In order to have a reasonable performance in the case of constant store indexing using the address register, we are going to have the possibility of using the physical memory port for read only. This way we can read 1 constant per clock and thus have a worst-case waterfall mode of 1 vertex per clock. There is a small synchronization issue related with this as we need for the SQ to make sure that the constants where actually written to memory (not only sent to the sequencer) before it can allow the first vector of pixels or vertices of the state to go thru the ALUs. To do so, the sequencer keeps 8 bits (one per render state) and sets the bits whenever the last render state is written to memory and clears the bit whenever a state is freed.

6. Looping and Branches

Loops and branches are planned to be supported and will have to be dealt with at the sequencer level. We plan on supporting constant loops and branches using a control program.

6.1 The controlling state.

The R400 controling state consists of:

Boolean[256:0]
Loop_count[7:0][31:0]
Loop_Start[7:0][31:0]
Loop_Step[7:0][31:0]

That is 256 Booleans and 32 loops.

We have a stack of 4 elements for nested calls of subroutines and 4 loop counters to allow for nested loops.

This state is available on a per shader program basis.

6.2 The Control Flow Program

We'd like to be able to code up a program of the form:

```
1:      Loop
2:      Exec    TexFetch
3:              TexFetch
4:              ALU
5:              ALU
6:              TexFetch
7:      End Loop
8:      ALU Export
```

But realize that 3: may be dependent on 2: and 4: is almost certainly dependent on 2: and 3:. Without clausing, these dependencies need to be expressed in the Control Flow instructions. Additionally, without separate 'texture clauses' and 'ALU clauses' we need to know which instructions to dispatch to the Texture Unit and which to the ALU unit. This information will be encapsulated in the flow control instructions.

Each control flow instruction will contain 2 bits of information for each (non-control flow) instruction:
a) ALU or Texture
b) Serialize Execution

(b) would force the thread to stop execution at this point (before the instruction is executed) and wait until all textures have been fetched. Given the allocation of reserved bits, this would mean that the count of an 'Exec' instruction would be limited to about 8 (non-control-flow) instructions. If more than this were needed, a second Exec (with the same conditions) would be issued.

Another function that relies upon 'clauses' is allocation and order of execution. We need to assure that pixels and vertices are exported in the correct order (even if not all execution is ordered) and that space in the output buffers are allocated in order. Additionally data can't be exported until space is allocated. A new control flow instruction:

Alloc <buffer select -- position,parameter, pixel or vertex memory. And the size required>.

would be created to mark where such allocation needs to be done. To assure allocation is done in order, the actual allocation for a given thread can not be performed unless the equivalent allocation for all previous threads is already completed. The implementation would also assure that execution of instruction(s) following the serialization due to the Alloc will occur in order -- at least until the next serialization or change from ALU to Texture. In most cases this will allow the exports to occur without any further synchronization. Only 'final' allocations or position allocations are

guaranteed to be ordered. Because strict ordering is required for pixels, parameters and positions, this implies only a single alloc for these structures. Vertex exports to memory do not require ordering during allocation and so multiple 'allocs' may be done.

6.2.1 *Control flow instructions table*

Here is the revised control flow instruction set.

Note that whenever a field is marked as RESERVED, it is assumed that all the bits of the field are cleared (0).

NOP		
47 … 44	43	42 … 0
0000	Addressing	RESERVED

This is a regular NOP.

Execute					
47 … 44	43	40 … 34	33 …16	15…12	11 … 0
0001	Addressing	RESERVED	Instructions type + serialize (9 instructions)	Count	Exec Address

Execute_End					
47 … 44	43	40 … 34	33 …16	15…12	11 … 0
0010	Addressing	RESERVED	Instructions type + serialize (9 instructions)	Count	Exec Address

Execute up to 9 instructions at the specified address in the instruction memory. The Instruction type field tells the sequencer the type of the instruction (LSB) (1 = Texture, 0 = ALU and whether to serialize or not the execution (MSB) (1 = Serialize, 0 = Non-Serialized). If Execute_End this is the last execution block of the shader program.

Conditional_Execute						
47 … 44	43	42	41 … 34	33…16	15 …12	11 … 0
0011	Addressing	Condition	Boolean address	Instructions type + serialize (9 instructions)	Count	Exec Address

Conditional_Execute_End						
47 … 44	43	42	41 … 34	33…16	15 …12	11 … 0
0100	Addressing	Condition	Boolean address	Instructions type + serialize (9 instructions)	Count	Exec Address

If the specified Boolean (8 bits can address 256 Booleans) meets the specified condition then execute the specified instructions (up to 9 instructions). If the condition is not met, we go on to the next control flow instruction. If Conditional_Execute_End and the condition is met, this is the last execution block of the shader program.

Conditional_Execute_Predicates							
47 … 44	43	42	41 … 36	35 … 34	33…16	15…12	11 … 0
0101	Addressing	Condition	RESERVED	Predicate vector	Instructions type + serialize (9 instructions)	Count	Exec Address

Conditional_Execute_Predicates_End							
47 … 44	43	42	41 … 36	35 … 34	33…16	15…12	11 … 0
0110	Addressing	Condition	RESERVED	Predicate vector	Instructions type + serialize (9 instructions)	Count	Exec Address

Check the AND/OR of all current predicate bits. If AND/OR matches the condition execute the specified number of instructions. We need to AND/OR this with the kill mask in order not to consider the pixels that aren't valid. If the

condition is not met, we go on to the next control flow instruction. If Conditional_Execute_Predicates_End and the condition is met, this is the last execution block of the shader program.

Conditional_Execute_Predicates_No_Stall							
47 … 44	43	42	41 … 36	35 … 34	33…16	15…12	11 … 0
1101	Addressing	Condition	RESERVED	Predicate vector	Instructions type + serialize (9 instructions)	Count	Exec Address

Conditional_Execute_Predicates_No_Stall_End							
47 … 44	43	42	41 … 36	35 … 34	33…16	15…12	11 … 0
1110	Addressing	Condition	RESERVED	Predicate vector	Instructions type + serialize (9 instructions)	Count	Exec Address

Same as Conditionnal_Execute_Predicates but the SQ is not going to wait for the predicate vector to be updated. You can only set this in the compiler if you know that the predicate set is only a refinement of the current one (like a nested if) because the optimization would still work.

Loop_Start					
47 … 44	43	42 … ~~17~~21	20 … 16	15…12	11 … 0
0111	Addressing	RESERVED	loop ID	RESERVED	Jump address

Loop Start. Compares the loop iterator with the end value. If loop condition not met jump to the address. Forward jump only. Also computes the index value. The loop id must match between the start to end, and also indicates which control flow constants should be used with the loop.

Loop_End						
47 … 44	43	42 … 24	23… 21	20 … 16	15…12	11 … 0
1000	Addressing	RESERVED	Predicate break	loop ID	RESERVED	start address

Loop end. Increments the counter by one, compares the loop count with the end value. If loop condition met, continue, else, jump BACK to the start of the loop. If predicate break != 0, then compares predicate vector n (specified by predicate break number). If all bits cleared then break the loop.

The way this is described does not prevent nested loops, and the inclusion of the loop id make this easy to do.

Conditionnal_Call						
47 … 44	43	42	41 … 34	33 … 13	12	11 … 0
1001	Addressing	Condition	Boolean address	RESERVED	Force Call	Jump address

If the condition is met, jumps to the specified address and pushes the control flow program counter on the stack. If force call is set the condition is ignored and the call is made always.

Return		
47 … 44	43	42 … 0
1010	Addressing	RESERVED

Pops the topmost address from the stack and jumps to that address. If nothing is on the stack, the program will just continue to the next instruction.

Conditionnal_Jump							
47 … 44	43	42	41… 34	33	32 … 13	12	11 … 0
1011	Addressing	Condition	Boolean address	FW only	RESERVED	Force Jump	Jump address

If force jump is set the condition is ignored and the jump is made always. If FW only is set then only forward jumps are allowed.

Allocate				
47 … 44	43	42…41	40 … 4	3 …0
1100	Debug	Buffer Select	RESERVED	Allocation size

Buffer Select takes a value of the following:
01 – position export (ordered export)
10 – parameter cache or pixel export (ordered export)
11 – pass thru (out of order exports).

Buffer Size takes a value of the following:
00 – 1 buffer
01 – 2 buffers
…
15 – 16 buffers

If debug is set this is a debug alloc (ignore if debug DB_ON register is set to off).

6.3 Implementation

The envisioned implementation has a buffer that maintains the state of each thread. A thread lives in a given location in the buffer during its entire life, but the buffer has FIFO qualities in that threads leave in the order that they enter. Actually two buffers are maintained -- one for Vertices and one for Pixels. The intended implementation would allow for:

16 entries for vertices
48 entries for pixels.

From each buffer, arbitration logic attempts to select 1 thread for the texture unit and 1 (interleaved) thread for the ALU unit. Once a thread is selected it is read out of the buffer, marked as invalid, and submitted to appropriate execution unit. It is returned to the buffer (at the same place) with its status updated once all possible sequential instructions have been executed. A switch from ALU to TEX or visa-versa or a Serialize_Execution modifier forces the thread to be returned to the buffer.

Each entry in the buffer will be stored across two physical pieces of memory - most bits will be stored in a 1 read port device. Only bits needed for thread arbitration will be stored in a highly multi-ported structure. The bits kept in the 1 read port device will be termed 'state'. The bits kept in the multi-read ported device will be termed 'status'.

'State Bits' needed include:

1. Control Flow Instruction Pointer (13 bits),
2. Execution Count Marker 4 bits),
3. Loop Iterators (4x9 bits),
4. Call return pointers (4x12 bits),
5. Predicate Bits (64 bits),
6. Export ID (1 bit),
7. Parameter Cache base Ptr (7 bits),
8. GPR Base Ptr (8 bits),
9. Context Ptr (3 bits).
10. LOD corrections (6x16 bits)
11. Valid bits (64 bits)

Absent from this list are 'Index' pointers. These are costly enough that I'm presuming that they are instead stored in the GPRs. The first seven fields above (Control Flow Ptr, Execution Count, Loop Counts, call return ptrs, Predicate bits, PC base ptr and export ID) are updated every time the thread is returned to the buffer based on how much progress has been mode on thread execution. GPR Base Ptr, Context Ptr and LOD corrections are unchanged throughout execution of the thread.

'Status Bits' needed include:

- Valid Thread
- Texture/ALU engine needed
- Texture Reads are outstanding
- Waiting on Texture Read to Complete
- Allocation Wait (2 bits)
- 00 – No allocation needed
- 01 – Position export allocation needed (ordered export)
- 10 – Parameter or pixel export needed (ordered export)
- 11 – pass thru (out of order export)
- Allocation Size (4 bits)
- Position Allocated
- First thread of a new context
- Event thread (NULL thread that needs to trickle down the pipe)
- Last (1 bit)
- Pulse SX (1 bit)

All of the above fields from all of the entries go into the arbitration circuitry. The arbitration circuitry will select a winner for both the Texture Engine and for the ALU engine. There are actually two sets of arbitration -- one for pixels and one for vertices. A final selection is then done between the two. But the rest of this implementation summary only considers the 'first' level selection which is similar for both pixels and vertices.

Texture arbitration requires no allocation or ordering so it is purely based on selecting the 'oldest' thread that requires the Texture Engine.

ALU arbitration is a little more complicated. First, only threads where either of Texture_Reads_outstanding or Waiting_on_Texture_Read_to_Complete are '0' are considered. Then if Allocation_Wait is active, these threads are further filtered based on whether space is available. If the allocation is position allocation, then the thread is only considered if all 'older' threads have already done their position allocation (position allocated bits set). If the allocation is parameter or pixel allocation, then the thread is only considered if it is the oldest thread. Also a thread is not considered if it is a parameter or pixel or position allocation, has its First_thread_of_a_new_context bit set and would cause ALU interleaving with another thread performing the same parameter or pixel or position allocation. Finally the 'oldest' of the threads that pass through the above filters is selected. If the thread needed to allocate, then at this time the allocation is done, based on Allocation_Size. If a thread has its “last” bit set, then it is also removed from the buffer, never to return.

If I now redefine 'clauses' to mean 'how many times the thread is removed from the thread buffer for the purpose of exection by either the ALU or Texture engine', then the minimum number of clauses needed is 2 -- one to perform the allocation for exports (execution automatically halts after an 'Alloc' instruction) (but doesn't performs the actual allocation) and one for the actual ALU/export instructions. As the 'Alloc' instruction could be part of a texture clause (presumably the final instruction in such a clause), a thread could still execute in this minimal number of 2 clauses, even if it involved texture fetching.

The Texture_Reads_Outstanding bit must be updated by the sequencer, based on keeping track of how many Texture Clauses have been executed by a given thread that have not yet had there data returned. Any number above 0 results in this bit being set. We could consider forcing synchronization such that two texture clauses for a given thread may not be outstanding at any time (that would be my preference for simplicity reasons and because it would require only very little change in the texture pipe interface). This would allow the sequencer to set the bit on execution of the texture clause, and allow the texture unit to return a pointer to the thread buffer on completion that clears the bit.

6.4 Data dependant predicate instructions

Data dependant conditionals will be supported in the R400. The only way we plan to support those is by supporting three vector/scalar predicate operations of the form:

PRED_SETE_# - similar to SETE except that the result is 'exported' to the sequencer.
PRED_SETNE_# - similar to SETNE except that the result is 'exported' to the sequencer.
PRED_SETGT_# - similar to SETGT except that the result is 'exported' to the sequencer
PRED_SETGTE_# - similar to SETGTE except that the result is 'exported' to the sequencer

For the scalar operations only we will also support the two following instructions:

PRED_SETE0_# – SETE0
PRED_SETE1_# – SETE1

The export is a single bit - 1 or 0 that is sent using the same data path as the MOVA instruction.   The sequencer will maintain 4 sets of 64 bit predicate vectors (in fact 8 sets because we interleave two programs but only 4 will be exposed) and use it to control the write masking. This predicate is not maintained across clause boundaries. The # sign is used to specify which predicate set you want to use 0 thru 3.

Then we have two conditional execute bits. The first bit is a conditional execute “on” bit and the second bit tells us if we execute on 1 or 0. For example, the instruction:

P0_ADD_# R0,R1,R2

Is only going to write the result of the ADD into those GPRs whose predicate bit is 0. Alternatively, P1_ADD_# would only write the results to the GPRs whose predicate bit is set. The use of the P0 or P1 without precharging the sequencer with a PRED instruction is undefined.

{Issue: do we have to have a NOP between PRED and the first instruction that uses a predicate?}

6.5 HW Detection of PV,PS

Because of the control program, the compiler cannot detect statically dependant instructions. In the case of non-masked writes and subsequent reads the sequencer will insert uses of PV,PS as needed. This will be done by comparing the read address and the write address of consecutive instructions. For masked writes, the sequencer will insert NOPs wherever there is a dependant read/write.

The sequencer will also have to insert NOPs between PRED_SET and MOVA instructions and their uses.

6.6 Register file indexing

Because we can have loops in fetch clause, we need to be able to index into the register file in order to retrieve the data created in a fetch clause loop and use it into an ALU clause. The instruction will include the base address for register indexing and the instruction will contain these controls:

Bit7	Bit 6	
0	0	'absolute register'
0	1	'relative register'
1	0	'previous vector'
1	1	'previous scalar'

In the case of an absolute register we just take the address as is. In the case of a relative register read we take the base address and we add to it the loop_index and this becomes our new address that we give to the shader pipe.

The sequencer is going to keep a loop index computed as such:

Index = Loop_iterator*Loop_step + Loop_start.

We loop until loop_iterator = loop_count. Loop_step is a signed value [-128…127]. The computed index value is a 10 bit counter that is also signed. Its real range is [-256,256]. The tenth bit is only there so that we can provide an out of range value to the “indexing logic” so that it knows when the provided index is out of range and thus can make the necessary arrangements.

6.7 Debugging the Shaders

In order to be able to debug the pixel/vertex shaders efficiently, we provide 2 methods.

6.7.1 *Method 1: Debugging registers*

Current plans are to expose 2 debugging, or error notification, registers:
1. address register where the first error occurred
2. count of the number of errors

The sequencer will detect the following groups of errors:
- count overflow
- constant indexing overflow
- register indexing overflow

Compiler recognizable errors:
- jump errors
    relative jump address > size of the control flow program
- call stack
    call with stack full
    return with stack empty

A jump error will always cause the program to break. In this case, a break means that a clause will halt execution, but allowing further clauses to be executed.

With all the other errors, program can continue to run, potentially to worst-case limits. The program will only break if the DB_PROB_BREAK register is set.

If indexing outside of the constant or the register range, causing an overflow error, the hardware is specified to return the value with an index of 0. This could be exploited to generate error tokens, by reserving and initializing the 0th register (or constant) for errors.

{ISSUE : Interrupt to the driver or not?}

6.7.2 *Method 2: Exporting the values in the GPRs*

1) The sequencer will have a debug active, count register and an address register for this mode.

Under the normal mode execution follows the normal course.

Under the debug mode it is assumed that the program is always exporting n debug vectors and that all other exports to the SX block (position, color, z, ect) will been turned off (changed into NOPs) by the sequencer (even if they occur before the address stated by the ADDR debug register).

7. Pixel Kill Mask

A vector of 64 bits is kept by the sequencer per group of pixels/vertices. Its purpose is to optimize the texture fetch requests and allow the shader pipe to kill pixels using the following instructions:

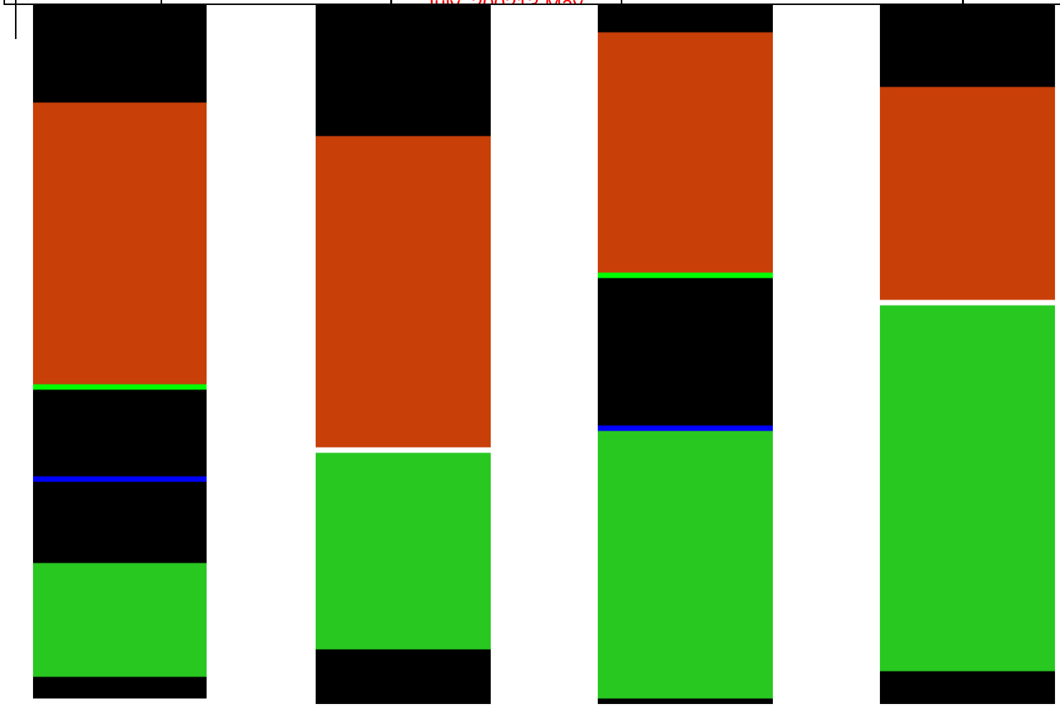
MASK_SETE
MASK_SETNE
MASK_SETGT
MASK_SETGTE

8. Multipass vertex shaders (HOS)

Multipass vertex shaders are able to export from the 6 last clauses but to memory ONLY.

9. Register file allocation

The register file allocation for vertices and pixels can either be static or dynamic. In both cases, the register file in managed using two round robins (one for pixels and one for vertices). In the dynamic case the boundary between pixels and vertices is allowed to move, in the static case it is fixed to 128-VERTEX_REG_SIZE for vertices and PIXEL_REG_SIZE for pixels.



Above is an example of how the algorithm works. Vertices come in from top to bottom; pixels come in from bottom to top. Vertices are in orange and pixels in green. The blue line is the tail of the vertices and the green line is the tail of the pixels. Thus anything between the two lines is shared. When pixels meets vertices the line turns white and the boundary is static until both vertices and pixels share the same “unallocated bubble”. Then the boundary is allowed to move again. The numbering of the GPRs starts from the bottom of the picture at index 0 and goes up to the top at index 127.

10. Fetch Arbitration

The fetch arbitration logic chooses one of the ~~8~~ n potentially pending fetch clauses to be executed. The choice is made by looking at the ~~fifos from 7 to 0~~Vs and Ps reservation stations and picking the first one ready to execute. Once chosen, the clause state machine will send one 2x2 fetch per clock (or 4 fetches in one clock every 4 clocks) until all the fetch instructions of the clause are sent. This means that there cannot be any dependencies between two fetches of the same clause.

The arbitrator will not wait for the fetches to return prior to selecting another clause for execution. The fetch pipe will be able to handle up to X(?) in flight fetches and thus there can be a fair number of active clauses waiting for their fetch return data.

11. ALU Arbitration

ALU arbitration proceeds in almost the same way than fetch arbitration. The ALU arbitration logic chooses one of the ~~8~~ n potentially pending ALU clauses to be executed. The choice is made by looking at the Vs and Ps reservation stations and picking the first one ready to execute~~The choice is made by looking at the fifos from 7 to 0 and picking the first one ready to execute~~. There are two ALU arbiters, one for the even clocks and one for the odd clocks. For example, here is the sequencing of two interleaved ALU clauses (E and O stands for Even and Odd sets of 4 clocks):

Einst0 Oinst0 Einst1 Oinst1 Einst2 Oinst2 Einst0 Oinst3 Einst1 Oinst4 Einst2 Oinst0…

Proceeding this way hides the latency of 8 clocks of the ALUs. Also note that the interleaving also occurs across clause boundaries.

12. Handling Stalls

When the output file is full, the sequencer prevents the ALU arbitration logic from selecting the last clause (this way nothing can exit the shader pipe until there is place in the output file. If the packet is a vertex packet and the position buffer is full (POS_FULL) then the sequencer also prevents a thread from entering ~~the~~ an exporting clause. ~~(3?).~~ The sequencer will set the OUT_FILE_FULL signal n clocks before the output file is actually full and thus the ALU arbiter will be able read this signal and act accordingly by not preventing exporting clauses to proceed.

13. Content of the reservation station FIFOs

The reservation FIFOs contain the state of the vector of pixels and vertices. We have two sets of those: one for pixels, and one for vertices. They contain 3 bits of Render State 7 bits for the base address of the GPRs, some bits for LOD correction and coverage mask information in order to fetch fetch for only valid pixels, the quad address.

14. The Output File

The output file is where pixels are put before they go to the RBs. The write BW to this store is 256 bits/clock. Just before this output file are staging registers with write BW 512 bits/clock and read BW 256 bits/clock. The staging registers are 4x128 (and there are 16 of those on the whole chip).

15. IJ Format

The IJ information sent by the PA is of this format on a per quad basis:

We have a vector of IJ's (one IJ per pixel at the centroid of the fragment or at the center of the pixel depending on the mode bit). ~~The interpolation is done at a different precision across the 2x2. The upper left~~All pixel's parameters are always interpolated at full 20x24 mantissa precision. ~~Then the result of the interpolation along with the difference in IJ in reduced precision is used to interpolate the parameter for the other three pixels of the 2x2. Here is how we do it:~~

~~Assuming P0 is the interpolated parameter at Pixel 0 having the barycentric coordinates I(0), J(0) and so on for P1,P2 and P3. Also assuming that A is the parameter value at V0 (interpolated with I), B is the parameter value at V1 (interpolated with J) and C is the parameter value at V2 (interpolated with (1-I-J).~~

$$P0 = A + I(0)*(B - A) + J(0)*(C - A)$$
$$P1 = A + I(1)*(B - A) + J(1)*(C - A)$$
$$P2 = A + I(2)*(B - A) + J(2)*(C - A)$$
$$P3 = A + I(3)*(B - A) + J(3)*(C - A)$$

P0	P1
P2	P3

~~P0 is computed at 20x24 mantissa precision and P1 to P3 are computed at 8X24 mantissa precision. So far no visual degradation of the image was seen using this scheme.~~

Multiplies (Full Precision): ~~2~~8
~~Multiplies (Reduced precision): 6~~
Subtracts 19x24 (Parameters): 2
Adds: 8

FORMAT OF P~~0~~'s IJ : Mantissa 20 Exp 4 for I + Sign

Mantissa 20 Exp 4 for J + Sign

~~FORMAT of Deltas (x3):Mantissa 8 Exp 4 for I + Sign~~
~~Mantissa 8 Exp 4 for J + Sign~~

Total number of bits : 20*~~2~~ 8 ~~+ 8*6~~ + 4*8 + 4*2 = 200.
~~128~~

All numbers are kept using the un-normalized floating point convention: if exponent is different than 0 the number is normalized if not, then the number is un-normalized. The maximum range for the IJs (Full precision) is +/- ~~63~~ 1024.~~and the range for the Deltas is +/- 127.~~

15.1 Interpolation of constant attributes

Because of the floating point imprecision, we need to take special provisions if all the interpolated terms are the same or if two of the ~~barycentric coordinates~~terms are the same.

~~We start with the premise that if A = B and B = C and C = A, then P0,1,2,3 = A. Since one or more of the IJ terms may be zero, so we extend this to:~~

```
~~if (A=B and B=C and C=A)~~
~~  P0,1,2,3 = A;~~
~~else if ((I = 0) or (J = 0)) and~~
~~        ((J = 0) or (1-I-J = 0)) and~~
~~        ((1-J-I = 0) or (I = 0))) {~~
~~            if(I != 0) {~~
~~               P0 = A;~~
~~            } else if(J != 0) {~~
~~               P0 = B;~~
~~            } else {~~
~~               P0 = C;~~
~~            }~~
~~          //rest of the quad interpolated normally~~
~~}~~
~~else~~
~~{~~
~~          normal interpolation~~
~~}~~
```

16. Staging Registers

In order for the reuse of the vertices to be 14, the sequencer will have to re-order the data sent IN ORDER by the VGT for it to be aligned with the parameter cache memory arrangement. Given the following group of vertices sent by the VGT:

0 1 2 3 4 5 6 7 8 9 10 11 12 13 14 15 || 16 17 18 19 20 21 22 23 24 25 26 27 28 29 30 31 || 32 33 34 35 36 37 38 39 40 41 42 43 44 45 46 47 || 48 49 50 51 52 53 54 55 56 57 58 59 60 61 62 63

The sequencer will re-arrange them in this fashion:

0 1 2 3 16 17 18 19 32 33 34 35 48 49 50 51 || 4 5 6 7 20 21 22 23 36 37 38 39 52 53 54 55 || 8 9 10 11 24 25 26 27 40 41 42 43 56 57 58 59 || 12 13 14 15 28 29 30 31 44 45 46 47 60 61 62 63

The || markers show the SP divisions. In the event a shader pipe is broken, the VGT will send padding to account for the missing pipe. For example, if SP1 is broken, vertices 4 5 6 7 20 21 22 23 36 37 38 39 52 53 54 55 will still be sent by the VGT to the SQ **BUT** will not be processed by the SP and thus should be considered invalid (by the SU and VGT).

The most straightforward, *non-compressed* interface method would be to convert, in the VGT, the data to 32-bit floating point prior to transmission to the VSISRs. In this scenario, the data would be transmitted to (and stored in) the VSISRs in full 32-bit floating point. This method requires three 24-bit fixed-to-float converters in the VGT. Unfortunately, it also requires and additional 3,072 bits of storage across the VSISRs. This interface is illustrated in Figure 11~~Figure 11~~~~Figure 11~~. The area of the fixed-to-float converters and the VSISRs for this method is roughly estimated as 0.759sqmm using the R300 process. The gate count estimate is shown in Figure 10~~Figure 10~~~~Figure 10~~.

Basis for 8-deep Latch Memory (from R300)

8x24-bit	11631 μ^2	60.57813 μ^2 per bit
Area of 96x8-deep Latch Memory	46524 μ^2	
Area of 24-bit Fix-to-float Converter	4712 μ^2 per converter	

Method 1

Block	Quantity	Area
F2F	3	14136
8x96 Latch	16	744384
		758520 μ^2

Figure 10:Area Estimate for VGT to Shader Interface

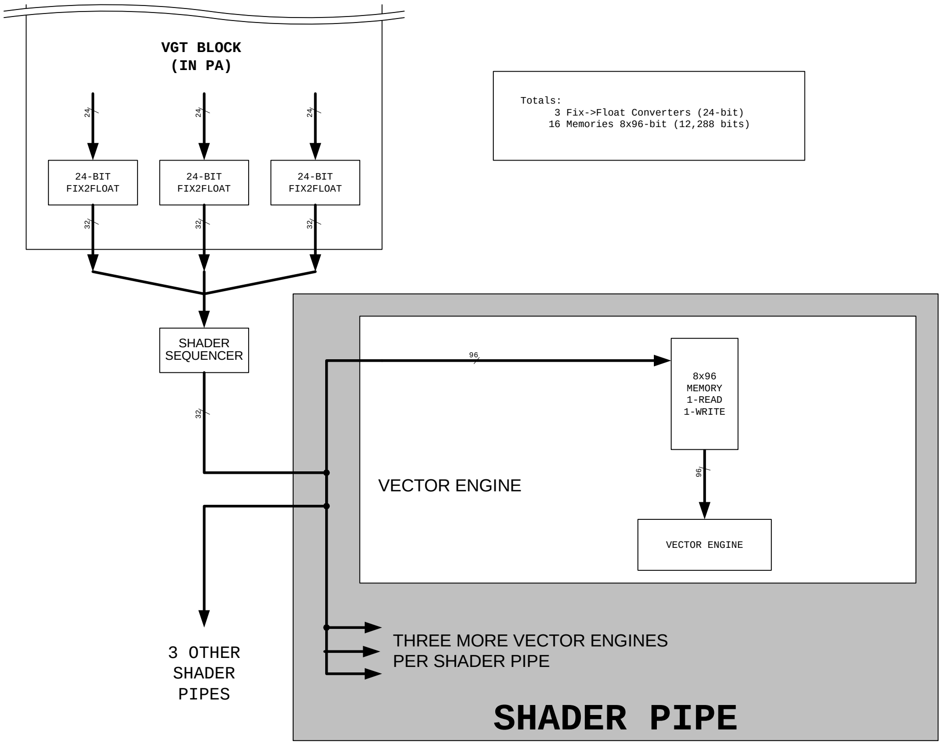


Figure 11:VGT to Shader Interface

17. The parameter cache

The parameter cache is where the vertex shaders export their data. It consists of 16 128x128 memories (1R/1W). The reuse engine will make it so that all vertexes of a given primitive will hit different memories. The allocation method for these memories is a simple round robin. The parameter cache pointers are mapped in the following way: 4MSBs are the memory number and the 7 LSBs are the address within this memory.

MEMORY NUMBER 4 bits	ADDRESS 7 bits

The PA generates the parameter cache addresses as the positions come from the SQ. All it needs to do is keep a Current_Location pointer (7 bits only) and as the positions comes increment the memory number. When the memory number field wraps around, the PA increments the Current_Location by VS_EXPORT_COUNT (a snooped register from the SQ). As an example, say the memories are all empty to begin with and the vertex shader is exporting 8 parameters per vertex (VS_EXPORT_COUNT = 8). The first position received is going to have the PC address 00000000000 the second one 00010000000, third one 00100000000 and so on up to 11110000000. Then the next position received (the 17th) is going to have the address 00000001000, the 18th 00010001000, the 19th 00100001000 and so on. The Current_location is NEVER reset BUT on chip resets. The only thing to be careful about is that if the SX doesn't send you a full group of positions (<64) then you need to fill the address space so that the next group starts correctly aligned (for example if you receive only 33 positions then you need to add 2*VS_EXPORT_COUNT to Current_Location and reset the memory count to 0 before the next vector begins).

17.1 Export restrictions

17.1.1 *Pixel exports:*

Pixels can export 1,2,3 or 4 color buffers to the SX(+z). The exports will be done in order. The PRED_OPTIMIZE function has to be turned of if the exports are done using interleaved predicated instructions. The exports will always be ordered to the SX.

17.1.2 *Vertex exports:*

Position or parameter caches can be exported in any order in the shader program. It is always better to export posistion as soon as possible. Position has to be exported in a single export block (no texture instructions can be placed between the exports). Parameter cache exports can be done in any order with texture instructions interleaved. The PRED_OPTIMIZE function has to be turned of if the exports are done using interleaved predicated instructions to the Parameter cache (see Arbitration restrictions for details). The exports will always be allocated in order to the SX.

17.1.3 *Pass thru exports:*

Pass thru exports have to be done in groups of the form:

```
Alloc 4 (8 or 12)
Execute ALU(ADDR) ALU(DATA) ALU(DATA) ALU(DATA)…
```

They cannot have texture instructions interleaved in the export block. These exports **are not guaranteed to be ordered**.

Also, when doing a pass thru export, Position MUST be exported AFTER all pass thru exports. This position export is used to synchronize the chip when doing a transition from pass thru shader to regular shader and vice versa.

17.2 Arbitration restrictions

Here are the Sequencer arbitration restrictions:

1) Cannot execute a serialized thread if the corresponding texture pending bit is set
2) Cannot allocate position if any older thread has not allocated position
3) If last thread is marked as not valid AND marked as last and we are about to execute the second to oldest thread also marked last then:

a. Both threads must be from the same context (cannot allow a first thread)
b. Must turn off the predicate optimization for the second thread

4) Cannot execute a texture clause if texture reads are pending
5) Cannot execute last if texture pending (even if not serial)

18. Export Types

The export type (or the location where the data should be put) is specified using the destination address field in the ALU instruction. Here is a list of all possible export modes:

18.1 Vertex Shading

0:15	- 16 parameter cache
16:31	- Empty (Reserved?)
32	- Export Address
33:40	- 8 vertex exports to the frame buffer and index
41:47	- Empty
48:55	- 8 debug export (interpret as normal vertex export)
60	- export addressing mode
61	- Empty
62	- position
63	- sprite size export that goes with position export (point_h,point_w,edgeflag,misc)

18.2 Pixel Shading

0	- Color for buffer 0 (primary)
1	- Color for buffer 1
2	- Color for buffer 2
3	- Color for buffer 3
4:7	- Empty
8	- Buffer 0 Color/Fog (primary)
9	- Buffer 1 Color/Fog
10	- Buffer 2 Color/Fog
11	- Buffer 3 Color/Fog
12:15	- Empty
16:31	- Empty (Reserved?)
32	- Export Address
33:40	- 8 exports for multipass pixel shaders.
41:47	- Empty
48:55	- 8 debug exports (interpret as normal pixel export)
60	- export addressing mode
61:62	- Empty
63	- Z for primary buffer (Z exported to 'alpha' component)

19. Special Interpolation modes

19.1 Real time commands

We are unable to use the parameter memory since there is no way for a command stream to write into it. Instead we need to add three 16x128 memories (one for each of three vertices x 16 interpolants). These will be mapped onto the register bus and written by type 0 packets, and output to the the parameter busses (the sequencer and/or PA need to be able to address the realtime parameter memory as well as the regular parameter store. For higher performance we should be able able to view them as two banks of 16 and do double buffering allowing one to be loaded, while the other is rasterized with. Most overlay shaders will need 2 or 4 scalar coordinates, one option might be to restrict the memory to 16x64 or 32x64 allowing only two interpolated scalars per cycle, the only problem I see with this is, if we view support for 16 vector-4 interpolants important (true only if we map Microsoft's high priority stream to the realtime stream), then the PA/sequencer need to support a realtime-specific mode where we need to address 32 vectors of parameters instead of 16. This mode is triggered by the primitive type: REAL TIME. The actual memories are in the in the SX blocks. The parameter data memories are hooked on the RBBM bus and are loaded by the CP using register mapped memory.

19.2 Sprites/ XY screen coordinates/ FB information

When working with sprites, one may want to overwrite the parameter 0 with SC generated data. Also, XY screen coordinates may be needed in the shader program. This functionality is controlled by the gen_I0 register (in SQ) in conjunction with the SND_XY register (in SC). Also it is possible to send the faceness information (for OGL front/back special operations) to the shader using the same control register. Here is a list of all the modes and how they interact together:

Gen_st is a bit taken from the interface between the SC and the SQ. This is the MSB of the primitive type. If the bit is set, it means we are dealing with Point AA, Line AA or sprite and in this case the vertex values are going to generated between 0 and 1.

Param_Gen_I0 disable, snd_xy disable, no gen_st – I0 = No modification
Param_Gen_I0 disable, snd_xy disable, gen_st – I0 = No modification
Param_Gen_I0 disable, snd_xy enable, no gen_st – I0 = No modification
Param_Gen_I0 disable, snd_xy enable, gen_st – I0 = No modification
Param_Gen_I0 enable, snd_xy disable, no gen_st – I0 = garbage, garbage, garbage, faceness
Param_Gen_I0 enable, snd_xy disable, gen_st – I0 = garbage, garbage, s, t
Param_Gen_I0 enable, snd_xy enable, no gen_st – I0 = screen x, screen y, garbage, faceness
Param_Gen_I0 enable, snd_xy enable, gen_st – I0 = screen x, screen y, s, t

19.3 Auto generated counters

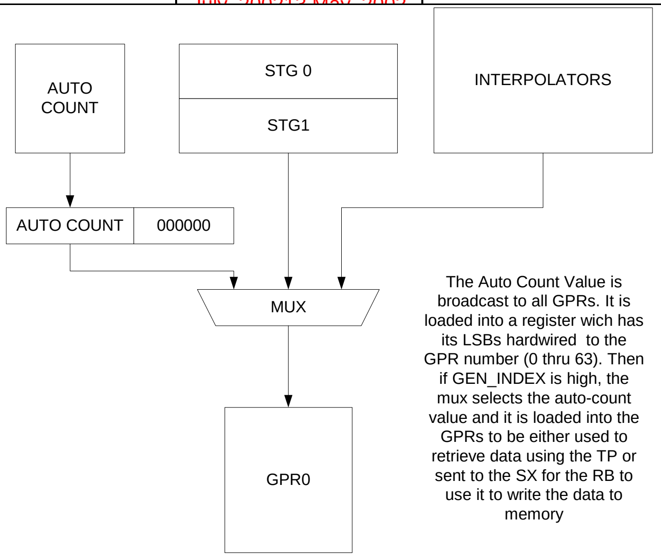
In the cases we are dealing with multipass shaders, the sequencer is going to generate a vector count to be able to both use this count to write the 1st pass data to memory and then use the count to retrieve the data on the 2nd pass. The count is always generated in the same way but it is passed to the shader in a slightly different way depending on the shader type (pixel or vertex). This is toggled on and off using the GEN_INDEX register. The sequencer is going to keep two counters, one for pixels and one for vertices. Every time a full vector of vertices or pixels is written to the GPRs the counter is incremented. Every time a state change is detected, the corresponding counter is reset. While there is only one count broadcast to the GPRs, the LSB are hardwired to specific values making the index different for all elements in the vector.

19.3.1 *Vertex shaders*

In the case of vertex shaders, if GEN_INDEX is set, the data will be put into the x field of the third register (it means that the compiler must allocate 3 GPRs in all multipass vertex shader modes).

19.3.2 *Pixel shaders*

In the case of pixel shaders, if GEN_INDEX is set and Param_Gen_I0 is enabled, the data will be put in the x field of the 2nd register (R1.x), else if GEN_INDEX is set the data will be put into the x field of the 1st register (R0.x).



The Auto Count Value is broadcast to all GPRs. It is loaded into a register wich has its LSBs hardwired to the GPR number (0 thru 63). Then if GEN_INDEX is high, the mux selects the auto-count value and it is loaded into the GPRs to be either used to retrieve data using the TP or sent to the SX for the RB to use it to write the data to memory

Figure 12: GPR input mux Control

20. State management

Every clock, the sequencer will report to the CP the oldest states still in the pipe. These are the states of the programs as they enter the last ALU clause.

20.1 Parameter cache synchronization

In order for the sequencer not to begin a group of pixels before the associated group of vertices has finished, the sequencer will keep a 6 bit count per state (for a total of 8 counters). These counters are initialized to 0 and every time a vertex shader exports its data TO THE PARAMETER CACHE, the corresponding pointer is incremented. When the SC sends a new vector of pixels with the SC_SQ_new_vector bit asserted, the sequencer will first check if the count is greater than 0 before accepting the transmission (it will in fact accept the transmission but then lower its ready to receive). Then the sequencer waits for the count to go to one and decrements it. The sequencer can then issue the group of pixels to the interpolators. Every time the state changes, the new state counter is initialized to 0.

21. XY Address imports

The SC will be able to send the XY addresses to the GPRs. It does so by interleaving the writes of the IJs (to the IJ buffer) with XY writes (to the XY buffer). Then when writing the data to the GPRs, the sequencer is going to interpolate the IJ data or pass the XY data thru a Fix→float converter and expander and write the converted values to the GPRs. The Xys are currently SCREEN SPACE COORDINATES. The values in the XY buffers will wrap. See section 19.2 for details on how to control the interpolation in this mode.

21.1 Vertex indexes imports

In order to import vertex indexes, we have 16 8x96 staging registers. These are loaded one line at a time by the VGT block (96 bits). They are loaded in floating point format and can be transferred in 4 or 8 clocks to the GPRs.

22. Registers

Please see the auto-generated web pages for register definitions.~~Control~~

~~REG_DYNAMIC Dynamic allocation (pixel/vertex) of the register file on or off.~~

~~REG_SIZE_PIX Size of the register file's pixel portion (minimal size when dynamic allocation turned on)~~
~~REG_SIZE_VTX Size of the register file's vertex portion (minimal size when dynamic allocation turned on)~~
~~ARBITRATION_POLICY policy of the arbitration between vertexes and pixels~~
~~INST_BASE_VTX start point for the vertex instruction store (RT always ends at vertex_base and Begins at 0)~~
~~INST_BASE_PIX start point for the pixel shader instruction store~~
~~ONE_THREAD debug state register. Only allows one program at a time into the GPRs~~
~~ONE_ALU debug state register. Only allows one ALU program at a time to be executed (instead of 2)~~
~~INSTRUCTION This is where the CP puts the base address of the instruction writes and type (auto-incremented on reads/writes) Register mapped~~
~~CONSTANTS 512*4 ALU constants + 32*6 Texture state 32 bits registers (logically mapped)~~
~~CONSTANTS_RT 256*4 ALU constants + 32*6 texture states? (physically mapped)~~
~~CONSTANT_EO_RT This is the size of the space reserved for real time in the constant store (from 0 to CONSTANT_EO_RT). The re-mapping table operates on the rest of the memory~~
~~TSTATE_EO_RT This is the size of the space reserved for real time in the fetch state store (from 0 to TSTATE_EO_RT). The re-mapping table operates on the rest of the memory~~

22.2 ~~Context~~

Formatted: Bullets and Numbering

~~PS_BASE base pointer for the pixel shader in the instruction store~~
~~VS_BASE base pointer for the vertex shader in the instruction store~~
~~VS_CF_SIZE size of the vertex shader (# of instructions in control program/2)~~
~~PS_CF_SIZE size of the pixel shader (# of instructions in control program/2)~~
~~PS_SIZE size of the pixel shader (cntl+instructions)~~
~~VS_SIZE size of the vertex shader (cntl+instructions)~~
~~PS_NUM_REG number of GPRs to allocate for pixel shader programs~~
~~VS_NUM_REG number of GPRs to allocate for vertex shader programs~~
~~PARAM_SHADE One 16 bit register specifying which parameters are to be gouraud shaded (0 = flat, 1 = gouraud)~~
~~PARAM_WRAP 64 bits: for which parameters (and channels (xyzw)) do we do the cyl wrapping (0=linear, 1=cylindrical).~~
~~PS_EXPORT_MODE 0xxxx : Normal mode~~
~~1xxxx : Multipass mode~~
~~If normal, bbbz where bbb is how many colors (0-4) and z is export z or not~~
~~If multipass 1-12 exports for color.~~
~~VS_EXPORT_MODE 0: position (1 vector), 1: position (2 vectors), 3:multipass~~
~~VS_EXPORT_COUNT Number of locations exported by the VS (and thus number of interpolated parameters)~~
~~PARAM_GEN_I0 Do we overwrite or not the parameter 0 with XY data and generated T and S values~~
~~GEN_INDEX Auto generates an address from 0 to XX. Puts the results into R0-1 for pixel shaders and R2 for vertex shaders~~
~~CONST_BASE_VTX (9 bits)Logical Base address for the constants of the Vertex shader~~
~~CONST_BASE_PIX (9 bits) Logical Base address for the constants of the Pixel shader~~
~~CONST_SIZE_PIX (8 bits) Size of the logical constant store for pixel shaders~~
~~CONST_SIZE_VTX (8 bits) Size of the logical constant store for vertex shaders~~
~~INST_PRED_OPTIMIZE Turns on the predicate bit optimization (if of, conditional_execute_predicates is always executed).~~
~~CF_BOOLEANS 256 boolean bits~~
~~CF_LOOP_COUNT 32x8 bit counters (number of times we traverse the loop)~~
~~CF_LOOP_START 32x8 bit counters (init value used in index computation)~~
~~CF_LOOP_STEP 32x8 bit counters (step value used in index computation)~~

~~23. DEBUG Registers~~

Formatted: Bullets and Numbering

~~23.1 Context~~

~~DB_PROB_ADDR~~	~~instruction address where the first problem occurred~~
~~DB_PROB_COUNT~~	~~number of problems encountered during the execution of the program~~
~~DB_PROB_BREAK~~	~~break the clause if an error is found.~~
~~DB_ON~~	~~turns on an off debug method 2~~
~~DB_INST_COUNT~~	~~instruction counter for debug method 2~~
~~DB_BREAK_ADDR~~	~~break address for method number 2~~

~~23.2 Control~~

Formatted: Bullets and Numbering

~~DB_ALUCST_MEMSIZE~~	~~Size of the physical ALU constant memory~~
~~DB_TSTATE_MEMSIZE~~	~~Size of the physical texture state memory~~

~~24.~~23. Interfaces

Formatted: Bullets and Numbering

~~24.1~~23.1 External Interfaces

Whenever an x is used, it means that the bus is broadcast to all units of the same name. For example, if a bus is named SQ→SPx it means that SQ is going to broadcast the same information to all SP instances.

~~24.2~~23.2 SC to SP Interfaces

Formatted: Bullets and Numbering

~~24.2.1~~23.2.1 *SC_SP#*

Formatted: Bullets and Numbering

There is one of these interfaces at front of each of the SP (buffer to stage pixel interpolators). This interface transmits the I,J data for pixel interpolation. For the entire system, two quads per clock are transferred to the 4 SPs, so each of these 4 interfaces transmits one half of a quad per clock. The interface below describes a half of a quad worth of data.
The actual data which is transferred per quad is

Ref Pix I => S4.20 Floating Point I value *4
Ref Pix J => S4.20 Floating Point J value *4
~~Delta Pix I (x3) => S4.8 Floating Point Delta I value~~
~~Delta Pix J (x3) => S4.8 Floating Point Delta J value~~

This equates to a total of ~~128~~ 200 bits which transferred over 2 clocks
and therefor needs an interface ~~64~~100 bits wide

Additionally, X,Y data (12-bit unsigned fixed) is conditionally sent across this data bus over the same wires in an additional clock. The X,Y data is sent on the lower 24 bits of the data bus with faceness in the msb.
Transfers across these interfaces are synchronized with the SC_SQ IJ Control Bus transfers.

The data transfer across each of these busses is controlled by a IJ_BUF_INUSE_COUNT in the SC. Each time the SC has sent a pixel vector's worth of data to the SPs, he will increment the IJ_BUF_INUSE_COUNT count. Prior to sending the next pixel vectors data, he will check to make sure the count is less than MAX_BUFER_MINUS_2, if not the SC will stall until the SQ returns a pipelined pulse to decrement the count when he has scheduled a buffer free. Note: We could/may optimize for the case of only sending only IJ to use all the buffers to pre-load more. Currently it is planned for the SP to hold 2 double buffers of I,J data and two buffers of X,Y data, so if either X,Y or Centers and Centroids are on, then the SC can send two Buffers.

In at least the initial version, the SC shall send 16 quads per pixel vector even if the vector is not full. This will increment buffer write address pointers correctly all the time. (We may revisit this for both the SX,SP,SQ and add a EndOfVector signal on all interfaces to quit early. We opted for the simple mode first with a belief that only the end of packet and multiple new vector signals should cause a partial vector and that this would not really be significant performance hit.)

Name	Bits	Description
SC_SP#_data	~~64~~100	IJ information sent over 2 clocks (or X,Y in 24 LSBs with faceness in upper bit) **Type 0 or 1**, First clock I, second clk J Field ULC URC LLC LRC Bits [63:39] [38:26] [25:13] [12:0] Format SE4M20 - SE4M20~~SE4M8~~ –SE4M20~~SE4M8~~ -SE4M20~~SE4M8~~ **Type 2** Field Face X Y Bits [63] [23:12] [11:0] Format Bit Unsigned Unsigned
SC_SP#_valid	1	Valid
SC_SP#_last_quad_data	1	This bit will be set on the last transfer of data per quad.
SC_SP#_type	2	0 -> Indicates centroids 1 -> Indicates centers 2 -> Indicates X,Y Data and faceness on data bus The SC shall look at state data to determine how many types to send for the interpolation process.

The # is included for clarity in the spec and will be replaced with a prefix of u#_ in the verilog module statement for the SC and the SP block will have neither because the instantiation will insert the prefix.

~~24.2.2~~23.2.2 *SC_SQ*

Formatted: Bullets and Numbering

This is the control information sent to the sequencer in order to synchronize and control the interpolation and/or loading data into the GPRs needed to execute a shader program on the sent pixels. This data will be sent over two clocks per transfer with 1 to 16 transfers. Therefore the bus (approx 94 bits) could be folded in half to approx 49 bits.

Name	Bits	Description
SC_SQ_data	46	Control Data sent to the SQ 1 clk transfers Event – valid data consist of event_id and state_id. Instruct SQ to post an event vector to send state id and event_id through request fifo and onto the reservation stations making sure state id and/or event_id gets back to the CP. Events only follow end of packets so no pixel vectors will be in progress. Empty Quad Mask – Transfer Control data consisting of pc_dealloc or new_vector. Receipt of this is to transfer pc_dealloc or new_vector without any valid quad data. New vector will always be posted to request fifo and pc_dealloc will be attached to any pixel vector outstanding or posted in request fifo if no valid quad outstanding. 2 clk transfers Quad Data Valid – Sending quad data with or without new_vector or pc_dealloc. New vector will be posted to request fifo with or without a pixel vector and

		pc_dealloc will be posted with a pixel vector unless none is in progress. In this case the pc_dealloc will be posted in the request queue. Filler quads will be transferred with The Quad mask set but the pixel corresponding pixel mask set to zero.
SC_SQ_valid	1	SC sending valid data, 2nd clk could be all zeroes

SC_SQ_data – first clock and second clock transfers are shown in the table below.

Name	BitField	Bits	Description
1st Clock Transfer			
SC_SQ_event	0	1	This transfer is a 1 clock event vector Force quad_mask = new_vector=pc_dealloc=0
SC_SQ_event_id	[4:1]	4	This field identifies the event 0 => denotes an End Of State Event 1 => TBD
SC_SQ_pc_dealloc	[7:5]	3	Deallocation token for the Parameter Cache
SC_SQ_new_vector	8	1	The SQ must wait for Vertex shader done count > 0 and after dispatching the Pixel Vector the SQ will decrement the count.
SC_SQ_quad_mask	[12:9]	4	Quad Write mask left to right SP0 => SP3
SC_SQ_end_of_prim	13	1	End Of the primitive
SC_SQ_state_id	[16:14]	3	State/constant pointer (6*3+3)
SC_SQ_pix_mask	[32:17]	16	Valid bits for all pixels SP0=>SP3 (UL,UR,LL,LR)
SC_SQ_provok_vtx	[37:36]	2	Provoking vertex for flat shading
SC_SQ_pc_ptr0	[48:38]	11	Parameter Cache pointer for vertex 0
2nd Clock Transfer			
SC_SQ_pc_ptr1	[10:0]	11	Parameter Cache pointer for vertex 1
SC_SQ_pc_ptr2	[21:11]	11	Parameter Cache pointer for vertex 2
SC_SQ_lod_correct	[45:22]	24	LOD correction per quad (6 bits per quad)
SC_SQ_prim_type	[48:46]	3~~3~~	Stippled line and Real time command need to load tex cords from alternate buffer 0~~0~~00: ~~Normal~~ Sprite (point) 001: Line 010: Tri_rect 10~~10~~0: ~~Realtime~~ Realtime Sprite (point) 101: Realtime Line 110: Realtime Tri_rect~~101: Line AA 110: Point AA (Sprite)~~

Name	Bits	Description
SQ_SC_free_buff	1	Pipelined bit that instructs SC to decrement count of buffers in use.
SQ_SC_dec_cntr_cnt	1	Pipelined bit that instructs SC to decrement count of new vector and/or event sent to prevent SC from overflowing SQ interpolator/Reservation request fifo.

The scan converter will submit a partial vector whenever:

1.) He gets a primitive marked with an end of packet signal.
2.) A current pixel vector is being assembled with at least one or more valid quads and the vector has been marked for deallocate when a primitive marked new_vector arrives. The Scan Converter will submit a partial vector (up to 16quads with zero pixel mask to fill out the vector) prior to submitting the new_vector marker\primitive.

(This will prevent a hang which can be demonstrated when all primitives in a packet three vectors are culled except for a one quad primitive that gets marked pc_dealloc (vertices maximum size). In this case two new_vectors are submitted and processed, but then one valid quad with the pc_dealloc creates a vector and then the new would wait for another vertex vector to be processed, but the one being waited for could never export until the pc_dealloc signal made it through and thus the hang.)

~~24.2.3~~23.2.3 *SQ to SX(SP): Interpolator bus*

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
SQ_SP~~X~~x_interp_flat_vtx	SQ→SPx	2	Provoking vertex for flat shading
SQ_SP~~X~~x_interp_flat_gouraud	SQ→SPx	1	Flat or gouraud shading
SQ_~~SXx~~SPx_interp_cyl_wrap	SQ→SPx	4	Wich channel needs to be cylindrical wrapped
SQ_SXx_pc_ptr0	SQ→SXx	11	Parameter Cache Pointer
SQ_SXx_pc_ptr1	SQ→SXx	11	Parameter Cache Pointer
SQ_SXx_pc_ptr2	SQ→SXx	11	Parameter Cache Pointer
SQ_SXx_rt_sel	SQ→SXx	1	Selects between RT and Normal data
SQ_SXx_pc_wr_en	SQ→SXx	1	Write enable for the PC memories
SQ_SXx_pc_wr_addr	SQ→SXx	7	Write address for the PCs
SQ_SXx_pc_channel_mask	SQ→SXx	4	Channel mask
SQ_SXx_pc_ptr_valid	SQ→SXx	1	Read pointers are valid.
SQ_SPx_interp_valid	SQ→SPx	1	Interpolation control valid

~~24.2.4~~23.2.4 *SQ to SP: Staging Register Data*

Formatted: Bullets and Numbering

This is a broadcast bus that sends the VSISR information to the staging registers of the shader pipes.

Name	Direction	Bits	Description
SQ_SPx_vsr_data	SQ→SPx	96	Pointers of indexes or HOS surface information
SQ_SPx_vsr_double	SQ→SPx	1	0: Normal 96 bits per vert 1: double 192 bits per vert
SQ_SP0_ vsr_valid	SQ→SP0	1	Data is valid
SQ_SP1_ vsr_ valid	SQ→SP1	1	Data is valid
SQ_SP2_ vsr_ valid	SQ→SP2	1	Data is valid
SQ_SP3_ vsr_ valid	SQ→SP3	1	Data is valid
SQ_SPx_vsr_read	SQ→SPx	1	Increment the read pointers

~~24.2.5~~23.2.5 *VGT to SQ : Vertex interface*

Formatted: Bullets and Numbering

~~24.2.5.1~~23.2.5.1 Interface Signal Table

The area difference between the two methods is not sufficient to warrant complicating the interface or the state requirements of the VSISRs. **Therefore, the POR for this interface is that the VGT will transmit the data to the VSISRs (via the Shader Sequencer) in full, 32-bit floating-point format.** The VGT can transmit up to six 32-bit floating-point values to each VSISR where four or more values require two transmission clocks. The data bus is 96 bits wide.

Name	Bits	Description
VGT_SQ_vsisr_data	96	Pointers of indexes or HOS surface information
VGT_SQ_event	1	VGT is sending an event
VGT_SQ_vsisr_~~double~~continued	1	0: Normal 96 bits per vert 1: double 192 bits per vert
VGT_SQ_end_of_~~vector~~vtx_vect	1	Indicates the last VSISR data set for the current process vector (for double vector data, "end_of_vector" is set on the first vector)
VGT_SQ_indx_valid	1	Vsisr data is valid
VGT_SQ_state	3	Render State (6*3+3 for constants). This signal is guaranteed to be correct when “VGT_SQ_vgt_end_of_vector” is high.
VGT_SQ_send	1	Data on the VGT_SQ is valid receive (see write-up for standard R400 SEND/RTR interface handshaking)
SQ_VGT_rtr	1	Ready to receive (see write-up for standard R400 SEND/RTR interface handshaking)

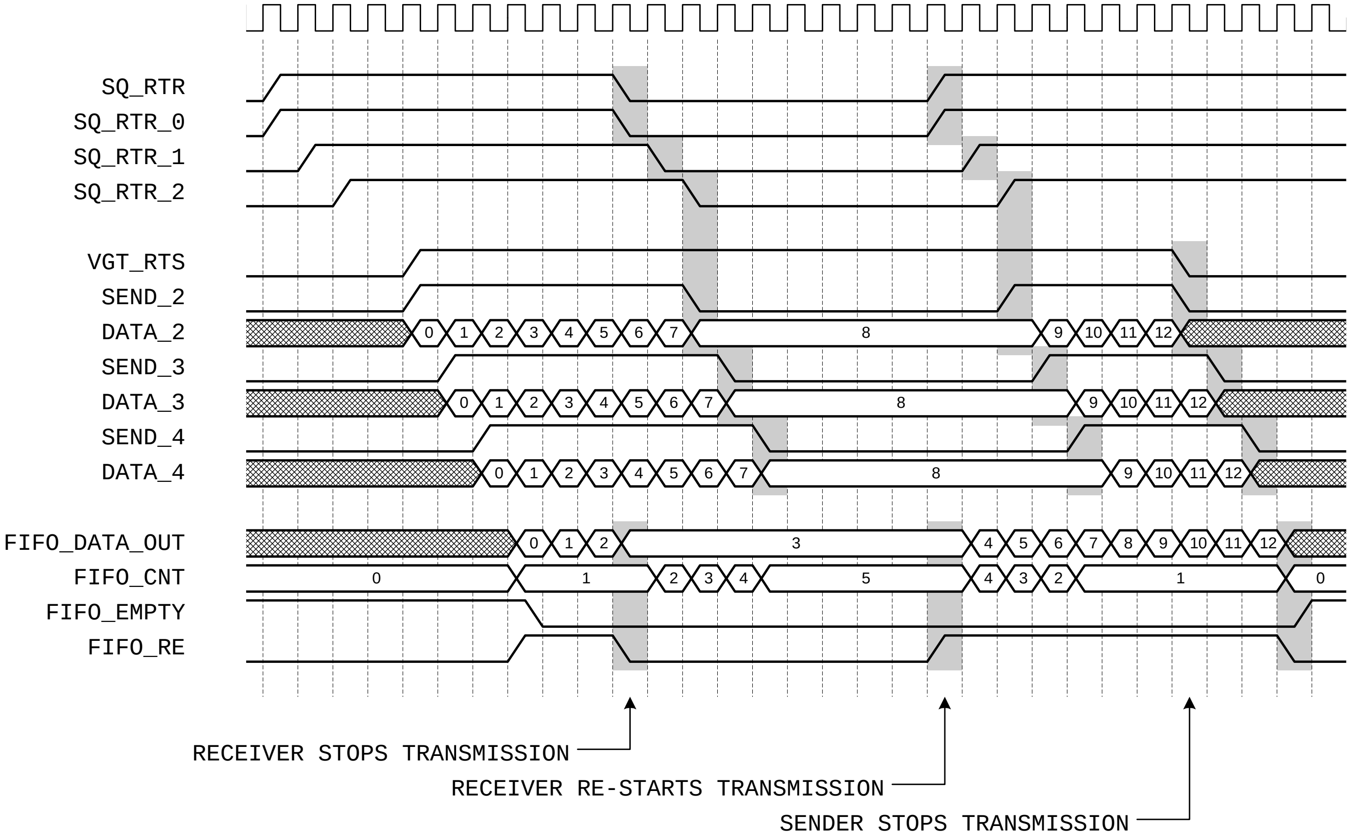

Figure 1. Detailed Logical Diagram for PA_SQ_vgt Interface.

~~24.2.6~~23.2.6 SQ to SX: Control bus

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
SQ_SXx_exp_type	SQ→SXx	2	00: Pixel without z (1 to 4 buffers) 01: Pixel with z (1 to 4 buffers) 10: Position (1 or 2 results) 11: Pass thru (4,8 or 12 results aligned)
SQ_SXx_exp_number	SQ→SXx	2	Number of locations needed in the export buffer (encoding depends on the type see bellow).
SQ_SXx_exp_alu_id	SQ→SXx	1	ALU ID
SQ_SXx_exp_valid	SQ→SXx	1	Valid bit
SQ_SXx_exp_state	SQ→SXx	3	State Context
SQ_SXx_free_done	SQ→SXx	1	Pulse to indicate that the previous export is finished (this can be sent with or without the other fields of the interface)
SQ_SXx_free_alu_id	SQ→SXx	1	ALU ID

Depending on the type the number of export location changes:

- Type 00 : Pixels without Z
    - 00 = 1 buffer
    - 01 = 2 buffers
    - 10 = 3 buffers
    - 11 = 4 buffer
- Type 01: Pixels with Z
    - 00 = 2 Buffers (color + Z)
    - 01 = 3 buffers (2 color + Z)
    - 10 = 4 buffers (3 color + Z)
    - 11 = 5 buffers (4 color + Z)
- Type 10 : Position export
    - 00 = 1 position
    - 01 = 2 positions
    - 1X = Undefined
- Type 11: Pass Thru
    - 00 = 4 buffers
    - 01 = 8 buffers
    - 10 = 12 buffers
    - 11 = Undefined

Below the thick black line is the end of transfer packet that tells the SX that a given export is finished. The report packet **will always arrive either before or at the same time than the next export to the same ALU id**.

~~24.2.7~~23.2.7 SX to SQ : Output file control

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
SXx_SQ_exp_count_rdy	SXx→SQ	1	Raised by SX0 to indicate that the following two fields reflect the result of the most recent export
SXx_SQ_exp_pos_avail	SXx→SQ	1	Specifies whether there is room for another position.
SXx_SQ_exp_buf_avail	SXx→SQ	7	Specifies the space available in the output buffers. 0: buffers are full 1: 2K-bits available (32-bits for each of the 64 pixels in a clause) ... 64: 128K-bits available (16 128-bit entries for each of 64 pixels) 65-127: RESERVED

~~24.2.8~~23.2.8 SQ to TP: Control bus

Formatted: Bullets and Numbering

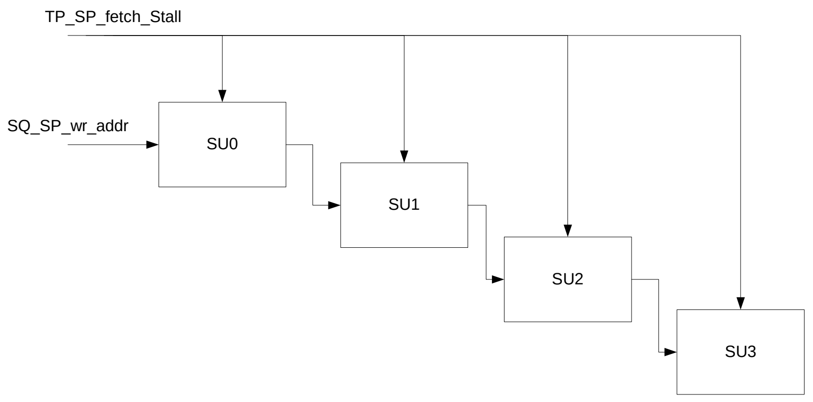
Once every clock, the fetch unit sends to the sequencer on which RS line it is now working and if the data in the GPRs is ready or not. This way the sequencer can update the fetch valid bits flags for the reservation station. The sequencer also provides the instruction and constants for the fetch to execute and the address in the register file where to write the fetch return data.

Name	Direction	Bits	Description
TPx_SQ_data_rdy	TPx→ SQ	1	Data ready
TPx_SQ_rs_line_num	TPx→ SQ	6	Line number in the Reservation station
TPx_SQ_type	TPx→ SQ	1	Type of data sent (0:PIXEL, 1:VERTEX)
SQ_TPx_send	SQ→TPx	1	Sending valid data
SQ_TPx_const	SQ→TPx	48	Fetch state sent over 4 clocks (192 bits total)
SQ_TPx_instr	SQ→TPx	24	Fetch instruction sent over 4 clocks
SQ_TPx_end_of_group	SQ→TPx	1	Last instruction of the group
SQ_TPx_Type	SQ→TPx	1	Type of data sent (0:PIXEL, 1:VERTEX)
SQ_TPx_gpr_phase	SQ→TPx	2	Write phase signal
SQ_TP0_lod_correct	SQ→TP0	6	LOD correct 3 bits per comp 2 components per quad
SQ_TP0_pix_mask	SQ→TP0	4	Pixel mask 1 bit per pixel
SQ_TP1_lod_correct	SQ→TP1	6	LOD correct 3 bits per comp 2 components per quad
SQ_TP1_pix_mask	SQ→TP1	4	Pixel mask 1 bit per pixel
SQ_TP2_lod_correct	SQ→TP2	6	LOD correct 3 bits per comp 2 components per quad
SQ_TP2_pix_mask	SQ→TP2	4	Pixel mask 1 bit per pixel
SQ_TP3_lod_correct	SQ→TP3	6	LOD correct 3 bits per comp 2 components per quad
SQ_TP3_pix_mask	SQ→TP3	4	Pixel mask 1 bit per pixel
SQ_TPx_rs_line_num	SQ→TPx	6	Line number in the Reservation station
SQ_TPx_write_gpr_index	SQ->TPx	7	Index into Register file for write of returned Fetch Data

~~24.2.9~~23.2.9 TP to SQ: Texture stall

Formatted: Bullets and Numbering

The TP sends this signal to the SQ and the SPs when its input buffer is full.



Name	Direction	Bits	Description
TP_SQ_fetch_stall	TP→ SQ	1	Do not send more texture request if asserted

~~24.2.10~~23.2.10 SQ to SP: Texture stall

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
SQ_SPx_fetch_stall	SQ→SPx	1	Do not send more texture request if asserted

~~24.2.11~~23.2.11 SQ to SP: GPR and auto counter

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
SQ_SPx_gpr_wr_addr	SQ→SPx	7	Write address
SQ_SPx_gpr_rd_addr	SQ→SPx	7	Read address
SQ_SPx_gpr_rd_en	SQ→SPx	1	Read Enable
SQ_SP0_gpr_wr_en	SQ→SPx	1	Write Enable for the GPRs of SP0
SQ_SP1_gpr_wr_en	SQ→SPx	1	Write Enable for the GPRs of SP1
SQ_SP2_gpr_wr_en	SQ→SPx	1	Write Enable for the GPRs of SP2
SQ_SP3_gpr_wr_en	SQ→SPx	1	Write Enable for the GPRs of SP3
SQ_SPx_gpr_phase	SQ→SPx	2	The phase mux (arbitrates between inputs, ALU SRC reads and writes)
SQ_SPx_channel_mask	SQ→SPx	4	The channel mask
SQ_SPx_gpr_input_sel	SQ→SPx	2	When the phase mux selects the inputs this tells from which source to read from: Interpolated data, VTX0, VTX1, autogen counter.
SQ_SPx_auto_count	SQ→SPx	12?	Auto count generated by the SQ, common for all shader pipes

~~24.2.12~~23.2.12 SQ to SPx: Instructions

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
SQ_SPx_instr_start	SQ→SPx	1	Instruction start
SQ_SP_instr	SQ→SPx	22~~1~~	Transferred over 4 cycles 0: SRC A Select 2:0 SRC A Argument Modifier 3:3 SRC A swizzle 11:4 VectorDst 17:12 ~~Unused~~ Per channel use mask (PV/Reg) ~~20~~21:18 -- 1: SRC B Select 2:0 SRC B Argument Modifier 3:3 SRC B swizzle 11:4 ScalarDst 17:12 Per channel use mask (PV/Reg) 21:18~~Unused 20:18~~ -- 2: SRC C Select 2:0 SRC C Argument Modifier 3:3 SRC C swizzle 11:4 Per channel use mask (PV/Reg) 21:18~~Unused 20:12~~ -- 3: Vector Opcode 4:0 Scalar Opcode 10:5 Vector Clamp 11:11 Scalar Clamp 12:12 Vector Write Mask 16:13 Scalar Write Mask 20:17
SQ_SPx_exp_alu_id	SQ→SPx	1	ALU ID
SQ_SPx_exporting	SQ→SPx	2	0: Not Exporting 1: Vector Exporting 2: Scalar Exporting
SQ_SPx_stall	SQ→SPx	1	Stall signal
SQ_SP0_write_mask	SQ→SP0	4	Result of pixel kill in the shader pipe, which must be output for all pixel exports (depth and all color buffers). 4x4 because 16 pixels are computed per clock
SQ_SP1_ write_mask	SQ→SP1	4	Result of pixel kill in the shader pipe, which must be output for all pixel exports (depth and all color buffers). 4x4 because 16 pixels are computed per clock
SQ_SP2_ write_mask	SQ→SP2	4	Result of pixel kill in the shader pipe, which must be output for all pixel exports (depth and all color buffers). 4x4 because 16 pixels are computed per clock
SQ_SP3_ write_mask	SQ→SP3	4	Result of pixel kill in the shader pipe, which must be output for all pixel exports (depth and all color buffers). 4x4 because 16 pixels are computed per clock
SQ_SPx_last	SQ→SPx	1	Last instruction of the block
SQ_SP0_pred_overwrite	SQ→SP0	4	Indicates to overwrite the use of PV/PS because of the predication (use the GPRs instead). This operation is done on a per-pixel basis.
SQ_SP1_pred_overwrite	SQ→SP1	4	Indicates to overwrite the use of PV/PS because of

			the predication (use the GPRs instead). This operation is done on a per-pixel basis.
SQ_SP2_pred_overwrite	SQ→SP2	4	Indicates to overwrite the use of PV/PS because of the predication (use the GPRs instead). This operation is done on a per-pixel basis.
SQ_SP3_pred_overwrite	SQ→SP3	4	Indicates to overwrite the use of PV/PS because of the predication (use the GPRs instead). This operation is done on a per-pixel basis.

~~24.2.13~~23.2.13 *SP to SQ: Constant address load/ Predicate Set*

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
SP0_SQ_const_addr	SP0→SQ	36	Constant address load / predicate vector load (4 bits only) to the sequencer
SP0_SQ_valid	SP0→SQ	1	Data valid
SP1_SQ_const_addr	SP1→SQ	36	Constant address load / predicate vector load (4 bits only) to the sequencer
SP1_SQ_valid	SP1→SQ	1	Data valid
SP2_SQ_const_addr	SP2→SQ	36	Constant address load / predicate vector load (4 bits only) to the sequencer
SP2_SQ_valid	SP2→SQ	1	Data valid
SP3_SQ_const_addr	SP3→SQ	36	Constant address load / predicate vector load (4 bits only) to the sequencer
SP3_SQ_valid	SP3→SQ	1	Data valid
SP0_SQ_data_type	SP→SQ	1	Data Type 0: Constant Load 1: Predicate Set

~~24.2.14~~23.2.14 *SQ to SPx: constant broadcast*

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
SQ_SPx_const	SQ→SPx	128	Constant broadcast

~~24.2.15~~23.2.15 *SP0 to SQ: Kill vector load*

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
SP0_SQ_kill_vect	SP0→SQ	4	Kill vector load
SP1_SQ_kill_vect	SP1→SQ	4	Kill vector load
SP2_SQ_kill_vect	SP2→SQ	4	Kill vector load
SP3_SQ_kill_vect	SP3→SQ	4	Kill vector load

~~24.2.16~~23.2.16 *SQ to CP: RBBM bus*

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
SQ_RBB_rs	SQ→CP	1	Read Strobe
SQ_RBB_rd	SQ→CP	32	Read Data
SQ_RBBM_nrtrtr	SQ→CP	1	Optional
SQ_RBBM_rtr	SQ→CP	1	Real-Time (Optional)

~~24.2.17~~23.2.17 *CP to SQ: RBBM bus*

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
rbbm_we	CP→SQ	1	Write Enable
rbbm_a	CP→SQ	15	Address -- Upper Extent is TBD (16:2)
rbbm_wd	CP→SQ	32	Data
rbbm_be	CP→SQ	4	Byte Enables
rbbm_re	CP→SQ	1	Read Enable
rbb_rs0	CP→SQ	1	Read Return Strobe 0
rbb_rs1	CP→SQ	1	Read Return Strobe 1
rbb_rd0	CP→SQ	32	Read Data 0

rbb_rd1	CP→SQ	32	Read Data 0
RBBM_SQ_soft_reset	CP→SQ	1	Soft Reset

~~24.2.18~~23.2.18 *SQ to CP: State report*

Formatted: Bullets and Numbering

Name	Direction	Bits	Description
SQ_CP_vs_event	SQ→CP	1	Vertex Shader Event
SQ_CP_vs_eventid	SQ→CP	2	Vertex Shader Event ID
SQ_CP_ps_event	SQ→CP	1	Pixel Shader Event
SQ_CP_ps_eventid	SQ→CP	2	Pixel Shader Event ID

eventid = 0 => *sEndOfState (i.e. VsEndOfState)
eventid = 1 => *sDone (i.e. VsDone)

So, the CP will assume the Vs is done with a state whenever it gets a pulse on the SQ_CP_vs_event and the SQ_CP_vs_eventid = 0.

~~24.3~~23.3 Example of control flow program execution

Formatted: Bullets and Numbering

We now provide some examples of execution to better illustrate the new design.

Given the program:

Alu 0
Alu 1
Tex 0
Tex 1
Alu 3 Serial
Alu 4
Tex 2
Alu 5
Alu 6 Serial
Tex 3
Alu 7
Alloc Position 1 buffer
Alu 8 Export
Tex 4
Alloc Parameter 3 buffers
Alu 9 Export 0
Tex 5
Alu 10 Serial Export 2
Alu 11 Export 1 End

Would be converted into the following CF instructions:

```
Execute ~~Alu ~~0 Alu ~~Alu ~~0 Alu ~~Tex ~~0 Tex ~~Tex ~~0 Tex ~~Alu ~~1 Alu ~~Alu ~~0 Alu ~~Tex ~~0 Tex ~~Alu ~~0
Alu ~~Alu ~~1 Alu ~~Tex ~~0 Tex
Execute ~~Alu ~~0 Alu
Alloc Position 1
Execute ~~Alu ~~0 Alu ~~Tex ~~0 Tex
Alloc Param 3
Execute_end ~~Alu ~~0 Alu ~~Tex ~~0 Tex ~~Alu ~~1 Alu ~~Alu ~~0 Alu ~~End~~
```

And the execution of this program would look like this:

Put thread in Vertex RS:

Control Flow Instruction Pointer (12 bits), (CFP)
Execution Count Marker (3 or 4 bits), (ECM)

Loop Iterators (4x9 bits), (LI)
Call return pointers (4x12 bits), (CRP)
Predicate Bits(4x64 bits), (PB)
Export ID (1 bit), (EXID)
GPR Base Ptr (8 bits), (GPR)
Export Base Ptr (7 bits), (EB)
Context Ptr (3 bits).(CPTR)
LOD correction bits (16x6 bits) (LOD)

State Bits

CFP	ECM	LI	CRP	PB	EXID	GPR	EB	CPTR	LOD
0	0	0	0	0	0	0	0	0	0

Valid Thread (VALID)
Texture/ALU engine needed (TYPE)
Texture Reads are outstanding (PENDING)
Waiting on Texture Read to Complete (SERIAL)
Allocation Wait (2 bits) (ALLOC)
    00 – No allocation needed
    01 – Position export allocation needed (ordered export)
    10 – Parameter or pixel export needed (ordered export)
    11 – pass thru (out of order export)
Allocation Size (4 bits) (SIZE)
Position Allocated (POS_ALLOC)
First thread of a new context (FIRST)
Last (1 bit), (LAST)

Status Bits

VALID	TYPE	PENDING	SERIAL	ALLOC	SIZE	POS_ALLOC	FIRST	LAST
1	ALU	0	0	0	0	0	1	0

Then the thread is picked up for the execution of the first control flow instruction:

Execute 0 Alu 0 Alu 0 Tex 0 Tex 1 Alu 0 Alu 0 Tex 0 Alu 1 Alu 0 Tex
~~Execute Alu 0 Alu 0 Tex 0 Tex 0 Alu 1 Alu 0 Tex 0 Alu 0 Alu 1 Tex 0~~

It executes the first two ALU instructions and goes back to the RS for a resource request change. Here is the state returned to the RS:

State Bits

CFP	ECM	LI	CRP	PB	EXID	GPR	EB	CPTR	LOD
0	2	0	0	0	0	0	0	0	0

Status Bits

VALID	TYPE	PENDING	SERIAL	ALLOC	SIZE	POS_ALLOC	FIRST	LAST
1	TEX	0	0	0	0	0	1	0

Then when the texture pipe frees up, the arbiter picks up the thread to issue the texture reads. The thread comes back in this state:

State Bits

CFP	ECM	LI	CRP	PB	EXID	GPR	EB	CPTR	LOD
0	4	0	0	0	0	0	0	0	0

Status Bits

VALID	TYPE	PENDING	SERIAL	ALLOC	SIZE	POS_ALLOC	FIRST	LAST

1	ALU	1	1	0	0	0	1	0

Because of the serial bit the arbiter must wait for the texture to return and clear the PENDING bit before it can pick the thread up. Lets say that the texture reads are complete, then the arbiter picks up the thread and returns it in this state:

State Bits

CFP	ECM	LI	CRP	PB	EXID	GPR	EB	CPTR	LOD
0	6	0	0	0	0	0	0	0	0

Status Bits

VALID	TYPE	PENDING	SERIAL	ALLOC	SIZE	POS_ALLOC	FIRST	LAST
1	TEX	0	0	0	0	0	1	0

Again the TP frees up, the arbiter picks up the thread and executes. It returns in this state:

State Bits

CFP	ECM	LI	CRP	PB	EXID	GPR	EB	CPTR	LOD
0	7	0	0	0	0	0	0	0	0

Status Bits

VALID	TYPE	PENDING	SERIAL	ALLOC	SIZE	POS_ALLOC	FIRST	LAST
1	ALU	1	0	0	0	0	1	0

Now, even if the texture has not returned we can still pick up the thread for ALU execution because the serial bit is not set. The thread will however come back to the RS for the second ALU instruction because it has the serial bit set.

State Bits

CFP	ECM	LI	CRP	PB	EXID	GPR	EB	CPTR	LOD
0	8	0	0	0	0	0	0	0	0

Status Bits

VALID	TYPE	PENDING	SERIAL	ALLOC	SIZE	POS_ALLOC	FIRST	LAST
1	ALU	1	1	0	0	0	1	0

As soon as the TP clears the pending bit the thread is picked up and returns:

State Bits

CFP	ECM	LI	CRP	PB	EXID	GPR	EB	CPTR	LOD
0	9	0	0	0	0	0	0	0	0

Status Bits

VALID	TYPE	PENDING	SERIAL	ALLOC	SIZE	POS_ALLOC	FIRST	LAST
1	TEX	0	0	0	0	0	1	0

Picked up by the TP and returns:

Execute 0 Alu

~~Execute Alu 0~~

State Bits									
CFP	ECM	LI	CRP	PB	EXID	GPR	EB	CPTR	LOD
1	0	0	0	0	0	0	0	0	0

Status Bits								
VALID	TYPE	PENDING	SERIAL	ALLOC	SIZE	POS_ALLOC	FIRST	LAST
1	ALU	1	0	0	0	0	1	0

Picked up by the ALU and returns (lets say the TP has not returned yet):

```
Alloc Position 1
```

State Bits									
CFP	ECM	LI	CRP	PB	EXID	GPR	EB	CPTR	LOD
2	0	0	0	0	0	0	0	0	0

Status Bits								
VALID	TYPE	PENDING	SERIAL	ALLOC	SIZE	POS_ALLOC	FIRST	LAST
1	ALU	1	0	01	1	0	1	0

If the SX has the place for the export, the SQ is going to allocate and pick up the thread for execution. It returns to the RS in this state:

Execute ~~Alu ~~0 Alu ~~Tex ~~0 Tex

State Bits									
CFP	ECM	LI	CRP	PB	EXID	GPR	EB	CPTR	LOD
3	1	0	0	0	0	0	0	0	0

Status Bits								
VALID	TYPE	PENDING	SERIAL	ALLOC	SIZE	POS_ALLOC	FIRST	LAST
1	TEX	1	0	0	0	1	1	0

Now, since the TP has not returned yet, we must wait for it to return because we cannot issue multiple texture requests. The TP returns, clears the PENDING bit and we proceed:

```
Alloc Param 3
```

State Bits									
CFP	ECM	LI	CRP	PB	EXID	GPR	EB	CPTR	LOD
4	0	0	0	0	1	0	0	0	0

Status Bits								
VALID	TYPE	PENDING	SERIAL	ALLOC	SIZE	POS_ALLOC	FIRST	LAST
1	ALU	1	0	10	3	1	1	0

Once again the SQ makes sure the SX has enough room in the Parameter cache before it can pick up this thread.

Execute_end ~~Alu ~~0 Alu ~~Tex ~~0 Tex ~~Alu ~~1 Alu ~~Alu ~~0 Alu~~End~~

State Bits									
CFP	ECM	LI	CRP	PB	EXID	GPR	EB	CPTR	LOD
5	1	0	0	0	1	0	100	0	0

Status Bits								
VALID	TYPE	PENDING	SERIAL	ALLOC	SIZE	POS_ALLOC	FIRST	LAST
1	TEX	1	0	0	0	1	1	0

This executes on the TP and then returns:

State Bits									
CFP	ECM	LI	CRP	PB	EXID	GPR	EB	CPTR	LOD
5	2	0	0	0	1	0	100	0	0

Status Bits								
VALID	TYPE	PENDING	SERIAL	ALLOC	SIZE	POS_ALLOC	FIRST	LAST
1	ALU	1	1	0	0	1	1	1

Waits for the TP to return because of the textures reads are pending (and SERIAL in this case). Then executes and does not return to the RS because the LAST bit is set. This is the end of this thread and before dropping it on the floor, the SQ notifies the SX of export completion.

Formatted: Bullets and Numbering

~~25.~~24. Open issues

Need to do some testing on the size of the register file as well as on the register file allocation method (dynamic VS static).

Saving power?

R400 Sequencer Specification

SQ

Version 2.04

Overview: This is an architectural specification for the R400 Sequencer block (SEQ). It provides an overview of the required capabilities and expected uses of the block. It also describes the block interfaces, internal sub-blocks, and provides internal state diagrams.

Revision Changes:

Rev 0.1 (Laurent Lefebvre) Date: May 7, 2001	First draft.
Rev 0.2 (Laurent Lefebvre) Date : July 9, 2001	Changed the interfaces to reflect the changes in the SP. Added some details in the arbitration section.
Rev 0.3 (Laurent Lefebvre) Date : August 6, 2001	Reviewed the Sequencer spec after the meeting on August 3, 2001.
Rev 0.4 (Laurent Lefebvre) Date : August 24, 2001	Added the dynamic allocation method for register file and an example (written in part by Vic) of the flow of pixels/vertices in the sequencer.
Rev 0.5 (Laurent Lefebvre) Date : September 7, 2001	Added timing diagrams (Vic)
Rev 0.6 (Laurent Lefebvre) Date : September 24, 2001	Changed the spec to reflect the new R400 architecture. Added interfaces.
Rev 0.7 (Laurent Lefebvre) Date : October 5, 2001	Added constant store management, instruction store management, control flow management and data dependant predication.
Rev 0.8 (Laurent Lefebvre) Date : October 8, 2001	Changed the control flow method to be more flexible. Also updated the external interfaces.
Rev 0.9 (Laurent Lefebvre) Date : October 17, 2001	Incorporated changes made in the 10/18/01 control flow meeting. Added a NOP instruction, removed the conditional_execute_or_jump. Added debug registers.
Rev 1.0 (Laurent Lefebvre) Date : October 19, 2001	Refined interfaces to RB. Added state registers.
Rev 1.1 (Laurent Lefebvre) Date : October 26, 2001	Added SEQ→SP0 interfaces. Changed delta precision. Changed VGT→SP0 interface. Debug Methods added.
Rev 1.2 (Laurent Lefebvre) Date : November 16, 2001	Interfaces greatly refined. Cleaned up the spec.
Rev 1.3 (Laurent Lefebvre) Date : November 26, 2001	Added the different interpolation modes.
Rev 1.4 (Laurent Lefebvre) Date : December 6, 2001	Added the auto incrementing counters. Changed the VGT→SQ interface. Added content on constant management. Updated GPRs.
Rev 1.5 (Laurent Lefebvre) Date : December 11, 2001	Removed from the spec all interfaces that weren't directly tied to the SQ. Added explanations on constant management. Added PA→SQ synchronization fields and explanation.
Rev 1.6 (Laurent Lefebvre) Date : January 7, 2002	Added more details on the staging register. Added detail about the parameter caches. Changed the call instruction to a Conditionnal_call instruction. Added details on constant management and updated the diagram.
Rev 1.7 (Laurent Lefebvre) Date : February 4, 2002	Added Real Time parameter control in the SX interface. Updated the control flow section.
Rev 1.8 (Laurent Lefebvre) Date : March 4, 2002	New interfaces to the SX block. Added the end of clause modifier, removed the end of clause instructions.
Rev 1.9 (Laurent Lefebvre) Date : March 18, 2002	Rearangement of the CF instruction bits in order to ensure byte alignement.
Rev 1.10 (Laurent Lefebvre) Date : March 25, 2002	Updated the interfaces and added a section on exporting rules.
Rev 1.11 (Laurent Lefebvre) Date : April 19, 2002	Added CP state report interface. Last version of the spec with the old control flow scheme
Rev 2.0 (Laurent Lefebvre) Date : April 19, 2002	New control flow scheme

Rev 2.01 (Laurent Lefebvre) Date : May 2, 2002	Changed slightly the control flow instructions to allow force jumps and calls.
Rev 2.02 (Laurent Lefebvre) Date : May 13, 2002	Updated the Opcodes. Added type field to the constant/pred interface. Added Last field to the SQ→SP instruction load interface.
Rev 2.03 (Laurent Lefebvre) Date : July 15, 2002	SP interface updated to include predication optimizations. Added the predicate no stall instructions,
Rev 2.04 (Laurent Lefebvre) Date :August 2, 2002	Documented the new parameter generation scheme for XY coordinates points and lines STs.

1. Overview

The sequencer chooses two ALU threads and a fetch hread to execute, and executes all of the instructions in a block before looking for a new clause of the same type. Two ALU threads are executed interleaved to hide the ALU latency. The arbitrator will give priority to older threads. There are two separate reservation stations, one for pixel vectors and one for vertices vectors. This way a pixel can pass a vertex and a vertex can pass a pixel.

To support the shader pipe the sequencer also contains the shader instruction cache, constant store, control flow constants and texture state. The four shader pipes also execute the same instruction thus there is only one sequencer for the whole chip.

The sequencer first arbitrates between vectors of 64 vertices that arrive directly from primitive assembly and vectors of 16 quads (64 pixels) that are generated in the scan converter.

The vertex or pixel program specifies how many GPRs it needs to execute. The sequencer will not start the next vector until the needed space is available in the GPRs.

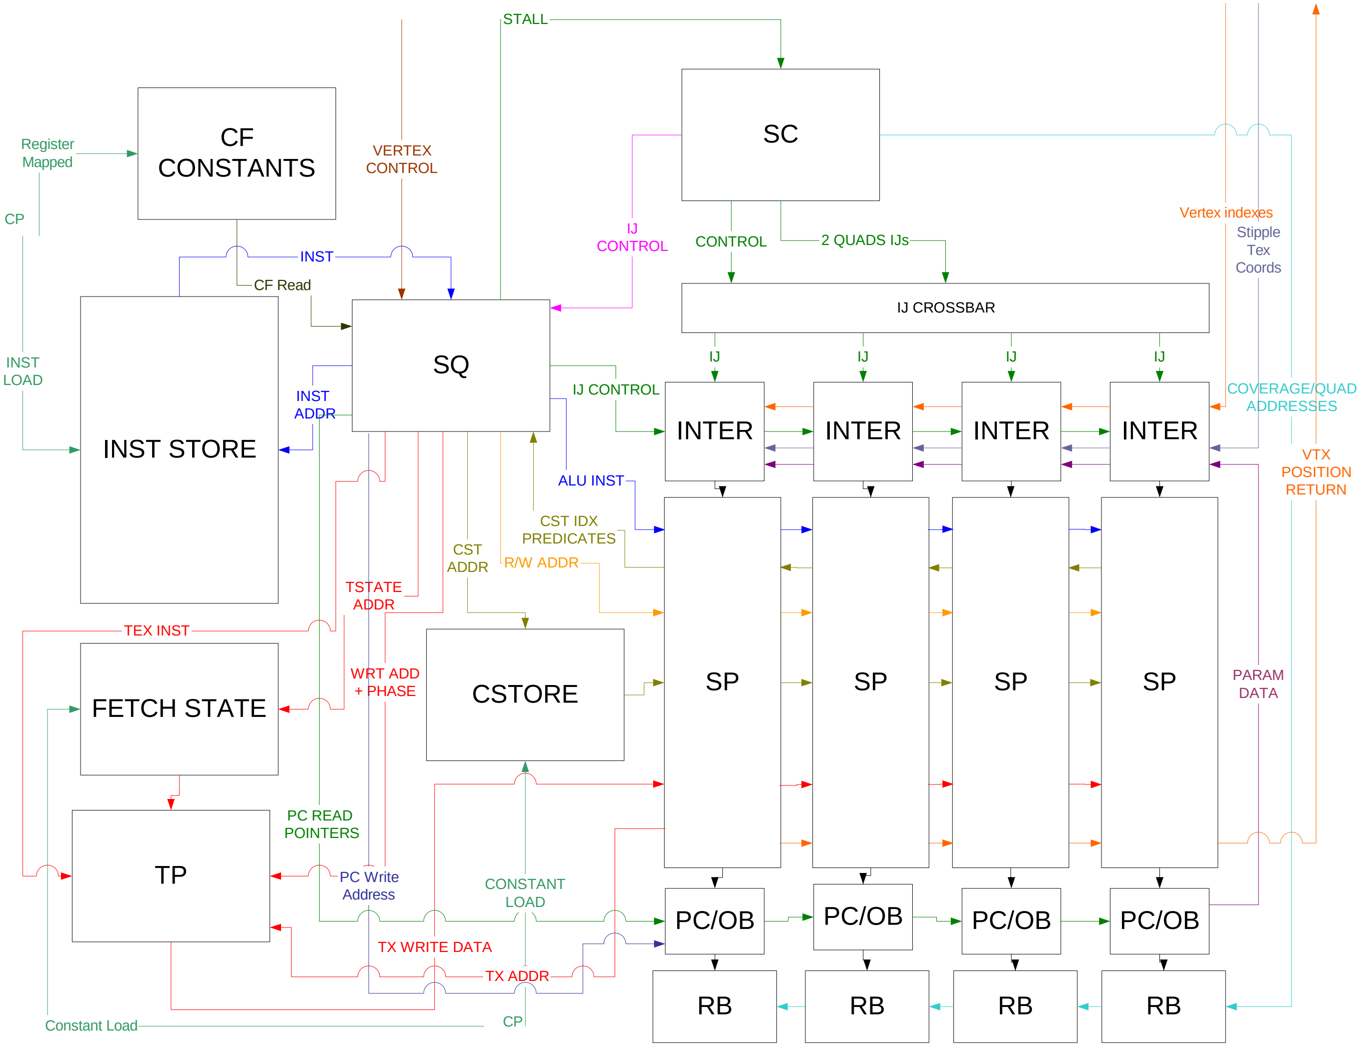

Figure 1: General Sequencer overview

1.1 Top Level Block Diagram

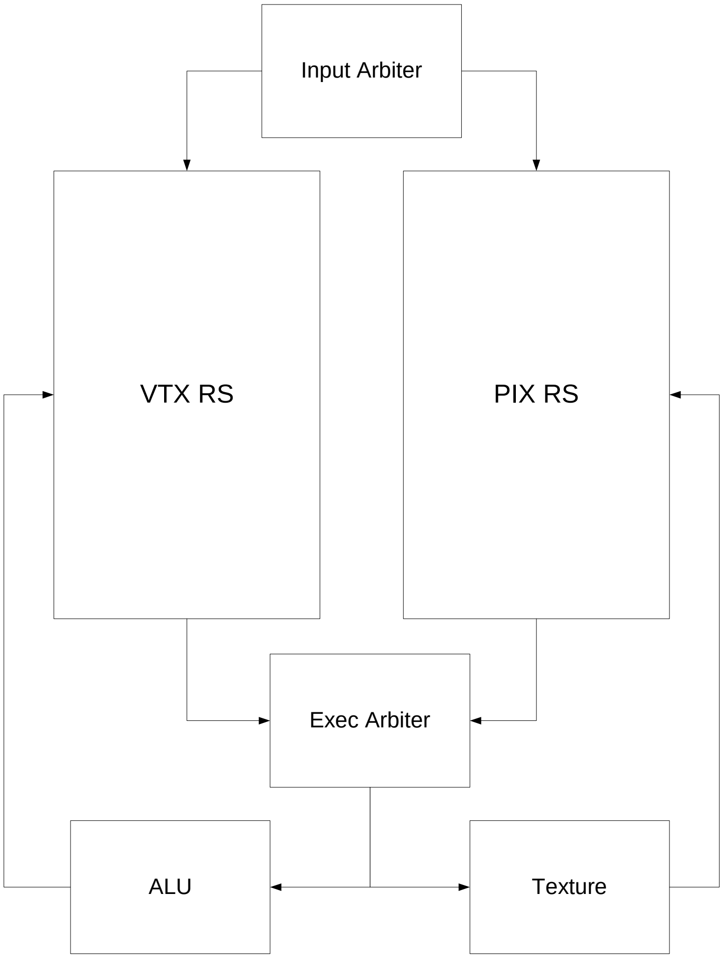

Figure 2: Reservation stations and arbiters

Under this new scheme, the sequencer (SQ) will only use one global state management machine per vector type (pixel, vertex) that we call the reservation station (RS).

1.2 Data Flow graph (SP)

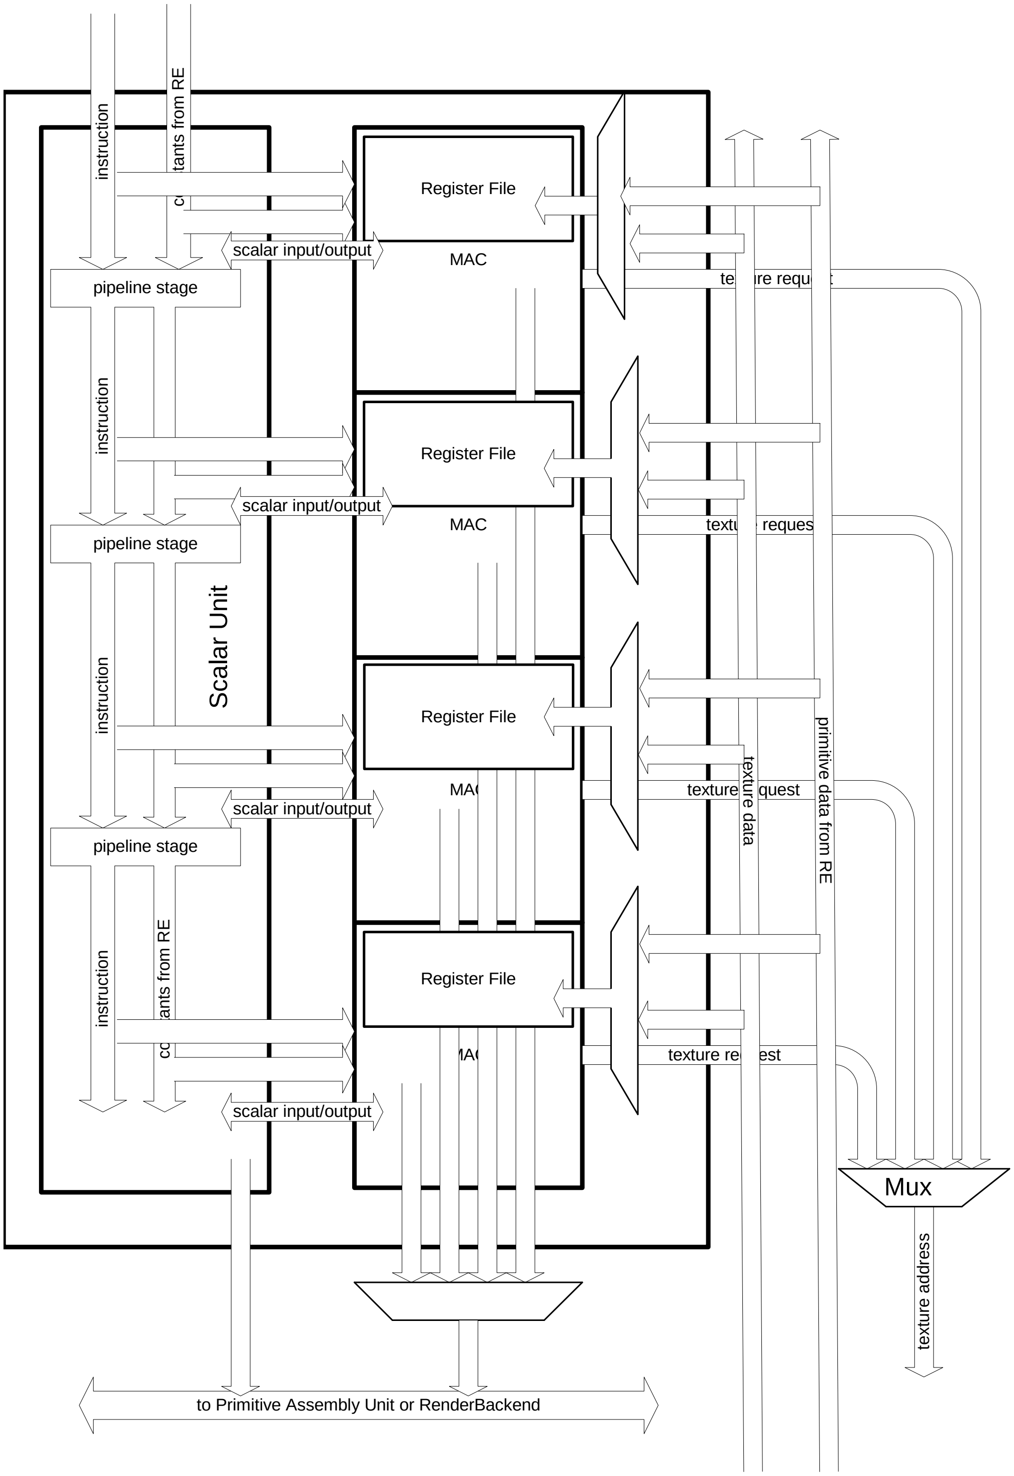

Figure 3: The shader Pipe

The gray area represents blocks that are replicated 4 times per shader pipe (16 times on the overall chip).

1.3 Control Graph

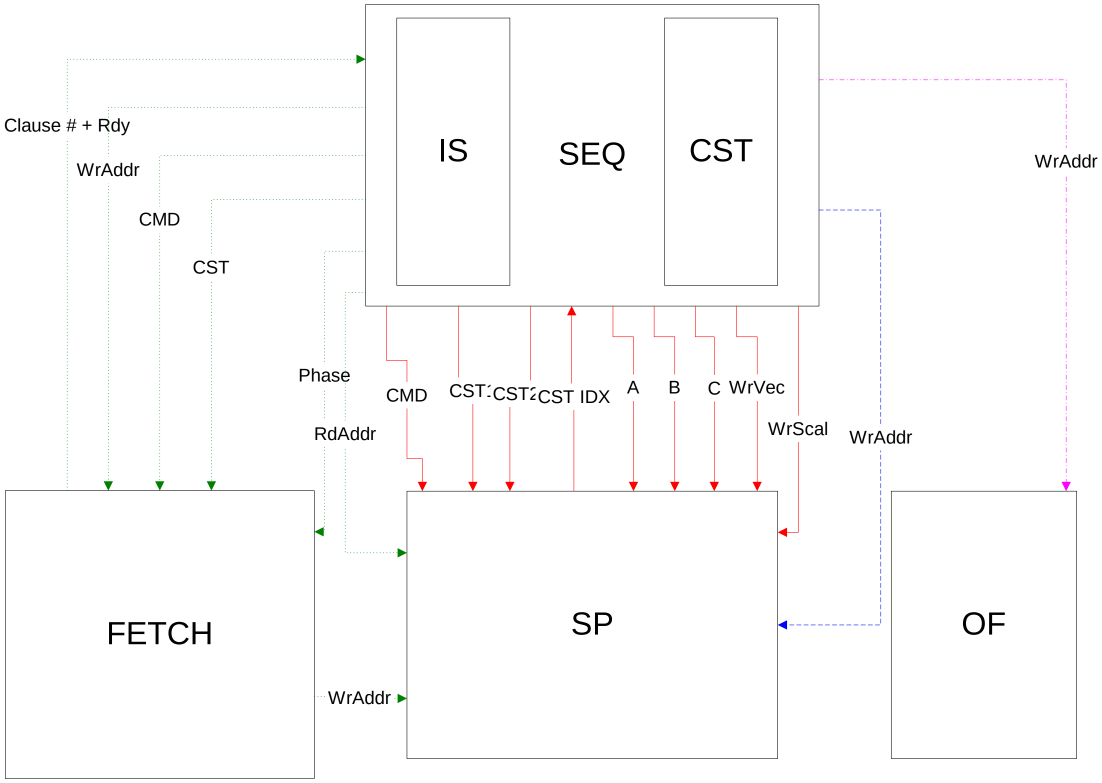

Figure 4: Sequencer Control interfaces

In green is represented the Fetch control interface, in red the ALU control interface, in blue the Interpolated/Vector control interface and in purple is the output file control interface.

2. Interpolated data bus

The interpolators contain an IJ buffer to pack the information as much as possible before writing it to the register file.

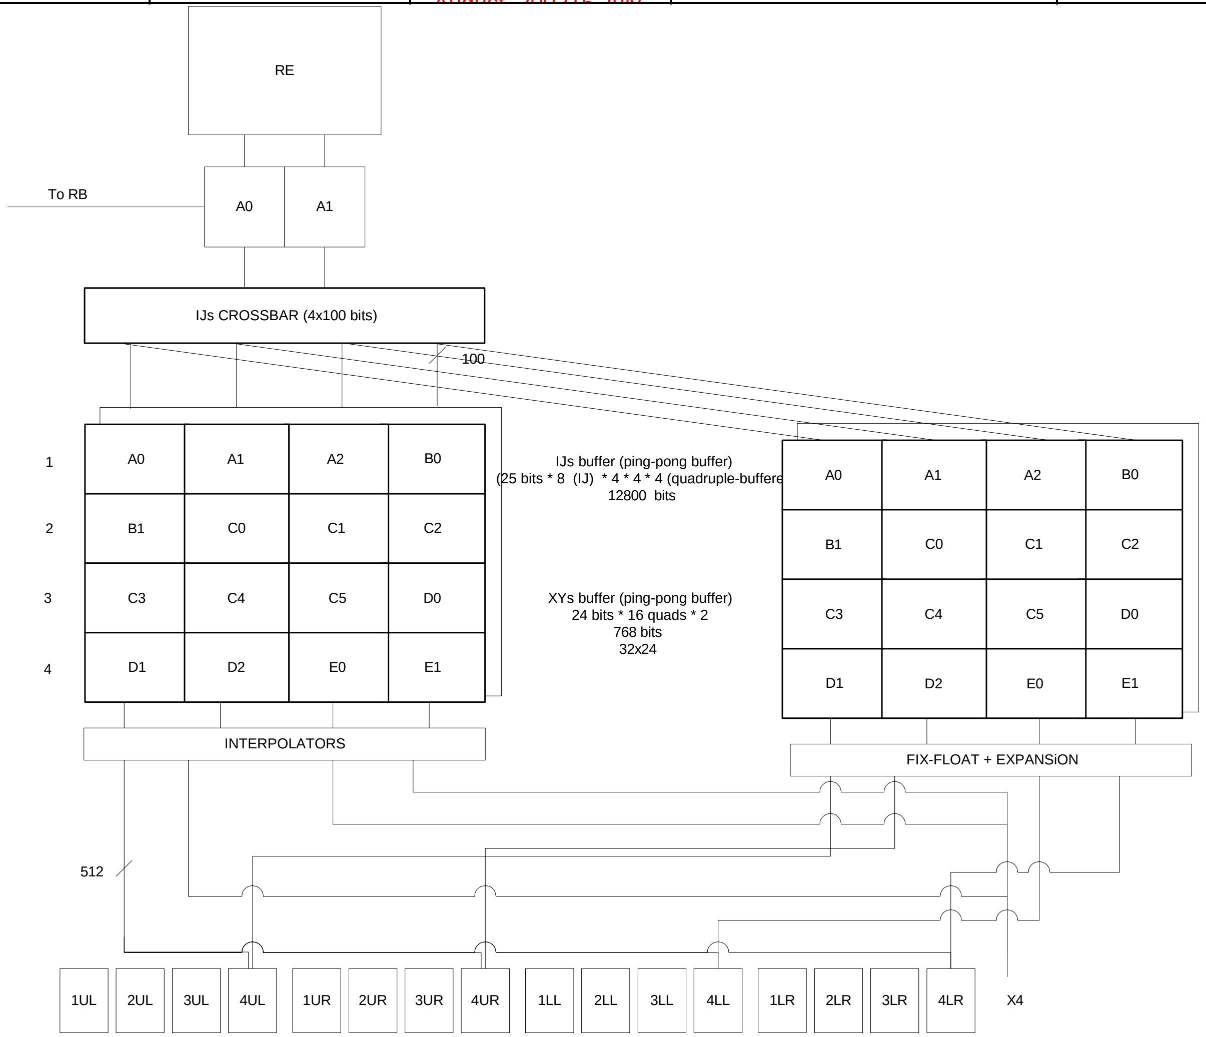

Figure 5: Interpolation buffers

Figure 6: Interpolation timing diagram

Above is an example of a tile the sequencer might receive from the SC. The write side is how the data get stacked into the XY and IJ buffers, the read side is how the data is passed to the GPRs. The IJ information is packed in the IJ buffer 4 quads at a time or two clocks. The sequencer allows at any given time as many as four quads to interpolate a parameter. They all have to come from the same primitive. Then the sequencer controls the write mask to the GPRs to write the valid data in.

3. Instruction Store

There is going to be only one instruction store for the whole chip. It will contain 4096 instructions of 96 bits each.

It is likely to be a 1 port memory; we use 1 clock to load the ALU instruction, 1 clocks to load the Fetch instruction, 1 clock to load 2 control flow instructions and 1 clock to write instructions.

The instruction store is loaded by the CP thru the register mapped registers.

The VS_BASE and PS_BASE context registers are used to specify for each context where its shader is in the instruction memory.

For the Real time commands the story is quite the same but for some small differences. There are no wrap-around points for real time so the driver must be careful not to overwrite regular shader data. The shared code (shared subroutines) uses the same path as real time.

4. Sequencer Instructions

All control flow instructions and move instructions are handled by the sequencer only. The ALUs will perform NOPs during this time (MOV PV,PV, PS,PS) if they have nothing else to do.

5. Constant Stores

5.1 Memory organizations

A likely size for the ALU constant store is 1024x128 bits. The read BW from the ALU constant store is 128 bits/clock and the write bandwidth is 32 bits/clock (directed by the CP bus size not by memory ports).

The maximum logical size of the constant store for a given shader is 256 constants. Or 512 for the pixel/vertex shader pair. The size of the re-mapping table is 128 lines (each line addresses 4 constants). The write granularity is 4 constants or 512 bits. It takes 16 clocks to write the four constants. Real time requires 256 lines in the physical memory (this is physically register mapped).

The texture state is also kept in a similar memory. The size of this memory is 320x96 bits (128 texture states for regular mode, 32 states for RT). The memory thus holds 128 texture states (192 bits per state). The logical size exposes 32 different states total, which are going to be shared between the pixel and the vertex shader. The size of the re-mapping table to for the texture state memory is 32 lines (each line addresses 1 texture state lines in the real memory). The CP write granularity is 1 texture state lines (or 192 bits). The driver sends 512 bits but the CP ignores the top 320 bits. It thus takes 6 clocks to write the texture state. Real time requires 32 lines in the physical memory (this is physically register mapped).

The control flow constant memory doesn't sit behind a renaming table. It is register mapped and thus the driver must reload its content each time there is a change in the control flow constants. Its size is 320*32 because it must hold 8 copies of the 32 dwords of control flow constants and the loop construct constants must be aligned.

The constant re-mapping tables for texture state and ALU constants are logically register mapped for regular mode and physically register mapped for RT operation.

5.2 Management of the Control Flow Constants

The control flow constants are register mapped, thus the CP writes to the according register to set the constant, the SQ decodes the address and writes to the block pointed by its current base pointer (CF_WR_BASE). On the read side, one level of indirection is used. A register (SQ_CONTEXT_MISC.CF_RD_BASE) keeps the current base pointer to the control flow block. This register is copied whenever there is a state change. Should the CP write to CF after the state change, the base register is updated with the (current pointer number +1)% number of states. This way, if the CP doesn't write to CF the state is going to use the previous CF constants.

5.3 Management of the re-mapping tables

5.3.1 *R400 Constant management*

The sequencer is responsible to manage two re-mapping tables (one for the constant store and one for the texture state). On a state change (by the driver), the sequencer will broadside copy the contents of its re-mapping tables to a new one. We have 8 different re-mapping tables we can use concurrently.

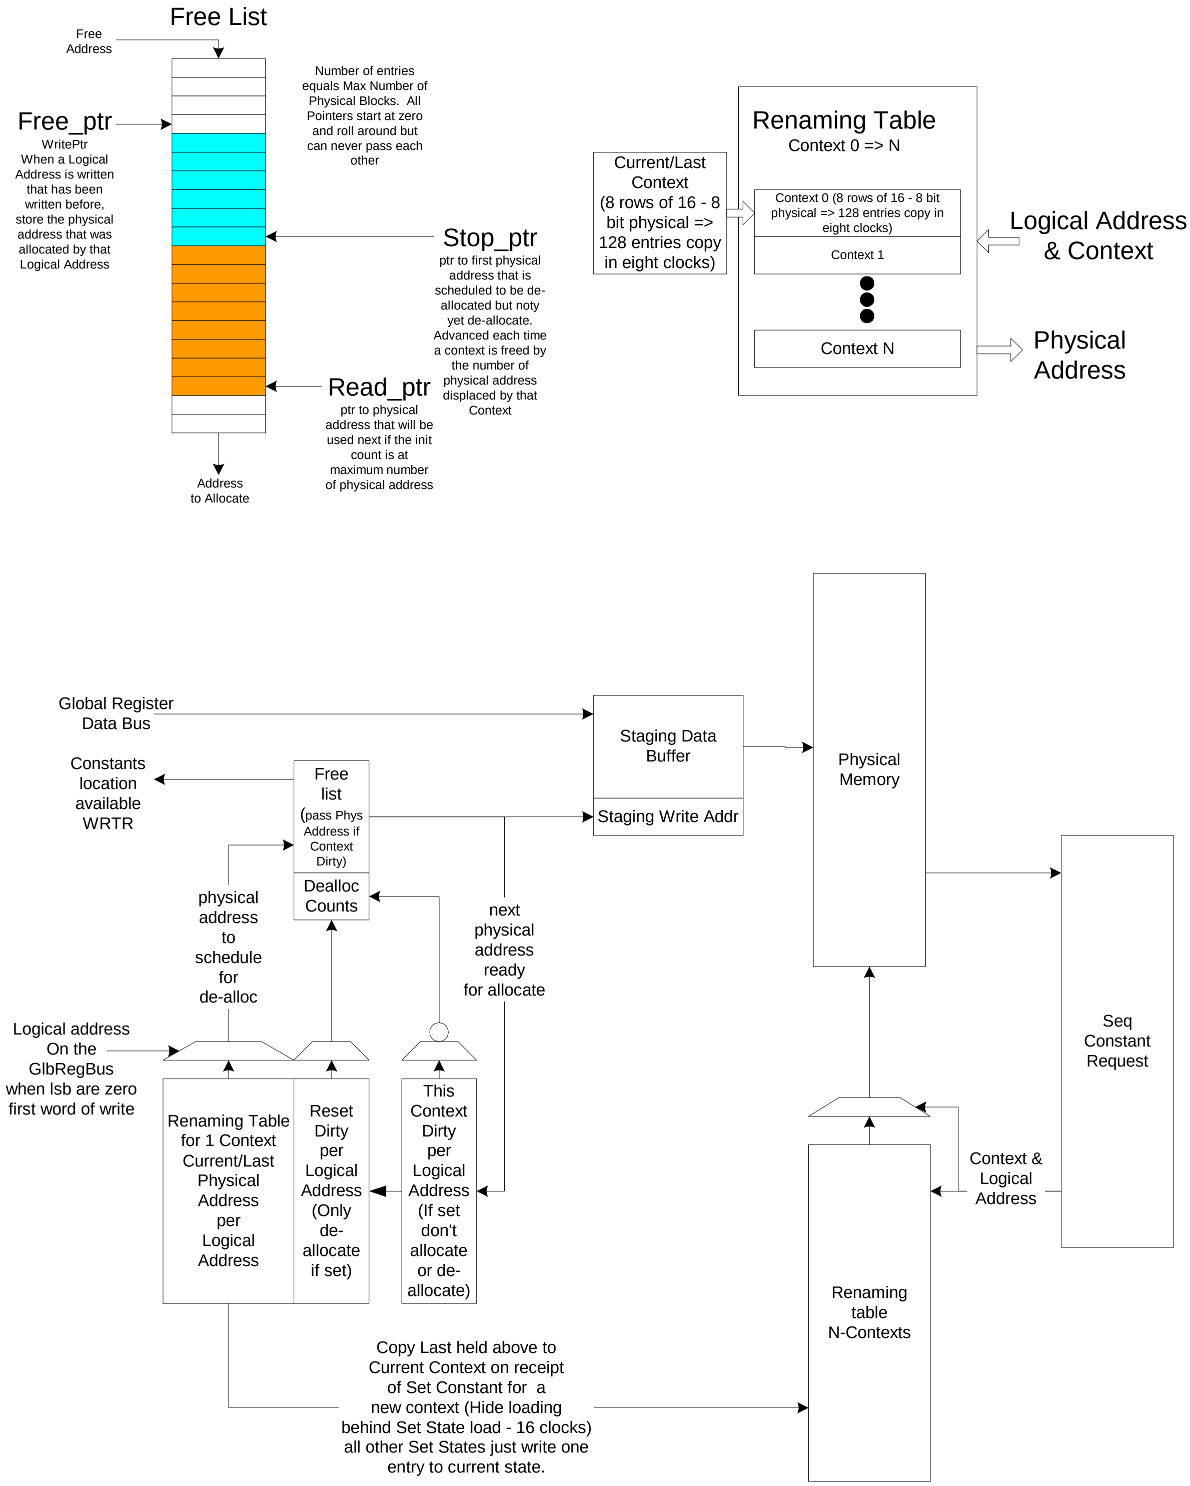
The constant memory update will be incremental, the driver only need to update the constants that actually changed between the two state changes.

For this model to work in its simplest form, the requirement is that the physical memory MUST be at least twice as large as the logical address space + the space allocated for Real Time. In our case, since the logical address space is 512 and the reserved RT space can be up to 256 entries, the memory must be of sizes 1280 and above. Similarly the size of the texture store must be of 32*2+32 = 96 entries and above.

5.3.2 *Proposal for R400LE constant management*

To make this scheme work with only 512+256 = 768 entries, upon reception of a CONTROL packet of state + 1, the sequencer would check for SQ_IDLE and PA_IDLE and if both are idle will erase the content of state to replace it with the new state (this is depicted in Figure 8: De-allocation mechanism~~Figure 8: De-allocation mechanism~~~~Figure 8: De-allocation mechanism~~). Note that in the case a state is cleared a value of 0 is written to the corresponding de-allocation counter location so that when the SQ is going to report a state change, nothing will be de-allocated upon the first report.

The second path sets all context dirty bits that were used in the current state to 1 (thus allowing the new state to reuse these physical addresses if needed).



Free List
Free Address
Free_ptr
WritePtr When a Logical Address is written that has been written before, store the physical address that was allocated by that Logical Address
Number of entries equals Max Number of Physical Blocks. All Pointers start at zero and roll around but can never pass each other
Stop_ptr
ptr to first physical address that is scheduled to be de-allocated but noty yet de-allocate. Advanced each time a context is freed by the number of physical address displaced by that Context
Read_ptr
ptr to physical address that will be used next if the init count is at maximum number of physical address
Address to Allocate
Renaming Table
Context 0 => N
Current/Last Context (8 rows of 16 - 8 bit physical => 128 entries copy in eight clocks)

Constants location available WRTR
Free list (pass Phys Address if Context Dirty)
Dealloc Counts
physical address to schedule for de-alloc
next physical address ready for allocate
Seq Constant Request
Logical address On the GlbRegBus when lsb are zero first word of write
Renaming Table for 1 Context Current/Last Physical Address per Logical Address
Reset Dirty per Logical Address (Only de-allocate if set)
This Context Dirty per Logical Address (If set don't allocate or de-allocate)
Context & Logical Address
Renaming table N-Contexts
Copy Last held above to Current Context on receipt of Set Constant for a new context (Hide loading behind Set State load - 16 clocks) all other Set States just write one entry to current state.

Figure 7: Constant management

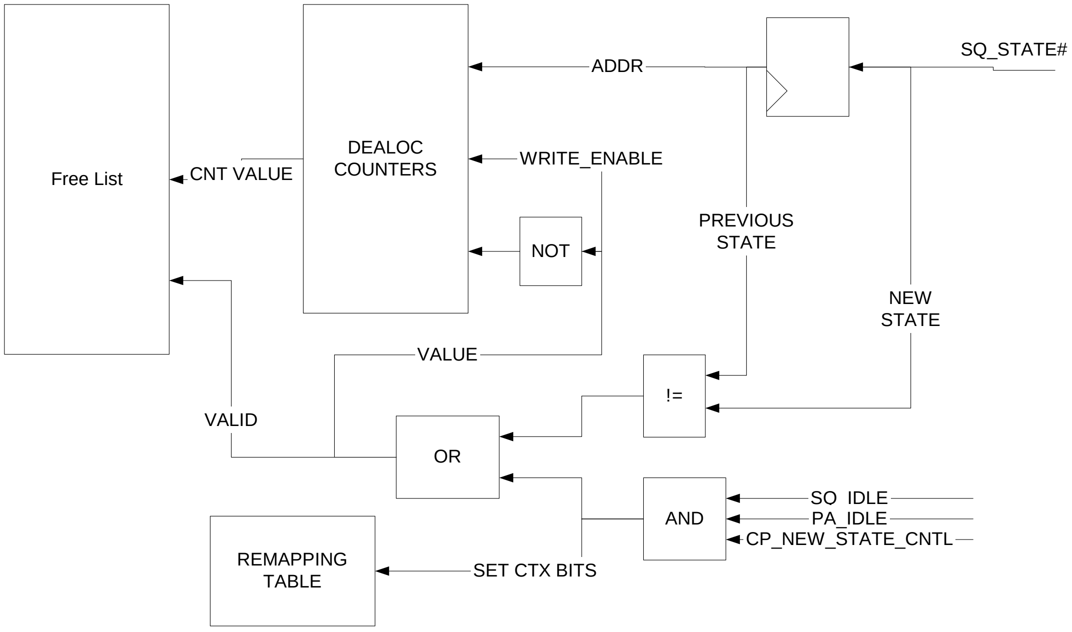

Figure 8: De-allocation mechanism for R400LE

5.3.3 *Dirty bits*

Two sets of dirty bits will be maintained per logical address. The first one will be set to zero on reset and set when the logical address is addressed. The second one will be set to zero whenever a new context is written and set for each address written while in this context. The reset dirty is not set, then writing to that logical address will not require de-allocation of whatever address stored in the renaming table. If it is set and the context dirty is not set, then the physical address store needs to be de-allocated and a new physical address is necessary to store the incoming data. If they are both set, then the data will be written into the physical address held in the renaming for the current logical address. No de-allocation or allocation takes place. This will happen when the driver does a set constant twice to the same logical address between context changes. NOTE: It is important to detect and prevent this, failure to do it will allow multiple writes to allocate all physical memory and thus hang because a context will not fit for rendering to start and thus free up space.

5.3.4 *Free List Block*

A free list block that would consist of a counter (called the IFC or Initial Free Counter) that would reset to zero and incremented every time a chunk of physical memory is used until they have all been used once. This counter would be checked each time a physical block is needed, and if the original ones have not been used up, us a new one, else check the free list for an available physical block address. The count is the physical address for when getting a chunk from the counter.

Storage of a free list big enough to store all physical block addresses.

Maintain three pointers for the free list that are reset to zero. The first one we will call write_ptr. This pointer will identify the next location to write the physical address of a block to be de-allocated. Note: we can never free more physical memory locations than we have. Once recording address the pointer will be incremented to walk the free list like a ring.

The second pointer will be called stop_ptr. The stop_ptr pointer will be advanced by the number of address chunks de-allocates when a context finishes. The address between the stop_ptr and write_ptr cannot be reused because they are still in use. But as soon as the context using then is dismissed the stop_ptr will be advanced.

The third pointer will be called read_ptr. This pointer will point will point to the next address that can be used for allocation as long as the read_ptr does not equal the stop_ptr and the IFC is at its maximum count.

5.3.5 *De-allocate Block*

This block will maintain a free physical address block count for each context. While in current context, a count shall be maintained specifying how many blocks were written into the free list at the write_ptr pointer. This count will be reset upon reset or when this context is active on the back and different than the previous context. It is actually a count of blocks in the previous context that will no longer be used. This count will be used to advance the write_ptr pointer to make available the set of physical blocks freed when the previous context was done. This allows the discard or de-allocation of any number of blocks in one clock.

5.3.6 *Operation of Incremental model*

The basic operation of the model would start with the write_ptr, stop_ptr, read_ptr pointers in the free list set to zero and the free list counter is set to zero. Also all the dirty bits and the previous context will be initialized to zero. When the first set constants happen, the reset dirty bit will not be set, so we will allocate a physical location from the free list counter because its not at the max value. The data will be written into physical address zero. Both the additional copy of the renaming table and the context zeros of the big renaming table will be updated for the logical address that was written by set start with physical address of 0. This process will be repeated for any logical address that are not dirty until the context changes. If a logical address is hit that has its dirty bits set while in the same context, both dirty bits would be set, so the new data will be over-written to the last physical address assigned for this logical address. When the first draw command of the context is detected, the previous context stored in the additional renaming table will be copied to the larger renaming table in the current (new) context location. Then the set constant logical address with be loaded with a new physical address during the copy and if the reset dirty was set, the physical address it replaced in the renaming table would be entered at the write_ptr pointer location on the free list and the write_ptr will be incremented. The de-allocation counter for the previous context (eight) will be incremented. This as set states come in for this context one of the following will happen:

1.) No dirty bits are set for the logical address being updated. A line will be allocated of the free-list counter or the free list at read_ptr pointer if read_ptr != to stop_ptr .
2.) Reset dirty set and Context dirty not set. A new physical address is allocated, the physical address in the renaming table is put on the free list at write_ptr and it is incremented along with the de-allocate counter for the last context.
3.) Context dirty is set then the data will be written into the physical address specified by the logical address.

This process will continue as long as set states arrive. This block will provide backpressure to the CP whenever he has not free list entries available (counter at max and stop_ptr == read_ptr). The command stream will keep a count of contexts of constants in use and prevent more than max constants contexts from being sent.

Whenever a draw packet arrives, the content of the re-mapping table is written to the correct re-mapping table for the context number. Also if the next context uses less constants than the current one all exceeding lines are moved to the free list to be de-allocated later. This happens in parallel with the writing of the re-mapping table to the correct memory.

Now preferable when the constant context leaves the last ALU clause it will be sent to this block and compared with the previous context that left. (Init to zero) If they differ than the older context will no longer be referenced and thus can be de-allocated in the physical memory. This is accomplished by adding the number of blocks freed this context to the stop_ptr pointer. This will make all the physical addresses used by this context available to the read_ptr allocate pointer for future allocation.

This device allows representation of multiple contexts of constants data with N copies of the logical address space. It also allows the second context to be represented as the first set plus some new additional data by just storing the delta's. It allows memory to be efficiently used and when the constants updates are small it can store multiple context. However, if the updates are large, less contexts will be stored and potentially performance will be degraded. Although it will still perform as well as a ring could in this case.

5.4 Constant Store Indexing

In order to do constant store indexing, the sequencer must be loaded first with the indexes (that come from the GPRs). There are 144 wires from the exit of the SP to the sequencer (9 bits pointers x 16 vertexes/clock). Since the data must pass thru the Shader pipe for the float to fixed conversion, there is a latency of 4 clocks (1 instruction)

between the time the sequencer is loaded and the time one can index into the constant store. The assembly will look like this

```
MOVA  R1.X,R2.X       // Loads the sequencer with the content of R2.X, also copies the content of R2.X into R1.X
NOP                   // latency of the float to fixed conversion
ADD   R3,R4,C0[R2.X]// Uses the state from the sequencer to add R4 to C0[R2.X] into R3
```

Note that we don’t really care about what is in the brackets because we use the state from the MOVA instruction. R2.X is just written again for the sake of simplicity and coherency.

The storage needed in the sequencer in order to support this feature is 2*64*9 bits = 1152 bits.

5.5 Real Time Commands

The real time commands constants are written by the CP using the register mapped registers allocated for RT. It works is the same way than when dealing with regular constant loads BUT in this case the CP is not sending a logical address but rather a physical address and the reads are not passing thru the re-mapping table but are directly read from the memory. The boundary between the two zones is defined by the CONST_EO_RT control register. Similarly, for the fetch state, the boundary between the two zones is defined by the TSTATE_EO_RT control register.

5.6 Constant Waterfalling

In order to have a reasonable performance in the case of constant store indexing using the address register, we are going to have the possibility of using the physical memory port for read only. This way we can read 1 constant per clock and thus have a worst-case waterfall mode of 1 vertex per clock. There is a small synchronization issue related with this as we need for the SQ to make sure that the constants where actually written to memory (not only sent to the sequencer) before it can allow the first vector of pixels or vertices of the state to go thru the ALUs. To do so, the sequencer keeps 8 bits (one per render state) and sets the bits whenever the last render state is written to memory and clears the bit whenever a state is freed.

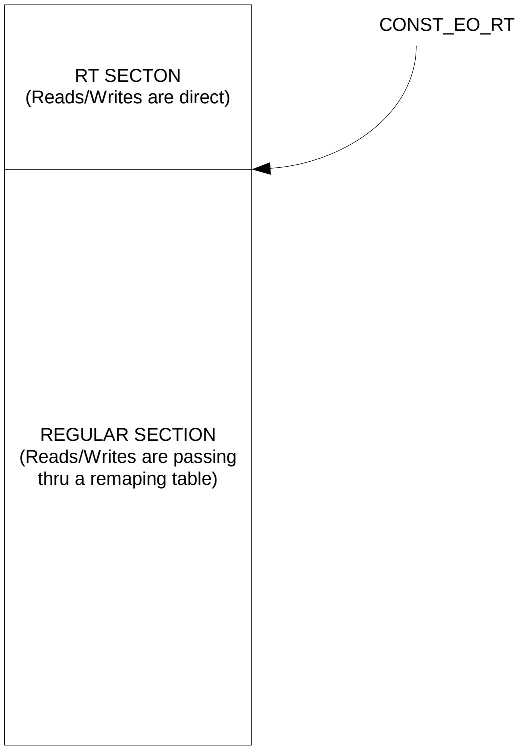

Figure 9: The Constant store

6. Looping and Branches

Loops and branches are planned to be supported and will have to be dealt with at the sequencer level. We plan on supporting constant loops and branches using a control program.

6.1 The controlling state.

The R400 controling state consists of:

Boolean[256:0]
Loop_count[7:0][31:0]
Loop_Start[7:0][31:0]
Loop_Step[7:0][31:0]

That is 256 Booleans and 32 loops.

We have a stack of 4 elements for nested calls of subroutines and 4 loop counters to allow for nested loops.

This state is available on a per shader program basis.

6.2 The Control Flow Program

We'd like to be able to code up a program of the form:

```
1:      Loop
2:      Exec    TexFetch
3:              TexFetch
4:              ALU
5:              ALU
6:              TexFetch
7:      End Loop
8:      ALU Export
```

But realize that 3: may be dependent on 2: and 4: is almost certainly dependent on 2: and 3:. Without clausing, these dependencies need to be expressed in the Control Flow instructions. Additionally, without separate 'texture clauses' and 'ALU clauses' we need to know which instructions to dispatch to the Texture Unit and which to the ALU unit. This information will be encapsulated in the flow control instructions.

Each control flow instruction will contain 2 bits of information for each (non-control flow) instruction:
a) ALU or Texture
b) Serialize Execution

(b) would force the thread to stop execution at this point (before the instruction is executed) and wait until all textures have been fetched. Given the allocation of reserved bits, this would mean that the count of an 'Exec' instruction would be limited to about 8 (non-control-flow) instructions. If more than this were needed, a second Exec (with the same conditions) would be issued.

Another function that relies upon 'clauses' is allocation and order of execution. We need to assure that pixels and vertices are exported in the correct order (even if not all execution is ordered) and that space in the output buffers are allocated in order. Additionally data can't be exported until space is allocated. A new control flow instruction:

Alloc <buffer select -- position,parameter, pixel or vertex memory. And the size required>.

would be created to mark where such allocation needs to be done. To assure allocation is done in order, the actual allocation for a given thread can not be performed unless the equivalent allocation for all previous threads is already completed. The implementation would also assure that execution of instruction(s) following the serialization due to the Alloc will occur in order -- at least until the next serialization or change from ALU to Texture. In most cases this will allow the exports to occur without any further synchronization. Only 'final' allocations or position allocations are

guaranteed to be ordered. Because strict ordering is required for pixels, parameters and positions, this implies only a single alloc for these structures. Vertex exports to memory do not require ordering during allocation and so multiple 'allocs' may be done.

6.2.1 *Control flow instructions table*

Here is the revised control flow instruction set.

Note that whenever a field is marked as RESERVED, it is assumed that all the bits of the field are cleared (0).

NOP		
47 … 44	43	42 … 0
0000	Addressing	RESERVED

This is a regular NOP.

Execute					
47 … 44	43	40 … 34	33 …16	15…12	11 … 0
0001	Addressing	RESERVED	Instructions type + serialize (9 instructions)	Count	Exec Address

Execute_End					
47 … 44	43	40 … 34	33 …16	15…12	11 … 0
0010	Addressing	RESERVED	Instructions type + serialize (9 instructions)	Count	Exec Address

Execute up to 9 instructions at the specified address in the instruction memory. The Instruction type field tells the sequencer the type of the instruction (LSB) (1 = Texture, 0 = ALU and whether to serialize or not the execution (MSB) (1 = Serialize, 0 = Non-Serialized). If Execute_End this is the last execution block of the shader program.

Conditional_Execute						
47 … 44	43	42	41 … 34	33…16	15 …12	11 … 0
0011	Addressing	Condition	Boolean address	Instructions type + serialize (9 instructions)	Count	Exec Address

Conditional_Execute_End						
47 … 44	43	42	41 … 34	33…16	15 …12	11 … 0
0100	Addressing	Condition	Boolean address	Instructions type + serialize (9 instructions)	Count	Exec Address

If the specified Boolean (8 bits can address 256 Booleans) meets the specified condition then execute the specified instructions (up to 9 instructions). If the condition is not met, we go on to the next control flow instruction. If Conditional_Execute_End and the condition is met, this is the last execution block of the shader program.

Conditional_Execute_Predicates							
47 … 44	43	42	41 … 36	35 … 34	33…16	15…12	11 … 0
0101	Addressing	Condition	RESERVED	Predicate vector	Instructions type + serialize (9 instructions)	Count	Exec Address

Conditional_Execute_Predicates_End							
47 … 44	43	42	41 … 36	35 … 34	33…16	15…12	11 … 0
0110	Addressing	Condition	RESERVED	Predicate vector	Instructions type + serialize (9 instructions)	Count	Exec Address

Check the AND/OR of all current predicate bits. If AND/OR matches the condition execute the specified number of instructions. We need to AND/OR this with the kill mask in order not to consider the pixels that aren't valid. If the

condition is not met, we go on to the next control flow instruction. If Conditional_Execute_Predicates_End and the condition is met, this is the last execution block of the shader program.

Conditional_Execute_Predicates_No_Stall							
47 … 44	43	42	41 … 36	35 … 34	33…16	15…12	11 … 0
1101	Addressing	Condition	RESERVED	Predicate vector	Instructions type + serialize (9 instructions)	Count	Exec Address

Conditional_Execute_Predicates_No_Stall_End							
47 … 44	43	42	41 … 36	35 … 34	33…16	15…12	11 … 0
1110	Addressing	Condition	RESERVED	Predicate vector	Instructions type + serialize (9 instructions)	Count	Exec Address

Same as Conditionnal_Execute_Predicates but the SQ is not going to wait for the predicate vector to be updated. You can only set this in the compiler if you know that the predicate set is only a refinement of the current one (like a nested if) because the optimization would still work.

Loop_Start					
47 … 44	43	42 … 21	20 … 16	15…12	11 … 0
0111	Addressing	RESERVED	loop ID	RESERVED	Jump address

Loop Start. Compares the loop iterator with the end value. If loop condition not met jump to the address. Forward jump only. Also computes the index value. The loop id must match between the start to end, and also indicates which control flow constants should be used with the loop.

Loop_End						
47 … 44	43	42 … 24	23… 21	20 … 16	15…12	11 … 0
1000	Addressing	RESERVED	Predicate break	loop ID	RESERVED	start address

Loop end. Increments the counter by one, compares the loop count with the end value. If loop condition met, continue, else, jump BACK to the start of the loop. If predicate break != 0, then compares predicate vector n (specified by predicate break number). If all bits cleared then break the loop.

The way this is described does not prevent nested loops, and the inclusion of the loop id make this easy to do.

Conditionnal_Call						
47 … 44	43	42	41 … 34	33 … 13	12	11 … 0
1001	Addressing	Condition	Boolean address	RESERVED	Force Call	Jump address

If the condition is met, jumps to the specified address and pushes the control flow program counter on the stack. If force call is set the condition is ignored and the call is made always.

Return		
47 … 44	43	42 … 0
1010	Addressing	RESERVED

Pops the topmost address from the stack and jumps to that address. If nothing is on the stack, the program will just continue to the next instruction.

Conditionnal_Jump							
47 … 44	43	42	41… 34	33	32 … 13	12	11 … 0
1011	Addressing	Condition	Boolean address	FW only	RESERVED	Force Jump	Jump address

If force jump is set the condition is ignored and the jump is made always. If FW only is set then only forward jumps are allowed.

Allocate				
47 … 44	43	42…41	40 … 4	3 …0
1100	Debug	Buffer Select	RESERVED	Allocation size

Buffer Select takes a value of the following:
01 – position export (ordered export)
10 – parameter cache or pixel export (ordered export)
11 – pass thru (out of order exports).

Buffer Size takes a value of the following:
00 – 1 buffer
01 – 2 buffers
…
15 – 16 buffers

If debug is set this is a debug alloc (ignore if debug DB_ON register is set to off).

6.3 Implementation

The envisioned implementation has a buffer that maintains the state of each thread. A thread lives in a given location in the buffer during its entire life, but the buffer has FIFO qualities in that threads leave in the order that they enter. Actually two buffers are maintained -- one for Vertices and one for Pixels. The intended implementation would allow for:

16 entries for vertices
48 entries for pixels.

From each buffer, arbitration logic attempts to select 1 thread for the texture unit and 1 (interleaved) thread for the ALU unit. Once a thread is selected it is read out of the buffer, marked as invalid, and submitted to appropriate execution unit. It is returned to the buffer (at the same place) with its status updated once all possible sequential instructions have been executed. A switch from ALU to TEX or visa-versa or a Serialize_Execution modifier forces the thread to be returned to the buffer.

Each entry in the buffer will be stored across two physical pieces of memory - most bits will be stored in a 1 read port device. Only bits needed for thread arbitration will be stored in a highly multi-ported structure. The bits kept in the 1 read port device will be termed 'state'. The bits kept in the multi-read ported device will be termed 'status'.

'State Bits' needed include:

1. Control Flow Instruction Pointer (13 bits),
2. Execution Count Marker 4 bits),
3. Loop Iterators (4x9 bits),
4. Call return pointers (4x12 bits),
5. Predicate Bits (64 bits),
6. Export ID (1 bit),
7. Parameter Cache base Ptr (7 bits),
8. GPR Base Ptr (8 bits),
9. Context Ptr (3 bits).
10. LOD corrections (6x16 bits)
11. Valid bits (64 bits)

Absent from this list are 'Index' pointers. These are costly enough that I'm presuming that they are instead stored in the GPRs. The first seven fields above (Control Flow Ptr, Execution Count, Loop Counts, call return ptrs, Predicate bits, PC base ptr and export ID) are updated every time the thread is returned to the buffer based on how much progress has been mode on thread execution. GPR Base Ptr, Context Ptr and LOD corrections are unchanged throughout execution of the thread.

'Status Bits' needed include:

- Valid Thread
- Texture/ALU engine needed
- Texture Reads are outstanding
- Waiting on Texture Read to Complete
- Allocation Wait (2 bits)
- 00 – No allocation needed
- 01 – Position export allocation needed (ordered export)
- 10 – Parameter or pixel export needed (ordered export)
- 11 – pass thru (out of order export)
- Allocation Size (4 bits)
- Position Allocated
- First thread of a new context
- Event thread (NULL thread that needs to trickle down the pipe)
- Last (1 bit)
- Pulse SX (1 bit)

All of the above fields from all of the entries go into the arbitration circuitry. The arbitration circuitry will select a winner for both the Texture Engine and for the ALU engine. There are actually two sets of arbitration -- one for pixels and one for vertices. A final selection is then done between the two. But the rest of this implementation summary only considers the 'first' level selection which is similar for both pixels and vertices.

Texture arbitration requires no allocation or ordering so it is purely based on selecting the 'oldest' thread that requires the Texture Engine.

ALU arbitration is a little more complicated. First, only threads where either of Texture_Reads_outstanding or Waiting_on_Texture_Read_to_Complete are '0' are considered. Then if Allocation_Wait is active, these threads are further filtered based on whether space is available. If the allocation is position allocation, then the thread is only considered if all 'older' threads have already done their position allocation (position allocated bits set). If the allocation is parameter or pixel allocation, then the thread is only considered if it is the oldest thread. Also a thread is not considered if it is a parameter or pixel or position allocation, has its First_thread_of_a_new_context bit set and would cause ALU interleaving with another thread performing the same parameter or pixel or position allocation. Finally the 'oldest' of the threads that pass through the above filters is selected. If the thread needed to allocate, then at this time the allocation is done, based on Allocation_Size. If a thread has its “last” bit set, then it is also removed from the buffer, never to return.

If I now redefine 'clauses' to mean 'how many times the thread is removed from the thread buffer for the purpose of exection by either the ALU or Texture engine', then the minimum number of clauses needed is 2 -- one to perform the allocation for exports (execution automatically halts after an 'Alloc' instruction) (but doesn't performs the actual allocation) and one for the actual ALU/export instructions. As the 'Alloc' instruction could be part of a texture clause (presumably the final instruction in such a clause), a thread could still execute in this minimal number of 2 clauses, even if it involved texture fetching.

The Texture_Reads_Outstanding bit must be updated by the sequencer, based on keeping track of how many Texture Clauses have been executed by a given thread that have not yet had there data returned. Any number above 0 results in this bit being set. We could consider forcing synchronization such that two texture clauses for a given thread may not be outstanding at any time (that would be my preference for simplicity reasons and because it would require only very little change in the texture pipe interface). This would allow the sequencer to set the bit on execution of the texture clause, and allow the texture unit to return a pointer to the thread buffer on completion that clears the bit.

6.4 Data dependant predicate instructions

Data dependant conditionals will be supported in the R400. The only way we plan to support those is by supporting three vector/scalar predicate operations of the form:

PRED_SETE_# - similar to SETE except that the result is 'exported' to the sequencer.
PRED_SETNE_# - similar to SETNE except that the result is 'exported' to the sequencer.
PRED_SETGT_# - similar to SETGT except that the result is 'exported' to the sequencer
PRED_SETGTE_# - similar to SETGTE except that the result is 'exported' to the sequencer

For the scalar operations only we will also support the two following instructions:
PRED_SETE0_# – SETE0
PRED_SETE1_# – SETE1

The export is a single bit - 1 or 0 that is sent using the same data path as the MOVA instruction. The sequencer will maintain 4 sets of 64 bit predicate vectors (in fact 8 sets because we interleave two programs but only 4 will be exposed) and use it to control the write masking. This predicate is not maintained across clause boundaries. The # sign is used to specify which predicate set you want to use 0 thru 3.

Then we have two conditional execute bits. The first bit is a conditional execute “on” bit and the second bit tells us if we execute on 1 or 0. For example, the instruction:

P0_ADD_# R0,R1,R2

Is only going to write the result of the ADD into those GPRs whose predicate bit is 0. Alternatively, P1_ADD_# would only write the results to the GPRs whose predicate bit is set. The use of the P0 or P1 without precharging the sequencer with a PRED instruction is undefined.

{Issue: do we have to have a NOP between PRED and the first instruction that uses a predicate?}

6.5 HW Detection of PV,PS

Because of the control program, the compiler cannot detect statically dependant instructions. In the case of non-masked writes and subsequent reads the sequencer will insert uses of PV,PS as needed. This will be done by comparing the read address and the write address of consecutive instructions. For masked writes, the sequencer will insert NOPs wherever there is a dependant read/write.

The sequencer will also have to insert NOPs between PRED_SET and MOVA instructions and their uses.

6.6 Register file indexing

Because we can have loops in fetch clause, we need to be able to index into the register file in order to retrieve the data created in a fetch clause loop and use it into an ALU clause. The instruction will include the base address for register indexing and the instruction will contain these controls:

Bit7	Bit 6	
0	0	'absolute register'
0	1	'relative register'
1	0	'previous vector'
1	1	'previous scalar'

In the case of an absolute register we just take the address as is. In the case of a relative register read we take the base address and we add to it the loop_index and this becomes our new address that we give to the shader pipe.

The sequencer is going to keep a loop index computed as such:

Index = Loop_iterator*Loop_step + Loop_start.

We loop until loop_iterator = loop_count. Loop_step is a signed value [-128…127]. The computed index value is a 10 bit counter that is also signed. Its real range is [-256,256]. The tenth bit is only there so that we can provide an out of range value to the “indexing logic” so that it knows when the provided index is out of range and thus can make the necessary arrangements.

6.7 Debugging the Shaders

In order to be able to debug the pixel/vertex shaders efficiently, we provide 2 methods.

6.7.1 *Method 1: Debugging registers*

Current plans are to expose 2 debugging, or error notification, registers:
1. address register where the first error occurred
2. count of the number of errors

The sequencer will detect the following groups of errors:
- count overflow
- constant indexing overflow
- register indexing overflow

Compiler recognizable errors:
- jump errors
    relative jump address > size of the control flow program
- call stack
    call with stack full
    return with stack empty

A jump error will always cause the program to break. In this case, a break means that a clause will halt execution, but allowing further clauses to be executed.

With all the other errors, program can continue to run, potentially to worst-case limits. The program will only break if the DB_PROB_BREAK register is set.

If indexing outside of the constant or the register range, causing an overflow error, the hardware is specified to return the value with an index of 0. This could be exploited to generate error tokens, by reserving and initializing the 0th register (or constant) for errors.

{ISSUE : Interrupt to the driver or not?}

6.7.2 *Method 2: Exporting the values in the GPRs*

1) The sequencer will have a debug active, count register and an address register for this mode.

Under the normal mode execution follows the normal course.

Under the debug mode it is assumed that the program is always exporting n debug vectors and that all other exports to the SX block (position, color, z, ect) will been turned off (changed into NOPs) by the sequencer (even if they occur before the address stated by the ADDR debug register).

7. Pixel Kill Mask

A vector of 64 bits is kept by the sequencer per group of pixels/vertices. Its purpose is to optimize the texture fetch requests and allow the shader pipe to kill pixels using the following instructions:

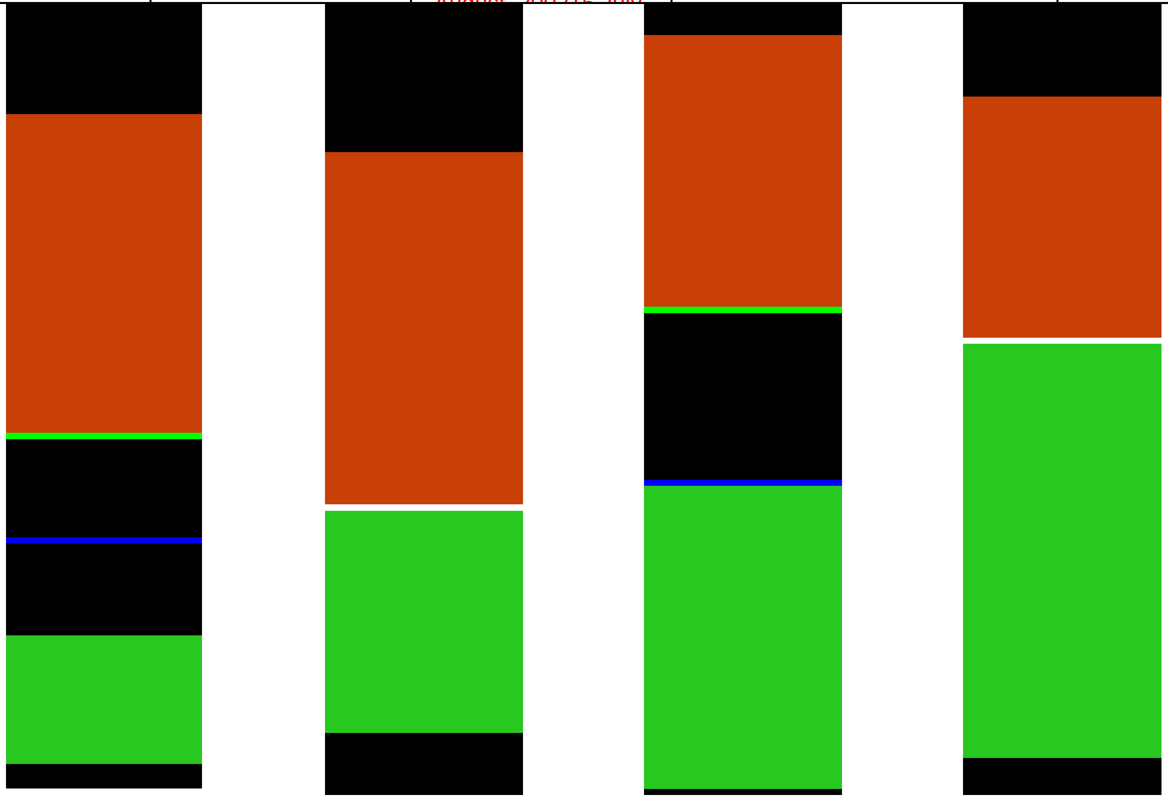
MASK_SETE
MASK_SETNE
MASK_SETGT
MASK_SETGTE

8. Multipass vertex shaders (HOS)

Multipass vertex shaders are able to export from the 6 last clauses but to memory ONLY.

9. Register file allocation

The register file allocation for vertices and pixels can either be static or dynamic. In both cases, the register file in managed using two round robins (one for pixels and one for vertices). In the dynamic case the boundary between pixels and vertices is allowed to move, in the static case it is fixed to 128-VERTEX_REG_SIZE for vertices and PIXEL_REG_SIZE for pixels.



Above is an example of how the algorithm works. Vertices come in from top to bottom; pixels come in from bottom to top. Vertices are in orange and pixels in green. The blue line is the tail of the vertices and the green line is the tail of the pixels. Thus anything between the two lines is shared. When pixels meets vertices the line turns white and the boundary is static until both vertices and pixels share the same “unallocated bubble”. Then the boundary is allowed to move again. The numbering of the GPRs starts from the bottom of the picture at index 0 and goes up to the top at index 127.

10. Fetch Arbitration

The fetch arbitration logic chooses one of the n potentially pending fetch clauses to be executed. The choice is made by looking at the Vs and Ps reservation stations and picking the first one ready to execute. Once chosen, the clause state machine will send one 2x2 fetch per clock (or 4 fetches in one clock every 4 clocks) until all the fetch instructions of the clause are sent. This means that there cannot be any dependencies between two fetches of the same clause.

The arbitrator will not wait for the fetches to return prior to selecting another clause for execution. The fetch pipe will be able to handle up to X(?) in flight fetches and thus there can be a fair number of active clauses waiting for their fetch return data.

11. ALU Arbitration

ALU arbitration proceeds in almost the same way than fetch arbitration. The ALU arbitration logic chooses one of the n potentially pending ALU clauses to be executed. The choice is made by looking at the Vs and Ps reservation stations and picking the first one ready to execute. There are two ALU arbiters, one for the even clocks and one for the odd clocks. For example, here is the sequencing of two interleaved ALU clauses (E and O stands for Even and Odd sets of 4 clocks):

Einst0 Oinst0 Einst1 Oinst1 Einst2 Oinst2 Einst0 Oinst3 Einst1 Oinst4 Einst2 Oinst0…

Proceeding this way hides the latency of 8 clocks of the ALUs. Also note that the interleaving also occurs across clause boundaries.

12. Handling Stalls

When the output file is full, the sequencer prevents the ALU arbitration logic from selecting the last clause (this way nothing can exit the shader pipe until there is place in the output file. If the packet is a vertex packet and the position buffer is full (POS_FULL) then the sequencer also prevents a thread from entering an exporting clause. The sequencer will set the OUT_FILE_FULL signal n clocks before the output file is actually full and thus the ALU arbiter will be able read this signal and act accordingly by not preventing exporting clauses to proceed.

13. Content of the reservation station FIFOs

The reservation FIFOs contain the state of the vector of pixels and vertices. We have two sets of those: one for pixels, and one for vertices. They contain 3 bits of Render State 7 bits for the base address of the GPRs, some bits for LOD correction and coverage mask information in order to fetch fetch for only valid pixels, the quad address.

14. The Output File

The output file is where pixels are put before they go to the RBs. The write BW to this store is 256 bits/clock. Just before this output file are staging registers with write BW 512 bits/clock and read BW 256 bits/clock. The staging registers are 4x128 (and there are 16 of those on the whole chip).

15. IJ Format

The IJ information sent by the PA is of this format on a per quad basis:

We have a vector of IJ's (one IJ per pixel at the centroid of the fragment or at the center of the pixel depending on the mode bit). All pixel's parameters are always interpolated at full 20x24 mantissa precision.

$$P0 = A + I(0)*(B-A) + J(0)*(C-A)$$
$$P1 = A + I(1)*(B-A) + J(1)*(C-A)$$
$$P2 = A + I(2)*(B-A) + J(2)*(C-A)$$
$$P3 = A + I(3)*(B-A) + J(3)*(C-A)$$

P0	P1
P2	P3

Multiples (Full Precision): 8
Subtracts 19x24 (Parameters): 2
Adds: 8

FORMAT OF P's IJ : Mantissa 20 Exp 4 for I + Sign
Mantissa 20 Exp 4 for J + Sign

Total number of bits : 20*8 + 4*8 + 4*2 = 200.

All numbers are kept using the un-normalized floating point convention: if exponent is different than 0 the number is normalized if not, then the number is un-normalized. The maximum range for the IJs (Full precision) is +/- 1024.

15.1 Interpolation of constant attributes

Because of the floating point imprecision, we need to take special provisions if all the interpolated terms are the same or if two of the terms are the same.

16. Staging Registers

In order for the reuse of the vertices to be 14, the sequencer will have to re-order the data sent IN ORDER by the VGT for it to be aligned with the parameter cache memory arrangement. Given the following group of vertices sent by the VGT:

0 1 2 3 4 5 6 7 8 9 10 11 12 13 14 15 || 16 17 18 19 20 21 22 23 24 25 26 27 28 29 30 31 || 32 33 34 35 36 37 38 39 40 41 42 43 44 45 46 47 || 48 49 50 51 52 53 54 55 56 57 58 59 60 61 62 63

The sequencer will re-arrange them in this fashion:

0 1 2 3 16 17 18 19 32 33 34 35 48 49 50 51 || 4 5 6 7 20 21 22 23 36 37 38 39 52 53 54 55 || 8 9 10 11 24 25 26 27 40 41 42 43 56 57 58 59 || 12 13 14 15 28 29 30 31 44 45 46 47 60 61 62 63

The || markers show the SP divisions. In the event a shader pipe is broken, the SQ ~~VGT will send~~is responsible to insert padding to account for the missing pipe. For example, if SP1 is broken, vertices 4 5 6 7 20 21 22 23 36 37 38 39 52 53 54 55 will ~~still be~~ not be sent by the VGT to the SQ ~~**BUT**~~ **AND** the SQ is responsible to “jump” over these vertices in order for no valid vertices to be sent to an invalid SP ~~will not be processed by the SP and thus should be considered invalid (by the SU and VGT)~~.

The most straightforward, *non-compressed* interface method would be to convert, in the VGT, the data to 32-bit floating point prior to transmission to the VSISRs. In this scenario, the data would be transmitted to (and stored in) the VSISRs in full 32-bit floating point. This method requires three 24-bit fixed-to-float converters in the VGT. Unfortunately, it also requires and additional 3,072 bits of storage across the VSISRs. This interface is illustrated in Figure 11~~Figure 11Figure 11~~. The area of the fixed-to-float converters and the VSISRs for this method is roughly estimated as 0.759sqmm using the R300 process. The gate count estimate is shown in Figure 10~~Figure 10Figure 10~~.

Basis for 8-deep Latch Memory (from R300)			
8x24-bit	11631 μ²		60.57813 μ² per bit
Area of 96x8-deep Latch Memory	46524 μ²		
Area of 24-bit Fix-to-float Converter	4712 μ² per converter		
Method 1	Block	Quantity	Area
	F2F	3	14136
	8x96 Latch	16	744384
			758520 μ²

Figure 10:Area Estimate for VGT to Shader Interface

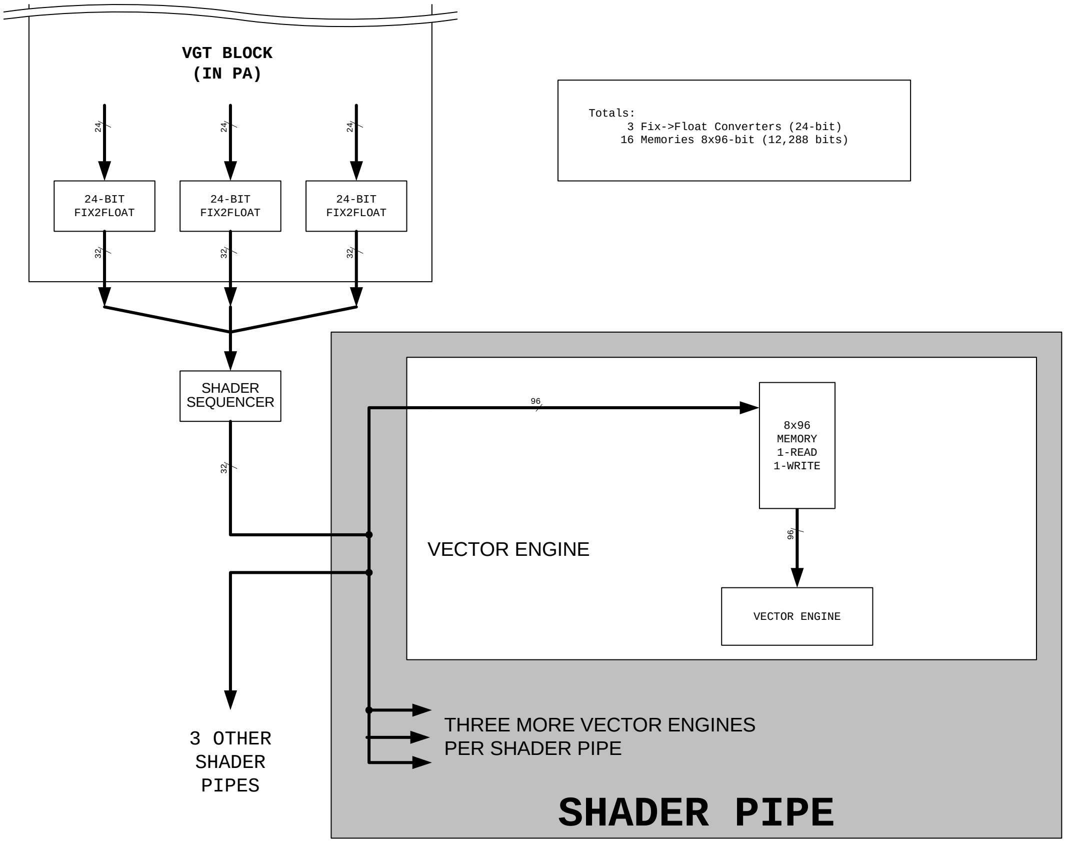


Figure 11:VGT to Shader Interface

17. The parameter cache

The parameter cache is where the vertex shaders export their data. It consists of 16 128x128 memories (1R/1W). The reuse engine will make it so that all vertexes of a given primitive will hit different memories. The allocation method for these memories is a simple round robin. The parameter cache pointers are mapped in the following way: 4MSBs are the memory number and the 7 LSBs are the address within this memory.

MEMORY NUMBER 4 bits	ADDRESS 7 bits

The PA generates the parameter cache addresses as the positions come from the SQ. All it needs to do is keep a Current_Location pointer (7 bits only) and as the positions comes increment the memory number. When the memory number field wraps around, the PA increments the Current_Location by VS_EXPORT_COUNT (a snooped register from the SQ). As an example, say the memories are all empty to begin with and the vertex shader is exporting 8 parameters per vertex (VS_EXPORT_COUNT = 8). The first position received is going to have the PC address 00000000000 the second one 00010000000, third one 00100000000 and so on up to 11110000000. Then the next position received (the 17th) is going to have the address 00000001000, the 18th 00010001000, the 19th 00100001000 and so on. The Current_location is NEVER reset BUT on chip resets. The only thing to be careful about is that if the SX doesn't send you a full group of positions (<64) then you need to fill the address space so that the next group starts correctly aligned (for example if you receive only 33 positions then you need to add 2*VS_EXPORT_COUNT to Current_Location and reset the memory count to 0 before the next vector begins).

17.1 Export restrictions

17.1.1 *Pixel exports:*

Pixels can export 1,2,3 or 4 color buffers to the SX(+z). The exports will be done in order. The PRED_OPTIMIZE function has to be turned of if the exports are done using interleaved predicated instructions. The exports will always be ordered to the SX.

17.1.2 *Vertex exports:*

Position or parameter caches can be exported in any order in the shader program. It is always better to export posistion as soon as possible. Position has to be exported in a single export block (no texture instructions can be placed between the exports). Parameter cache exports can be done in any order with texture instructions interleaved. The PRED_OPTIMIZE function has to be turned of if the exports are done using interleaved predicated instructions to the Parameter cache (see Arbitration restrictions for details). The exports will always be allocated in order to the SX.

17.1.3 *Pass thru exports:*

Pass thru exports have to be done in groups of the form:

```
Alloc 4 (8 or 12)
Execute ALU(ADDR) ALU(DATA) ALU(DATA) ALU(DATA)…
```

They cannot have texture instructions interleaved in the export block. These exports **are not guaranteed to be ordered**.

Also, when doing a pass thru export, Position MUST be exported AFTER all pass thru exports. This position export is used to synchronize the chip when doing a transition from pass thru shader to regular shader and vice versa.

17.2 Arbitration restrictions

Here are the Sequencer arbitration restrictions:

1) Cannot execute a serialized thread if the corresponding texture pending bit is set
2) Cannot allocate position if any older thread has not allocated position
3) If last thread is marked as not valid AND marked as last and we are about to execute the second to oldest thread also marked last then:
    a. Both threads must be from the same context (cannot allow a first thread)
    b. Must turn off the predicate optimization for the second thread
4) Cannot execute a texture clause if texture reads are pending
5) Cannot execute last if texture pending (even if not serial)

18. Export Types

The export type (or the location where the data should be put) is specified using the destination address field in the ALU instruction. Here is a list of all possible export modes:

18.1 Vertex Shading

0:15	- 16 parameter cache
16:31	- Empty (Reserved?)
32	- Export Address
33:40	- 8 vertex exports to the frame buffer and index
41:47	- Empty
48:55	- 8 debug export (interpret as normal vertex export)
60	- export addressing mode
61	- Empty
62	- position

63	- sprite size export that goes with position export (point_h,point_w,edgeflag,misc)

18.2 Pixel Shading

0	- Color for buffer 0 (primary)
1	- Color for buffer 1
2	- Color for buffer 2
3	- Color for buffer 3
4:7	- Empty
8	- Buffer 0 Color/Fog (primary)
9	- Buffer 1 Color/Fog
10	- Buffer 2 Color/Fog
11	- Buffer 3 Color/Fog
12:15	- Empty
16:31	- Empty (Reserved?)
32	- Export Address
33:40	- 8 exports for multipass pixel shaders.
41:47	- Empty
48:55	- 8 debug exports (interpret as normal pixel export)
60	- export addressing mode
61:62	- Empty
63	- Z for primary buffer (Z exported to 'alpha' component)

19. Special Interpolation modes

19.1 Real time commands

We are unable to use the parameter memory since there is no way for a command stream to write into it. Instead we need to add three 16x128 memories (one for each of three vertices x 16 interpolants). These will be mapped onto the register bus and written by type 0 packets, and output to the the parameter busses (the sequencer and/or PA need to be able to address the reatime parameter memory as well as the regular parameter store. For higher performance we should be able able to view them as two banks of 16 and do double buffering allowing one to be loaded, while the other is rasterized with. Most overlay shaders will need 2 or 4 scalar coordinates, one option might be to restrict the memory to 16x64 or 32x64 allowing only two interpolated scalars per cycle, the only problem I see with this is, if we view support for 16 vector-4 interpolants important (true only if we map Microsoft's high priority stream to the realtime stream), then the PA/sequencer need to support a realtime-specific mode where we need to address 32 vectors of parameters instead of 16. This mode is triggered by the primitive type: REAL TIME. The actual memories are in the in the SX blocks. The parameter data memories are hooked on the RBBM bus and are loaded by the CP using register mapped memory.

19.2 Sprites/ XY screen coordinates/ FB information

~~When working with sprites, one may want to overwrite the parameter 0 with SC generated data. Also,~~ XY screen coordinates may be needed in the shader program. This functionality is controlled by the param_gen_I0 register (in SQ) in conjunction with the SND_XY register (in SC) and the param_gen_pos. Also it is possible to send the faceness information (for OGL front/back special operations) to the shader using the same control register. Here is a list of all the modes and how they interact together:

The Data is going to be written in the register specified by the param_gen_pos register.

~~Gen_st is a bit taken from the interface between the SC and the SQ. This is the MSB of the primitive type. If the bit is set, it means we are dealing with Point AA, Line AA or sprite and in this case the vertex values are going to generated between 0 and 1.~~

Param_Gen_I0 disable, snd_xy disable~~, no gen_st – I0~~ = No modification
~~Param_Gen_I0 disable, snd_xy disable, gen_st – I0 = No modification~~
Param_Gen_I0 disable, snd_xy enable~~, no gen_st – I0~~ = No modification

~~Param_Gen_I0 disable, snd_xy enable, gen_st – I0 = No modification~~
Param_Gen_I0 enable, snd_xy disable~~, no gen_st – I0~~ = Sign(faceness)garbage,(Sign Point)~~-~~garbage,Sign(Line) ~~garbage, facenesss~~, t
~~Param_Gen_I0 enable, snd_xy disable, gen_st – I0 = garbage, garbage, s, t~~
Param_Gen_I0 enable, snd_xy enable~~, no gen_st – I0~~ = Sign(faceness)screenX,(Sign Point)screenY,Sign(Line)s, t

In other words,

The generated vector is (X in RED, Y in GREEN, S in BLUE and T in ALPHA):
X,Y,S,T
These values are always supposed to be positive and any shader use of them should use the ABS function (as their sign bits will now be used for flags).
SignX = BackFacing
SignY = Point Primitive
SignS = Line Primitive
SignT = currently unused as a flag.

If !Point & !Line, then it is a Poly.

I would assume that one implementation which allows for generic texture lookup (using 3D maps) for poly stipple and AA for the driver would be

if(Y<0) {
        R = 0.0 (Point)
} else if (S < 0) {
        R = 1.0 (Line)
} else {
        R = 2.0 (Poly)
}~~screen x, screen y, garbage, faceness~~
~~Param_Gen_I0 enable, snd_xy enable, gen_st – I0 = screen x, screen y, s, t~~

19.3 Auto generated counters

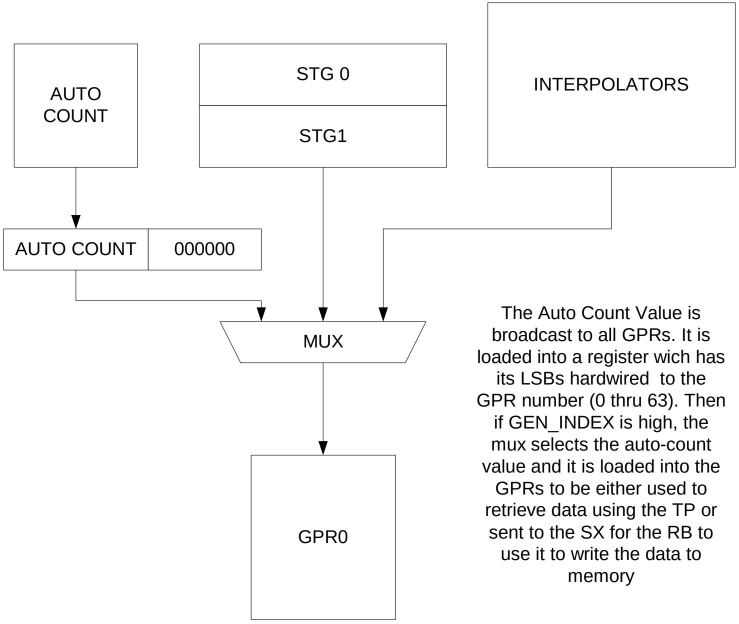
In the cases we are dealing with multipass shaders, the sequencer is going to generate a vector count to be able to both use this count to write the 1st pass data to memory and then use the count to retrieve the data on the 2nd pass. The count is always generated in the same way but it is passed to the shader in a slightly different way depending on the shader type (pixel or vertex). This is toggled on and off using the GEN_INDEX register. The sequencer is going to keep two counters, one for pixels and one for vertices. Every time a full vector of vertices or pixels is written to the GPRs the counter is incremented. Every time a state change is detected, the corresponding counter is reset. While there is only one count broadcast to the GPRs, the LSB are hardwired to specific values making the index different for all elements in the vector.

19.3.1 *Vertex shaders*

In the case of vertex shaders, if GEN_INDEX is set, the data will be put into the x field of the third register (it means that the compiler must allocate 3 GPRs in all multipass vertex shader modes).

19.3.2 *Pixel shaders*

In the case of pixel shaders, if GEN_INDEX is set~~ and Param_Gen_I0 is enabled~~, the data will be put in the x field of the ~~2nd~~ ~~-~~param_gen_pos+1 register~~ (R1.x), else if GEN_INDEX is set the data will be put into the x field of the 1st register (R0.x)~~.



The Auto Count Value is broadcast to all GPRs. It is loaded into a register wich has its LSBs hardwired to the GPR number (0 thru 63). Then if GEN_INDEX is high, the mux selects the auto-count value and it is loaded into the GPRs to be either used to retrieve data using the TP or sent to the SX for the RB to use it to write the data to memory

Figure 12: GPR input mux Control

20. State management

Every clock, the sequencer will report to the CP the oldest states still in the pipe. These are the states of the programs as they enter the last ALU clause.

20.1 Parameter cache synchronization

In order for the sequencer not to begin a group of pixels before the associated group of vertices has finished, the sequencer will keep a 6 bit count per state (for a total of 8 counters). These counters are initialized to 0 and every time a vertex shader exports its data TO THE PARAMETER CACHE, the corresponding pointer is incremented. When the SC sends a new vector of pixels with the SC_SQ_new_vector bit asserted, the sequencer will first check if the count is greater than 0 before accepting the transmission (it will in fact accept the transmission but then lower its ready to receive). Then the sequencer waits for the count to go to one and decrements it. The sequencer can then issue the group of pixels to the interpolators. Every time the state changes, the new state counter is initialized to 0.

21. XY Address imports

The SC will be able to send the XY addresses to the GPRs. It does so by interleaving the writes of the IJs (to the IJ buffer) with XY writes (to the XY buffer). Then when writing the data to the GPRs, the sequencer is going to interpolate the IJ data or pass the XY data thru a Fix→float converter and expander and write the converted values to the GPRs. The Xys are currently SCREEN SPACE COORDINATES. The values in the XY buffers will wrap. See section 19.2 for details on how to control the interpolation in this mode.

21.1 Vertex indexes imports

In order to import vertex indexes, we have 16 8x96 staging registers. These are loaded one line at a time by the VGT block (96 bits). They are loaded in floating point format and can be transferred in 4 or 8 clocks to the GPRs.

22. Registers

Please see the auto-generated web pages for register definitions.

23. Interfaces

23.1 External Interfaces

Whenever an x is used, it means that the bus is broadcast to all units of the same name. For example, if a bus is named SQ→SPx it means that SQ is going to broadcast the same information to all SP instances.

23.2 SC to SP Interfaces

23.2.1 *SC_SP#*

There is one of these interfaces at front of each of the SP (buffer to stage pixel interpolators). This interface transmits the I,J data for pixel interpolation. For the entire system, two quads per clock are transferred to the 4 SPs, so each of these 4 interfaces transmits one half of a quad per clock. The interface below describes a half of a quad worth of data.
The actual data which is transferred per quad is
Ref Pix I => S4.20 Floating Point I value *4
Ref Pix J => S4.20 Floating Point J value *4

This equates to a total of 200 bits which transferred over 2 clocks
and therefor needs an interface 100 bits wide

Additionally, X,Y data (12-bit unsigned fixed) is conditionally sent across this data bus over the same wires in an additional clock. The X,Y data is sent on the lower 24 bits of the data bus with faceness in the msb.
Transfers across these interfaces are synchronized with the SC_SQ IJ Control Bus transfers.

The data transfer across each of these busses is controlled by a IJ_BUF_INUSE_COUNT in the SC. Each time the SC has sent a pixel vector's worth of data to the SPs, he will increment the IJ_BUF_INUSE_COUNT count. Prior to sending the next pixel vectors data, he will check to make sure the count is less than MAX_BUFER_MINUS_2, if not the SC will stall until the SQ returns a pipelined pulse to decrement the count when he has scheduled a buffer free. Note: We could/may optimize for the case of only sending only IJ to use all the buffers to pre-load more. Currently it is planned for the SP to hold 2 double buffers of I,J data and two buffers of X,Y data, so if either X,Y or Centers and Centroids are on, then the SC can send two Buffers.

In at least the initial version, the SC shall send 16 quads per pixel vector even if the vector is not full. This will increment buffer write address pointers correctly all the time. (We may revisit this for both the SX,SP,SQ and add a EndOfVector signal on all interfaces to quit early. We opted for the simple mode first with a belief that only the end of packet and multiple new vector signals should cause a partial vector and that this would not really be significant performance hit.)

Name	Bits	Description
SC_SP#_data	100	IJ information sent over 2 clocks (or X,Y in 24 LSBs with faceness in upper bit) **Type 0 or 1**, First clock I, second clk J Field ULC URC LLC LRC Bits [63:39] [38:26] [25:13] [12:0] Format SE4M20 SE4M20 SE4M20 SE4M20 **Type 2** Field Face X Y Bits [63] [23:12] [11:0] Format Bit Unsigned Unsigned
SC_SP#_valid	1	Valid
SC_SP#_last_quad_data	1	This bit will be set on the last transfer of data per quad.
SC_SP#_type	2	0 -> Indicates centroids 1 -> Indicates centers 2 -> Indicates X,Y Data and faceness on data bus The SC shall look at state data to determine how many types to send for the

		interpolation process.

The # is included for clarity in the spec and will be replaced with a prefix of u#_ in the verilog module statement for the SC and the SP block will have neither because the instantiation will insert the prefix.

23.2.2 *SC_SQ*

This is the control information sent to the sequencer in order to synchronize and control the interpolation and/or loading data into the GPRs needed to execute a shader program on the sent pixels. This data will be sent over two clocks per transfer with 1 to 16 transfers. Therefore the bus (approx 94 bits) could be folded in half to approx 49 bits.

Name	**Bits**	**Description**
SC_SQ_data	46	Control Data sent to the SQ 1 clk transfers Event – valid data consist of event_id and state_id. Instruct SQ to post an event vector to send state id and event_id through request fifo and onto the reservation stations making sure state id and/or event_id gets back to the CP. Events only follow end of packets so no pixel vectors will be in progress. Empty Quad Mask – Transfer Control data consisting of pc_dealloc or new_vector. Receipt of this is to transfer pc_dealloc or new_vector without any valid quad data. New vector will always be posted to request fifo and pc_dealloc will be attached to any pixel vector outstanding or posted in request fifo if no valid quad outstanding. 2 clk transfers Quad Data Valid – Sending quad data with or without new_vector or pc_dealloc. New vector will be posted to request fifo with or without a pixel vector and pc_dealloc will be posted with a pixel vector unless none is in progress. In this case the pc_dealloc will be posted in the request queue. Filler quads will be transferred with The Quad mask set but the pixel corresponding pixel mask set to zero.
SC_SQ_valid	1	SC sending valid data, 2nd clk could be all zeroes

SC_SQ_data – first clock and second clock transfers are shown in the table below.

Name	**BitField**	**Bits**	**Description**
1st Clock Transfer			
SC_SQ_event	0	1	This transfer is a 1 clock event vector Force quad_mask = new_vector=pc_dealloc=0
SC_SQ_event_id	[4:1]	4	This field identifies the event 0 => denotes an End Of State Event 1 => TBD

SC_SQ_pc_dealloc	[7:5]	3	Deallocation token for the Parameter Cache
SC_SQ_new_vector	8	1	The SQ must wait for Vertex shader done count > 0 and after dispatching the Pixel Vector the SQ will decrement the count.
SC_SQ_quad_mask	[12:9]	4	Quad Write mask left to right SP0 => SP3
SC_SQ_end_of_prim	13	1	End Of the primitive
SC_SQ_state_id	[16:14]	3	State/constant pointer (6*3+3)
SC_SQ_pix_mask	[32:17]	16	Valid bits for all pixels SP0=>SP3 (UL,UR,LL,LR)
SC_SQ_provok_vtx	[37:36]	2	Provoking vertex for flat shading
SC_SQ_pc_ptr0	[48:38]	11	Parameter Cache pointer for vertex 0
2nd Clock Transfer			
SC_SQ_pc_ptr1	[10:0]	11	Parameter Cache pointer for vertex 1
SC_SQ_pc_ptr2	[21:11]	11	Parameter Cache pointer for vertex 2
SC_SQ_lod_correct	[45:22]	24	LOD correction per quad (6 bits per quad)
SC_SQ_prim_type	[48:46]	3	Stippled line and Real time command need to load tex cords from alternate buffer 000: Sprite (point) 001: Line 010: Tri_rect 100: Realtime Sprite (point) 101: Realtime Line 110: Realtime Tri_rect

Name	Bits	Description
SQ_SC_free_buff	1	Pipelined bit that instructs SC to decrement count of buffers in use.
SQ_SC_dec_cntr_cnt	1	Pipelined bit that instructs SC to decrement count of new vector and/or event sent to prevent SC from overflowing SQ interpolator/Reservation request fifo.

The scan converter will submit a partial vector whenever:

1.) He gets a primitive marked with an end of packet signal.
2.) A current pixel vector is being assembled with at least one or more valid quads and the vector has been marked for deallocate when a primitive marked new_vector arrives. The Scan Converter will submit a partial vector (up to 16quads with zero pixel mask to fill out the vector) prior to submitting the new_vector marker\primitive.

(This will prevent a hang which can be demonstrated when all primitives in a packet three vectors are culled except for a one quad primitive that gets marked pc_dealloc (vertices maximum size). In this case two new_vectors are submitted and processed, but then one valid quad with the pc_dealloc creates a vector and then the new would wait for another vertex vector to be processed, but the one being waited for could never export until the pc_dealloc signal made it through and thus the hang.)

23.2.3 *SQ to SX(SP): Interpolator bus*

Name	Direction	Bits	Description
SQ_SPx_interp_flat_vtx	SQ→SPx	2	Provoking vertex for flat shading
SQ_SPx_interp_flat_gouraud	SQ→SPx	1	Flat or gouraud shading
SQ_SPx_interp_cyl_wrap	SQ→SPx	4	Wich channel needs to be cylindrical wrapped
SQ_SXx_pc_ptr0	SQ→SXx	11	Parameter Cache Pointer
SQ_SXx_pc_ptr1	SQ→SXx	11	Parameter Cache Pointer
SQ_SXx_pc_ptr2	SQ→SXx	11	Parameter Cache Pointer
SQ_SXx_rt_sel	SQ→SXx	1	Selects between RT and Normal data
SQ_SXx_pc_wr_en	SQ→SXx	1	Write enable for the PC memories
SQ_SXx_pc_wr_addr	SQ→SXx	7	Write address for the PCs
SQ_SXx_pc_channel_mask	SQ→SXx	4	Channel mask
SQ_SXx_pc_ptr_valid	SQ→SXx	1	Read pointers are valid.
SQ_SPx_interp_valid	SQ→SPx	1	Interpolation control valid

23.2.4 *SQ to SP: Staging Register Data*

This is a broadcast bus that sends the VSISR information to the staging registers of the shader pipes.

Name	Direction	Bits	Description
SQ_SPx_vsr_data	SQ→SPx	96	Pointers of indexes or HOS surface information
SQ_SPx_vsr_double	SQ→SPx	1	0: Normal 96 bits per vert 1: double 192 bits per vert
SQ_SP0_ vsr_valid	SQ→SP0	1	Data is valid
SQ_SP1_ vsr_ valid	SQ→SP1	1	Data is valid
SQ_SP2_ vsr_ valid	SQ→SP2	1	Data is valid
SQ_SP3_ vsr_ valid	SQ→SP3	1	Data is valid
SQ_SPx_vsr_read	SQ→SPx	1	Increment the read pointers

23.2.5 *VGT to SQ : Vertex interface*

23.2.5.1 Interface Signal Table

The area difference between the two methods is not sufficient to warrant complicating the interface or the state requirements of the VSISRs. **Therefore, the POR for this interface is that the VGT will transmit the data to the VSISRs (via the Shader Sequencer) in full, 32-bit floating-point format.** The VGT can transmit up to six 32-bit floating-point values to each VSISR where four or more values require two transmission clocks. The data bus is 96 bits wide.

Name	Bits	Description
VGT_SQ_vsisr_data	96	Pointers of indexes or HOS surface information
VGT_SQ_event	1	VGT is sending an event
VGT_SQ_vsisr_continued	1	0: Normal 96 bits per vert 1: double 192 bits per vert
VGT_SQ_end_of_vtx_vect	1	Indicates the last VSISR data set for the current process vector (for double vector data, "end_of_vector" is set on the first vector)
VGT_SQ_indx_valid	1	Vsisr data is valid
VGT_SQ_state	3	Render State (6*3+3 for constants). This signal is guaranteed to be correct when “VGT_SQ_vgt_end_of_vector” is high.
VGT_SQ_send	1	Data on the VGT_SQ is valid receive (see write-up for standard R400 SEND/RTR interface handshaking)
SQ_VGT_rtr	1	Ready to receive (see write-up for standard R400 SEND/RTR interface handshaking)

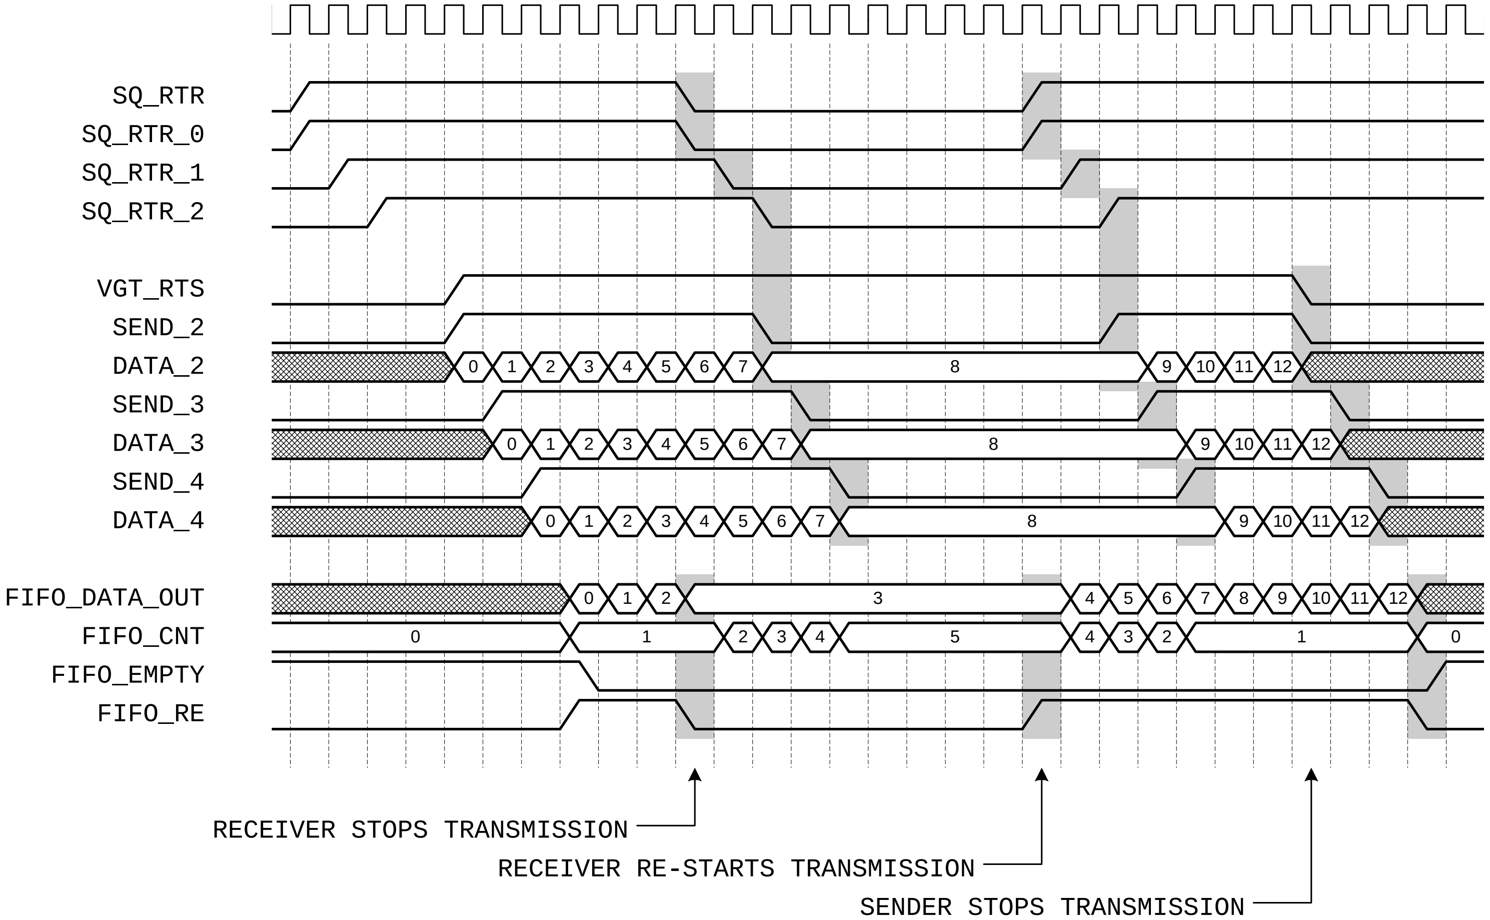

Figure 1. Detailed Logical Diagram for PA_SQ_vgt Interface.

23.2.6 *SQ to SX: Control bus*

Name	**Direction**	**Bits**	**Description**
SQ_SXx_exp_type	SQ→SXx	2	00: Pixel without z (1 to 4 buffers) 01: Pixel with z (1 to 4 buffers) 10: Position (1 or 2 results) 11: Pass thru (4,8 or 12 results aligned)
SQ_SXx_exp_number	SQ→SXx	2	Number of locations needed in the export buffer (encoding depends on the type see bellow).
SQ_SXx_exp_alu_id	SQ→SXx	1	ALU ID
SQ_SXx_exp_valid	SQ→SXx	1	Valid bit
SQ_SXx_exp_state	SQ→SXx	3	State Context
SQ_SXx_free_done	SQ→SXx	1	~~Pulse to indicate that the previous export is finished (this can be sent with or without the other fields of the interface)~~Pulse that indicates that the previous export is finished **from the point of view of the SP. This does not necessarily mean that the data has been transferred to RB or PA, or that the space in export buffer for that particular vector thread has been freed up.**
SQ_SXx_free_alu_id	SQ→SXx	1	ALU ID

Depending on the type the number of export location changes:

- Type 00 : Pixels without Z
    - 00 = 1 buffer
    - 01 = 2 buffers
    - 10 = 3 buffers
    - 11 = 4 buffer
- Type 01: Pixels with Z
    - 00 = 2 Buffers (color + Z)
    - 01 = 3 buffers (2 color + Z)
    - 10 = 4 buffers (3 color + Z)
    - 11 = 5 buffers (4 color + Z)
- Type 10 : Position export
    - 00 = 1 position
    - 01 = 2 positions
    - 1X = Undefined
- Type 11: Pass Thru
    - 00 = 4 buffers
    - 01 = 8 buffers
    - 10 = 12 buffers
    - 11 = Undefined

Below the thick black line is the end of transfer packet that tells the SX that a given export is finished. The report packet **will always arrive either before or at the same time than the next export to the same ALU id**.

23.2.7 *SX to SQ : Output file control*

Name	**Direction**	**Bits**	**Description**
SXx_SQ_exp_count_rdy	SXx→SQ	1	Raised by SX0 to indicate that the following two fields reflect the result of the most recent export
SXx_SQ_exp_pos_avail	SXx→SQ	1	Specifies whether there is room for another position.
SXx_SQ_exp_buf_avail	SXx→SQ	7	Specifies the space available in the output buffers. 0: buffers are full 1: 2K-bits available (32-bits for each of the 64 pixels in a clause)

			... 64: 128K-bits available (16 128-bit entries for each of 64 pixels) 65-127: RESERVED

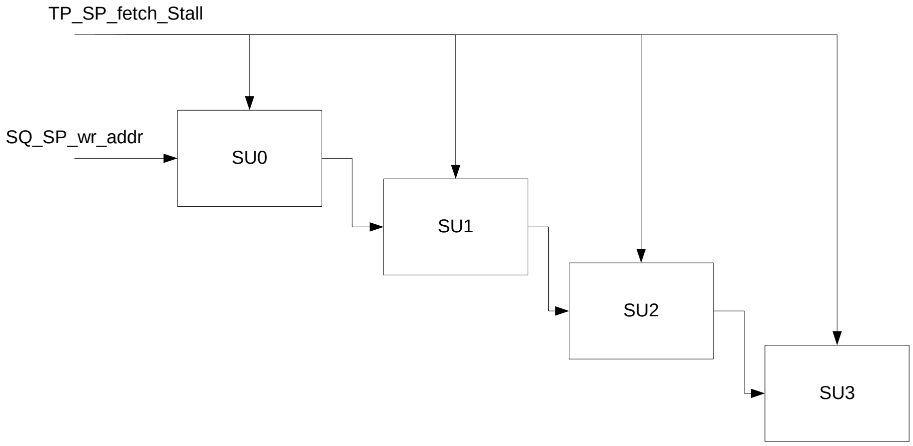
23.2.8 *SQ to TP: Control bus*

Once every clock, the fetch unit sends to the sequencer on which RS line it is now working and if the data in the GPRs is ready or not. This way the sequencer can update the fetch valid bits flags for the reservation station. The sequencer also provides the instruction and constants for the fetch to execute and the address in the register file where to write the fetch return data.

Name	**Direction**	**Bits**	**Description**
TPx_SQ_data_rdy	TPx→ SQ	1	Data ready
TPx_SQ_rs_line_num	TPx→ SQ	6	Line number in the Reservation station
TPx_SQ_type	TPx→ SQ	1	Type of data sent (0:PIXEL, 1:VERTEX)
SQ_TPx_send	SQ→TPx	1	Sending valid data
SQ_TPx_const	SQ→TPx	48	Fetch state sent over 4 clocks (192 bits total)
SQ_TPx_instr	SQ→TPx	24	Fetch instruction sent over 4 clocks
SQ_TPx_end_of_group	SQ→TPx	1	Last instruction of the group
SQ_TPx_Type	SQ→TPx	1	Type of data sent (0:PIXEL, 1:VERTEX)
SQ_TPx_gpr_phase	SQ→TPx	2	Write phase signal
SQ_TP0_lod_correct	SQ→TP0	6	LOD correct 3 bits per comp 2 components per quad
SQ_TP0_pix_mask	SQ→TP0	4	Pixel mask 1 bit per pixel
SQ_TP1_lod_correct	SQ→TP1	6	LOD correct 3 bits per comp 2 components per quad
SQ_TP1_pix_mask	SQ→TP1	4	Pixel mask 1 bit per pixel
SQ_TP2_lod_correct	SQ→TP2	6	LOD correct 3 bits per comp 2 components per quad
SQ_TP2_pix_mask	SQ→TP2	4	Pixel mask 1 bit per pixel
SQ_TP3_lod_correct	SQ→TP3	6	LOD correct 3 bits per comp 2 components per quad
SQ_TP3_pix_mask	SQ→TP3	4	Pixel mask 1 bit per pixel
SQ_TPx_rs_line_num	SQ→TPx	6	Line number in the Reservation station
SQ_TPx_write_gpr_index	SQ->TPx	7	Index into Register file for write of returned Fetch Data

23.2.9 *TP to SQ: Texture stall*

The TP sends this signal to the SQ and the SPs when its input buffer is full.



Name	**Direction**	**Bits**	**Description**

TP_SQ_fetch_stall	TP→ SQ	1	Do not send more texture request if asserted

23.2.10 SQ to SP: Texture stall

Name	Direction	Bits	Description
SQ_SPx_fetch_stall	SQ→SPx	1	Do not send more texture request if asserted

23.2.11 SQ to SP: GPR and auto counter

Name	Direction	Bits	Description
SQ_SPx_gpr_wr_addr	SQ→SPx	7	Write address
SQ_SPx_gpr_rd_addr	SQ→SPx	7	Read address
SQ_SPx_gpr_rd_en	SQ→SPx	1	Read Enable
SQ_SP0_gpr_wr_en	SQ→SPx	1	Write Enable for the GPRs of SP0
SQ_SP1_gpr_wr_en	SQ→SPx	1	Write Enable for the GPRs of SP1
SQ_SP2_gpr_wr_en	SQ→SPx	1	Write Enable for the GPRs of SP2
SQ_SP3_gpr_wr_en	SQ→SPx	1	Write Enable for the GPRs of SP3
SQ_SPx_gpr_phase	SQ→SPx	2	The phase mux (arbitrates between inputs, ALU SRC reads and writes)
SQ_SPx_channel_mask	SQ→SPx	4	The channel mask
SQ_SPx_gpr_input_sel	SQ→SPx	2	When the phase mux selects the inputs this tells from which source to read from: Interpolated data, VTX0, VTX1, autogen counter.
SQ_SPx_auto_count	SQ→SPx	12?	Auto count generated by the SQ, common for all shader pipes

23.2.12 *SQ to SPx: Instructions*

Name	Direction	Bits	Description
SQ_SPx_instr_start	SQ→SPx	1	Instruction start
SQ_SP_instr	SQ→SPx	22	Transferred over 4 cycles 0: SRC A Select 2:0 SRC A Argument Modifier 3:3 SRC A swizzle 11:4 VectorDst 17:12 Per channel use mask (PV/Reg) 21:18 --- - 1: SRC B Select 2:0 SRC B Argument Modifier 3:3 SRC B swizzle 11:4 ScalarDst 17:12 Per channel use mask (PV/Reg) 21:18 --- - 2: SRC C Select 2:0 SRC C Argument Modifier 3:3 SRC C swizzle 11:4 Per channel use mask (PV/Reg) 21:18 --- - 3: Vector Opcode 4:0 Scalar Opcode 10:5 Vector Clamp 11:11 Scalar Clamp 12:12 Vector Write Mask 16:13 Scalar Write Mask 20:17
SQ_SPx_exp_alu_id	SQ→SPx	1	ALU ID
SQ_SPx_exporting	SQ→SPx	1~~2~~	0: Not Exporting 1: ~~Vector~~ Exporting ~~2: Scalar Exporting~~
SQ_SPx_stall	SQ→SPx	1	Stall signal
SQ_SP0_write_mask	SQ→SP0	4	Result of pixel kill in the shader pipe, which must be output for all pixel exports (depth and all color buffers). 4x4 because 16 pixels are computed per clock
SQ_SP1_ write_mask	SQ→SP1	4	Result of pixel kill in the shader pipe, which must be output for all pixel exports (depth and all color buffers). 4x4 because 16 pixels are computed per clock
SQ_SP2_ write_mask	SQ→SP2	4	Result of pixel kill in the shader pipe, which must be output for all pixel exports (depth and all color buffers). 4x4 because 16 pixels are computed per clock
SQ_SP3_ write_mask	SQ→SP3	4	Result of pixel kill in the shader pipe, which must be output for all pixel exports (depth and all color buffers). 4x4 because 16 pixels are computed per clock
SQ_SPx_last	SQ→SPx	1	Last instruction of the block
SQ_SP0_pred_overwrite	SQ→SP0	4	Indicates to overwrite the use of PV/PS because of the predication (use the GPRs instead). This operation is done on a per-pixel basis.
SQ_SP1_pred_overwrite	SQ→SP1	4	Indicates to overwrite the use of PV/PS because of the predication (use the GPRs instead). This operation is done on a per-pixel basis.
SQ_SP2_pred_overwrite	SQ→SP2	4	Indicates to overwrite the use of PV/PS because of

			the predication (use the GPRs instead). This operation is done on a per-pixel basis.
SQ_SP3_pred_overwrite	SQ→SP3	4	Indicates to overwrite the use of PV/PS because of the predication (use the GPRs instead). This operation is done on a per-pixel basis.

23.2.13 *SP to SQ: Constant address load/ Predicate Set*

Name	**Direction**	**Bits**	**Description**
SP0_SQ_const_addr	SP0→SQ	36	Constant address load / predicate vector load (4 bits only) to the sequencer
SP0_SQ_valid	SP0→SQ	1	Data valid
SP1_SQ_const_addr	SP1→SQ	36	Constant address load / predicate vector load (4 bits only) to the sequencer
SP1_SQ_valid	SP1→SQ	1	Data valid
SP2_SQ_const_addr	SP2→SQ	36	Constant address load / predicate vector load (4 bits only) to the sequencer
SP2_SQ_valid	SP2→SQ	1	Data valid
SP3_SQ_const_addr	SP3→SQ	36	Constant address load / predicate vector load (4 bits only) to the sequencer
SP3_SQ_valid	SP3→SQ	1	Data valid
SP0_SQ_data_type	SP→SQ	1	Data Type 0: Constant Load 1: Predicate Set

23.2.14 *SQ to SPx: constant broadcast*

Name	**Direction**	**Bits**	**Description**
SQ_SPx_const	SQ→SPx	128	Constant broadcast

23.2.15 *SP0 to SQ: Kill vector load*

Name	**Direction**	**Bits**	**Description**
SP0_SQ_kill_vect	SP0→SQ	4	Kill vector load
SP1_SQ_kill_vect	SP1→SQ	4	Kill vector load
SP2_SQ_kill_vect	SP2→SQ	4	Kill vector load
SP3_SQ_kill_vect	SP3→SQ	4	Kill vector load

23.2.16 *SQ to CP: RBBM bus*

Name	**Direction**	**Bits**	**Description**
SQ_RBB_rs	SQ→CP	1	Read Strobe
SQ_RBB_rd	SQ→CP	32	Read Data
SQ_RBBM_nrtrtr	SQ→CP	1	Optional
SQ_RBBM_rtr	SQ→CP	1	Real-Time (Optional)

23.2.17 *CP to SQ: RBBM bus*

Name	**Direction**	**Bits**	**Description**
rbbm_we	CP→SQ	1	Write Enable
rbbm_a	CP→SQ	15	Address -- Upper Extent is TBD (16:2)
rbbm_wd	CP→SQ	32	Data
rbbm_be	CP→SQ	4	Byte Enables
rbbm_re	CP→SQ	1	Read Enable
rbb_rs0	CP→SQ	1	Read Return Strobe 0
rbb_rs1	CP→SQ	1	Read Return Strobe 1
rbb_rd0	CP→SQ	32	Read Data 0
rbb_rd1	CP→SQ	32	Read Data 0
RBBM_SQ_soft_reset	CP→SQ	1	Soft Reset

23.2.18 *SQ to CP: State report*

Name	Direction	Bits	Description
SQ_CP_vs_event	SQ→CP	1	Vertex Shader Event
SQ_CP_vs_eventid	SQ→CP	2	Vertex Shader Event ID
SQ_CP_ps_event	SQ→CP	1	Pixel Shader Event
SQ_CP_ps_eventid	SQ→CP	2	Pixel Shader Event ID

eventid = 0 => *sEndOfState (i.e. VsEndOfState)
eventid = 1 => *sDone (i.e. VsDone)

So, the CP will assume the Vs is done with a state whenever it gets a pulse on the SQ_CP_vs_event and the SQ_CP_vs_eventid = 0.

23.3 Example of control flow program execution

We now provide some examples of execution to better illustrate the new design.

Given the program:

Alu 0
Alu 1
Tex 0
Tex 1
Alu 3 Serial
Alu 4
Tex 2
Alu 5
Alu 6 Serial
Tex 3
Alu 7
Alloc Position 1 buffer
Alu 8 Export
Tex 4
Alloc Parameter 3 buffers
Alu 9 Export 0
Tex 5
Alu 10 Serial Export 2
Alu 11 Export 1 End

Would be converted into the following CF instructions:

```
Execute 0 Alu 0 Alu 0 Tex 0 Tex 1 Alu 0 Alu 0 Tex 0 Alu 1 Alu 0 Tex
Execute 0 Alu
Alloc Position 1
Execute 0 Alu 0 Tex
Alloc Param 3
Execute_end 0 Alu 0 Tex 1 Alu 0 Alu
```

And the execution of this program would look like this:

Put thread in Vertex RS:

Control Flow Instruction Pointer (12 bits), (CFP)
Execution Count Marker (3 or 4 bits), (ECM)
Loop Iterators (4x9 bits), (LI)
Call return pointers (4x12 bits), (CRP)
Predicate Bits(4x64 bits), (PB)
Export ID (1 bit), (EXID)

GPR Base Ptr (8 bits), (GPR)
Export Base Ptr (7 bits), (EB)
Context Ptr (3 bits).(CPTR)
LOD correction bits (16x6 bits) (LOD)

State Bits

CFP	ECM	LI	CRP	PB	EXID	GPR	EB	CPTR	LOD
0	0	0	0	0	0	0	0	0	0

Valid Thread (VALID)
Texture/ALU engine needed (TYPE)
Texture Reads are outstanding (PENDING)
Waiting on Texture Read to Complete (SERIAL)
Allocation Wait (2 bits) (ALLOC)
    00 – No allocation needed
    01 – Position export allocation needed (ordered export)
    10 – Parameter or pixel export needed (ordered export)
    11 – pass thru (out of order export)
Allocation Size (4 bits) (SIZE)
Position Allocated (POS_ALLOC)
First thread of a new context (FIRST)
Last (1 bit), (LAST)

Status Bits

VALID	TYPE	PENDING	SERIAL	ALLOC	SIZE	POS_ALLOC	FIRST	LAST
1	ALU	0	0	0	0	0	1	0

Then the thread is picked up for the execution of the first control flow instruction:

```
Execute 0 Alu 0 Alu 0 Tex 0 Tex 1 Alu 0 Alu 0 Tex 0 Alu 1 Alu 0 Tex
```

It executes the first two ALU instructions and goes back to the RS for a resource request change. Here is the state returned to the RS:

State Bits

CFP	ECM	LI	CRP	PB	EXID	GPR	EB	CPTR	LOD
0	2	0	0	0	0	0	0	0	0

Status Bits

VALID	TYPE	PENDING	SERIAL	ALLOC	SIZE	POS_ALLOC	FIRST	LAST
1	TEX	0	0	0	0	0	1	0

Then when the texture pipe frees up, the arbiter picks up the thread to issue the texture reads. The thread comes back in this state:

State Bits

CFP	ECM	LI	CRP	PB	EXID	GPR	EB	CPTR	LOD
0	4	0	0	0	0	0	0	0	0

Status Bits

VALID	TYPE	PENDING	SERIAL	ALLOC	SIZE	POS_ALLOC	FIRST	LAST
1	ALU	1	1	0	0	0	1	0

Because of the serial bit the arbiter must wait for the texture to return and clear the PENDING bit before it can pick the thread up. Lets say that the texture reads are complete, then the arbiter picks up the thread and returns it in this state:

State Bits									
CFP	ECM	LI	CRP	PB	EXID	GPR	EB	CPTR	LOD
0	6	0	0	0	0	0	0	0	0

Status Bits								
VALID	TYPE	PENDING	SERIAL	ALLOC	SIZE	POS_ALLOC	FIRST	LAST
1	TEX	0	0	0	0	0	1	0

Again the TP frees up, the arbiter picks up the thread and executes. It returns in this state:

State Bits									
CFP	ECM	LI	CRP	PB	EXID	GPR	EB	CPTR	LOD
0	7	0	0	0	0	0	0	0	0

Status Bits								
VALID	TYPE	PENDING	SERIAL	ALLOC	SIZE	POS_ALLOC	FIRST	LAST
1	ALU	1	0	0	0	0	1	0

Now, even if the texture has not returned we can still pick up the thread for ALU execution because the serial bit is not set. The thread will however come back to the RS for the second ALU instruction because it has the serial bit set.

State Bits									
CFP	ECM	LI	CRP	PB	EXID	GPR	EB	CPTR	LOD
0	8	0	0	0	0	0	0	0	0

Status Bits								
VALID	TYPE	PENDING	SERIAL	ALLOC	SIZE	POS_ALLOC	FIRST	LAST
1	ALU	1	1	0	0	0	1	0

As soon as the TP clears the pending bit the thread is picked up and returns:

State Bits									
CFP	ECM	LI	CRP	PB	EXID	GPR	EB	CPTR	LOD
0	9	0	0	0	0	0	0	0	0

Status Bits								
VALID	TYPE	PENDING	SERIAL	ALLOC	SIZE	POS_ALLOC	FIRST	LAST
1	TEX	0	0	0	0	0	1	0

Picked up by the TP and returns:

```
Execute 0 Alu
```

State Bits									
CFP	ECM	LI	CRP	PB	EXID	GPR	EB	CPTR	LOD
1	0	0	0	0	0	0	0	0	0

Status Bits								
VALID	TYPE	PENDING	SERIAL	ALLOC	SIZE	POS_ALLOC	FIRST	LAST
1	ALU	1	0	0	0	0	1	0

Picked up by the ALU and returns (lets say the TP has not returned yet):

```
Alloc Position 1
```

State Bits									
CFP	ECM	LI	CRP	PB	EXID	GPR	EB	CPTR	LOD
2	0	0	0	0	0	0	0	0	0

Status Bits								
VALID	TYPE	PENDING	SERIAL	ALLOC	SIZE	POS_ALLOC	FIRST	LAST
1	ALU	1	0	01	1	0	1	0

If the SX has the place for the export, the SQ is going to allocate and pick up the thread for execution. It returns to the RS in this state:

```
Execute 0 Alu 0 Tex
```

State Bits									
CFP	ECM	LI	CRP	PB	EXID	GPR	EB	CPTR	LOD
3	1	0	0	0	0	0	0	0	0

Status Bits								
VALID	TYPE	PENDING	SERIAL	ALLOC	SIZE	POS_ALLOC	FIRST	LAST
1	TEX	1	0	0	0	1	1	0

Now, since the TP has not returned yet, we must wait for it to return because we cannot issue multiple texture requests. The TP returns, clears the PENDING bit and we proceed:

```
Alloc Param 3
```

State Bits									
CFP	ECM	LI	CRP	PB	EXID	GPR	EB	CPTR	LOD
4	0	0	0	0	1	0	0	0	0

Status Bits								
VALID	TYPE	PENDING	SERIAL	ALLOC	SIZE	POS_ALLOC	FIRST	LAST
1	ALU	1	0	10	3	1	1	0

Once again the SQ makes sure the SX has enough room in the Parameter cache before it can pick up this thread.

```
Execute_end 0 Alu 0 Tex 1 Alu 0 Alu
```

State Bits									
CFP	ECM	LI	CRP	PB	EXID	GPR	EB	CPTR	LOD
5	1	0	0	0	1	0	100	0	0

Status Bits								
VALID	TYPE	PENDING	SERIAL	ALLOC	SIZE	POS_ALLOC	FIRST	LAST
1	TEX	1	0	0	0	1	1	0

This executes on the TP and then returns:

State Bits									
CFP	ECM	LI	CRP	PB	EXID	GPR	EB	CPTR	LOD
5	2	0	0	0	1	0	100	0	0

Status Bits								
VALID	TYPE	PENDING	SERIAL	ALLOC	SIZE	POS_ALLOC	FIRST	LAST
1	ALU	1	1	0	0	1	1	1

Waits for the TP to return because of the textures reads are pending (and SERIAL in this case). Then executes and does not return to the RS because the LAST bit is set. This is the end of this thread and before dropping it on the floor, the SQ notifies the SX of export completion.

24. Open issues

Need to do some testing on the size of the register file as well as on the register file allocation method (dynamic VS static).

Saving power?

R400 Sequencer Specification

SQ

Version 2.054

Overview: This is an architectural specification for the R400 Sequencer block (SEQ). It provides an overview of the required capabilities and expected uses of the block. It also describes the block interfaces, internal sub-blocks, and provides internal state diagrams.

~~**25. OPEN ISSUES .... 50**~~

Revision Changes:

Rev 0.1 (Laurent Lefebvre) Date: May 7, 2001	First draft.
Rev 0.2 (Laurent Lefebvre) Date : July 9, 2001	Changed the interfaces to reflect the changes in the SP. Added some details in the arbitration section.
Rev 0.3 (Laurent Lefebvre) Date : August 6, 2001	Reviewed the Sequencer spec after the meeting on August 3, 2001.
Rev 0.4 (Laurent Lefebvre) Date : August 24, 2001	Added the dynamic allocation method for register file and an example (written in part by Vic) of the flow of pixels/vertices in the sequencer.
Rev 0.5 (Laurent Lefebvre) Date : September 7, 2001	Added timing diagrams (Vic)
Rev 0.6 (Laurent Lefebvre) Date : September 24, 2001	Changed the spec to reflect the new R400 architecture. Added interfaces.
Rev 0.7 (Laurent Lefebvre) Date : October 5, 2001	Added constant store management, instruction store management, control flow management and data dependant predication.
Rev 0.8 (Laurent Lefebvre) Date : October 8, 2001	Changed the control flow method to be more flexible. Also updated the external interfaces.
Rev 0.9 (Laurent Lefebvre) Date : October 17, 2001	Incorporated changes made in the 10/18/01 control flow meeting. Added a NOP instruction, removed the conditional_execute_or_jump. Added debug registers.
Rev 1.0 (Laurent Lefebvre) Date : October 19, 2001	Refined interfaces to RB. Added state registers.
Rev 1.1 (Laurent Lefebvre) Date : October 26, 2001	Added SEQ→SP0 interfaces. Changed delta precision. Changed VGT→SP0 interface. Debug Methods added.
Rev 1.2 (Laurent Lefebvre) Date : November 16, 2001	Interfaces greatly refined. Cleaned up the spec.
Rev 1.3 (Laurent Lefebvre) Date : November 26, 2001	Added the different interpolation modes.
Rev 1.4 (Laurent Lefebvre) Date : December 6, 2001	Added the auto incrementing counters. Changed the VGT→SQ interface. Added content on constant management. Updated GPRs.
Rev 1.5 (Laurent Lefebvre) Date : December 11, 2001	Removed from the spec all interfaces that weren't directly tied to the SQ. Added explanations on constant management. Added PA→SQ synchronization fields and explanation.
Rev 1.6 (Laurent Lefebvre) Date : January 7, 2002	Added more details on the staging register. Added detail about the parameter caches. Changed the call instruction to a Conditionnal_call instruction. Added details on constant management and updated the diagram.
Rev 1.7 (Laurent Lefebvre) Date : February 4, 2002	Added Real Time parameter control in the SX interface. Updated the control flow section.
Rev 1.8 (Laurent Lefebvre) Date : March 4, 2002	New interfaces to the SX block. Added the end of clause modifier, removed the end of clause instructions.
Rev 1.9 (Laurent Lefebvre) Date : March 18, 2002	Rearangement of the CF instruction bits in order to ensure byte alignement.
Rev 1.10 (Laurent Lefebvre) Date : March 25, 2002	Updated the interfaces and added a section on exporting rules.
Rev 1.11 (Laurent Lefebvre) Date : April 19, 2002	Added CP state report interface. Last version of the spec with the old control flow scheme
Rev 2.0 (Laurent Lefebvre) Date : April 19, 2002	New control flow scheme

Rev 2.01 (Laurent Lefebvre) Date : May 2, 2002	Changed slightly the control flow instructions to allow force jumps and calls.
Rev 2.02 (Laurent Lefebvre) Date : May 13, 2002	Updated the Opcodes. Added type field to the constant/pred interface. Added Last field to the SQ→SP instruction load interface.
Rev 2.03 (Laurent Lefebvre) Date : July 15, 2002	SP interface updated to include predication optimizations. Added the predicate no stall instructions,
Rev 2.04 (Laurent Lefebvre) Date :August 2, 2002	Documented the new parameter generation scheme for XY coordinates points and lines STs.
Rev 2.05 (Laurent Lefebvre) Date :	

1. Overview

The sequencer chooses two ALU threads and a fetch hread to execute, and executes all of the instructions in a block before looking for a new clause of the same type. Two ALU threads are executed interleaved to hide the ALU latency. The arbitrator will give priority to older threads. There are two separate reservation stations, one for pixel vectors and one for vertices vectors. This way a pixel can pass a vertex and a vertex can pass a pixel.

To support the shader pipe the sequencer also contains the shader instruction cache, constant store, control flow constants and texture state. The four shader pipes also execute the same instruction thus there is only one sequencer for the whole chip.

The sequencer first arbitrates between vectors of 64 vertices that arrive directly from primitive assembly and vectors of 16 quads (64 pixels) that are generated in the scan converter.

The vertex or pixel program specifies how many GPRs it needs to execute. The sequencer will not start the next vector until the needed space is available in the GPRs.

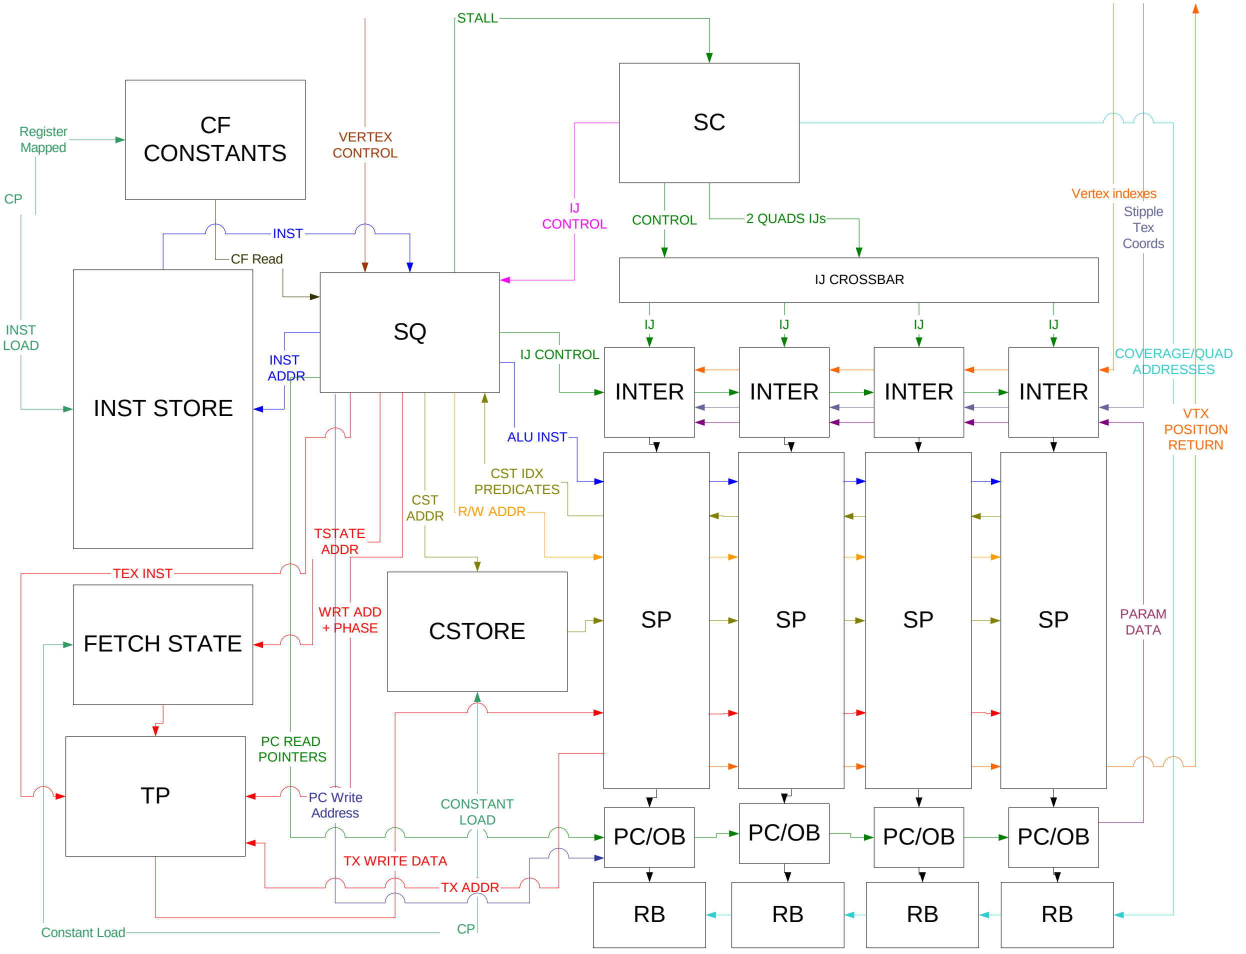

Figure 1: General Sequencer overview

1.1 Top Level Block Diagram

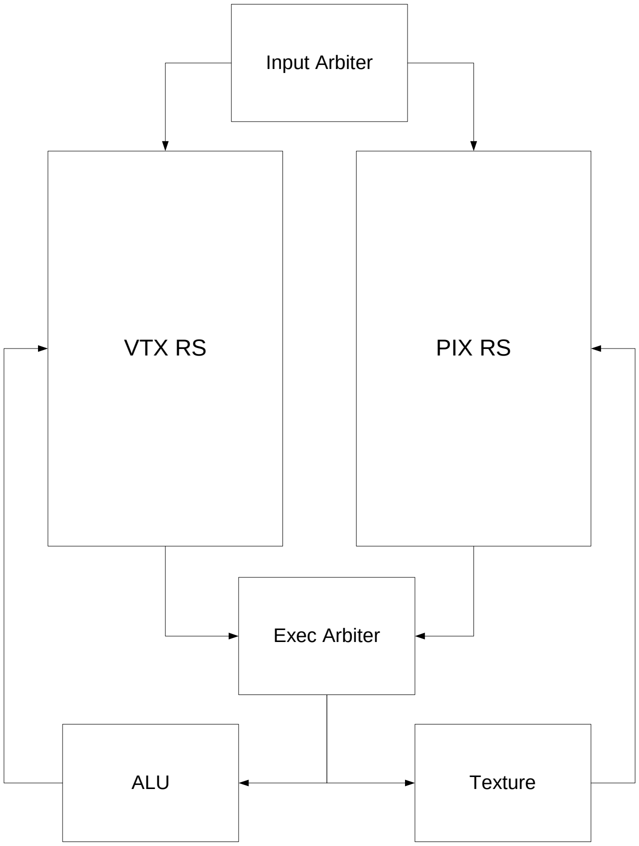

Figure 2: Reservation stations and arbiters

Under this new scheme, the sequencer (SQ) will only use one global state management machine per vector type (pixel, vertex) that we call the reservation station (RS).

1.2 Data Flow graph (SP)

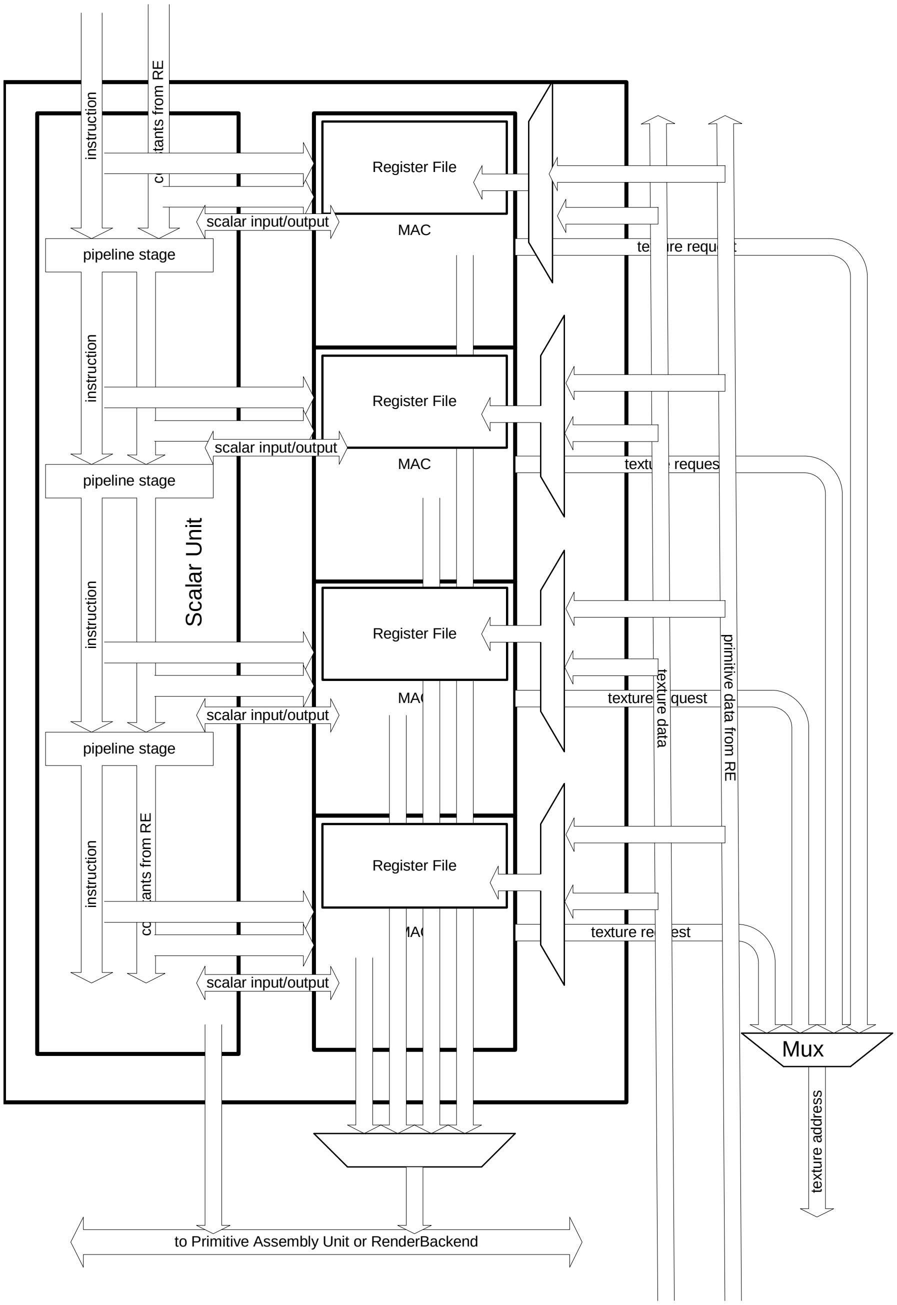

Figure 3: The shader Pipe

The gray area represents blocks that are replicated 4 times per shader pipe (16 times on the overall chip).

1.3 Control Graph

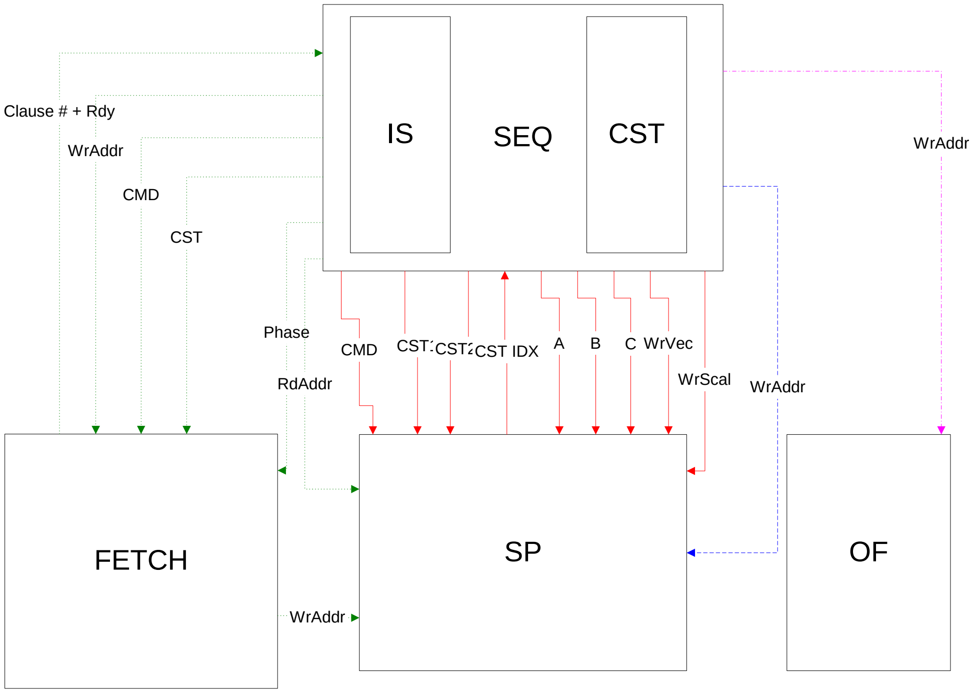

Figure 4: Sequencer Control interfaces

In green is represented the Fetch control interface, in red the ALU control interface, in blue the Interpolated/Vector control interface and in purple is the output file control interface.

2. Interpolated data bus

The interpolators contain an IJ buffer to pack the information as much as possible before writing it to the register file.

			XY					P1									P2						VTX	

Figure 6: Interpolation timing diagram

Above is an example of a tile the sequencer might receive from the SC. The write side is how the data get stacked into the XY and IJ buffers, the read side is how the data is passed to the GPRs. The IJ information is packed in the IJ buffer 4 quads at a time or two clocks. The sequencer allows at any given time as many as four quads to interpolate a parameter. They all have to come from the same primitive. Then the sequencer controls the write mask to the GPRs to write the valid data in.

3. Instruction Store

There is going to be only one instruction store for the whole chip. It will contain 4096 instructions of 96 bits each.

It is likely to be a 1 port memory; we use 1 clock to load the ALU instruction, 1 clocks to load the Fetch instruction, 1 clock to load 2 control flow instructions and 1 clock to write instructions.

The instruction store is loaded by the CP thru the register mapped registers.

The VS_BASE and PS_BASE context registers are used to specify for each context where its shader is in the instruction memory.

For the Real time commands the story is quite the same but for some small differences. There are no wrap-around points for real time so the driver must be careful not to overwrite regular shader data. The shared code (shared subroutines) uses the same path as real time.

4. Sequencer Instructions

All control flow instructions and move instructions are handled by the sequencer only. The ALUs will perform NOPs during this time (MOV PV,PV, PS,PS) if they have nothing else to do.

5. Constant Stores

5.1 Memory organizations

A likely size for the ALU constant store is 1024x128 bits. The read BW from the ALU constant store is 128 bits/clock and the write bandwidth is 32 bits/clock (directed by the CP bus size not by memory ports).

The maximum logical size of the constant store for a given shader is 256 constants. Or 512 for the pixel/vertex shader pair. The size of the re-mapping table is 128 lines (each line addresses 4 constants). The write granularity is 4 constants or 512 bits. It takes 16 clocks to write the four constants. Real time requires 256 lines in the physical memory (this is physically register mapped).

The texture state is also kept in a similar memory. The size of this memory is 320x96 bits (128 texture states for regular mode, 32 states for RT). The memory thus holds 128 texture states (192 bits per state). The logical size exposes 32 different states total, which are going to be shared between the pixel and the vertex shader. The size of the re-mapping table to for the texture state memory is 32 lines (each line addresses 1 texture state lines in the real memory). The CP write granularity is 1 texture state lines (or 192 bits). The driver sends 512 bits but the CP ignores the top 320 bits. It thus takes 6 clocks to write the texture state. Real time requires 32 lines in the physical memory (this is physically register mapped).

The control flow constant memory doesn't sit behind a renaming table. It is register mapped and thus the driver must reload its content each time there is a change in the control flow constants. Its size is 320*32 because it must hold 8 copies of the 32 dwords of control flow constants and the loop construct constants must be aligned.

The constant re-mapping tables for texture state and ALU constants are logically register mapped for regular mode and physically register mapped for RT operation.

5.2 Management of the Control Flow Constants

The control flow constants are register mapped, thus the CP writes to the according register to set the constant, the SQ decodes the address and writes to the block pointed by its current base pointer (CF_WR_BASE). On the read side, one level of indirection is used. A register (SQ_CONTEXT_MISC.CF_RD_BASE) keeps the current base pointer to the control flow block. This register is copied whenever there is a state change. Should the CP write to CF after the state change, the base register is updated with the (current pointer number +1)% number of states. This way, if the CP doesn't write to CF the state is going to use the previous CF constants.

5.3 Management of the re-mapping tables

5.3.1 *R400 Constant management*

The sequencer is responsible to manage two re-mapping tables (one for the constant store and one for the texture state). On a state change (by the driver), the sequencer will broadside copy the contents of its re-mapping tables to a new one. We have 8 different re-mapping tables we can use concurrently.

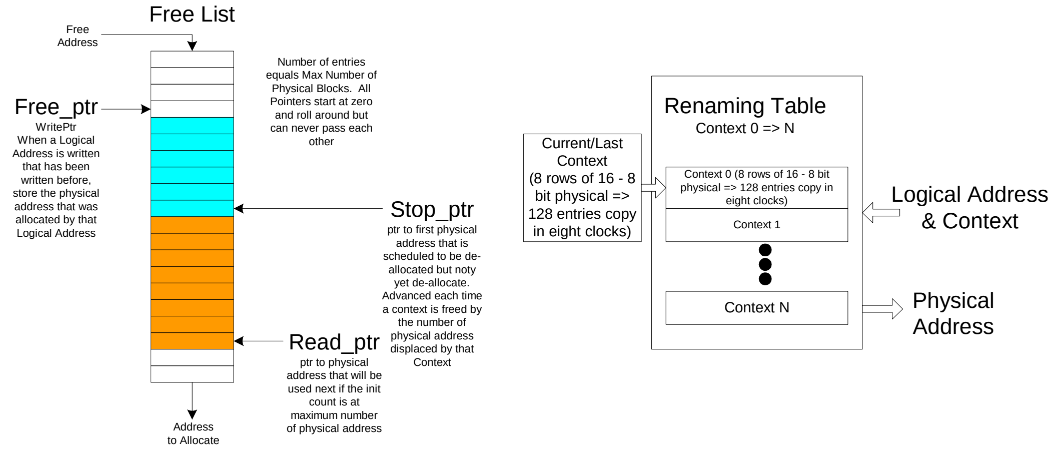
The constant memory update will be incremental, the driver only need to update the constants that actually changed between the two state changes.

For this model to work in its simplest form, the requirement is that the physical memory MUST be at least twice as large as the logical address space + the space allocated for Real Time. In our case, since the logical address space is 512 and the reserved RT space can be up to 256 entries, the memory must be of sizes 1280 and above. Similarly the size of the texture store must be of 32*2+32 = 96 entries and above.

5.3.2 *Proposal for R400LE constant management*

To make this scheme work with only 512+256 = 768 entries, upon reception of a CONTROL packet of state + 1, the sequencer would check for SQ_IDLE and PA_IDLE and if both are idle will erase the content of state to replace it with the new state (this is depicted in Figure 8: De-allocation mechanism~~Figure 8: De-allocation mechanismFigure 8: De-allocation mechanism~~). Note that in the case a state is cleared a value of 0 is written to the corresponding de-allocation counter location so that when the SQ is going to report a state change, nothing will be de-allocated upon the first report.

The second path sets all context dirty bits that were used in the current state to 1 (thus allowing the new state to reuse these physical addresses if needed).



Free List
Free Address
Free_ptr
WritePtr When a Logical Address is written that has been written before, store the physical address that was allocated by that Logical Address
Number of entries equals Max Number of Physical Blocks. All Pointers start at zero and roll around but can never pass each other
Stop_ptr
ptr to first physical address that is scheduled to be de-allocated but noty yet de-allocate. Advanced each time a context is freed by the number of physical address displaced by that Context
Read_ptr
ptr to physical address that will be used next if the init count is at maximum number of physical address
Address to Allocate
Current/Last Context (8 rows of 16 - 8 bit physical => 128 entries copy in eight clocks)

Figure 7: Constant management

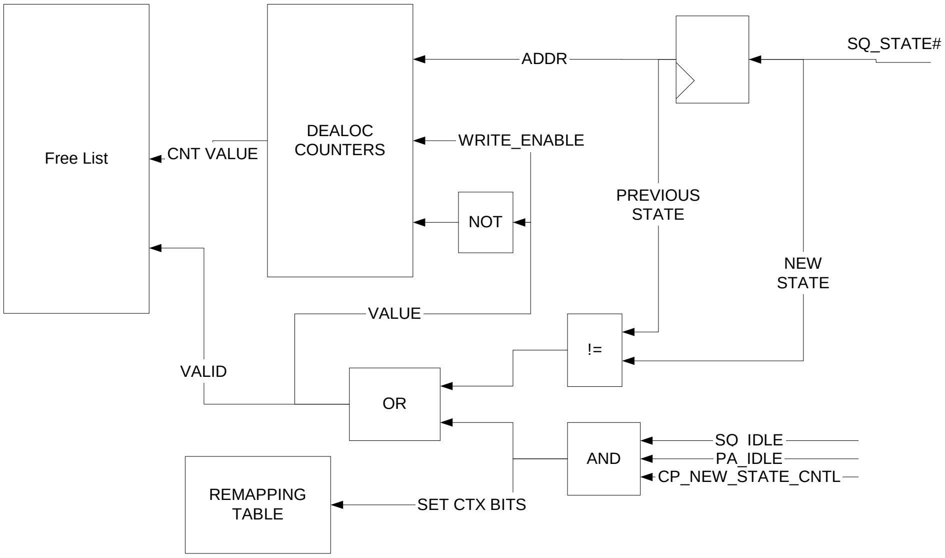

Figure 8: De-allocation mechanism for R400LE

5.3.3 *Dirty bits*

Two sets of dirty bits will be maintained per logical address. The first one will be set to zero on reset and set when the logical address is addressed. The second one will be set to zero whenever a new context is written and set for each address written while in this context. The reset dirty is not set, then writing to that logical address will not require de-allocation of whatever address stored in the renaming table. If it is set and the context dirty is not set, then the physical address store needs to be de-allocated and a new physical address is necessary to store the incoming data. If they are both set, then the data will be written into the physical address held in the renaming for the current logical address. No de-allocation or allocation takes place. This will happen when the driver does a set constant twice to the same logical address between context changes. NOTE: It is important to detect and prevent this, failure to do it will allow multiple writes to allocate all physical memory and thus hang because a context will not fit for rendering to start and thus free up space.

5.3.4 *Free List Block*

A free list block that would consist of a counter (called the IFC or Initial Free Counter) that would reset to zero and incremented every time a chunk of physical memory is used until they have all been used once. This counter would be checked each time a physical block is needed, and if the original ones have not been used up, us a new one, else check the free list for an available physical block address. The count is the physical address for when getting a chunk from the counter.

Storage of a free list big enough to store all physical block addresses.

Maintain three pointers for the free list that are reset to zero. The first one we will call write_ptr. This pointer will identify the next location to write the physical address of a block to be de-allocated. Note: we can never free more physical memory locations than we have. Once recording address the pointer will be incremented to walk the free list like a ring.

The second pointer will be called stop_ptr. The stop_ptr pointer will be advanced by the number of address chunks de-allocates when a context finishes. The address between the stop_ptr and write_ptr cannot be reused because they are still in use. But as soon as the context using then is dismissed the stop_ptr will be advanced.

The third pointer will be called read_ptr. This pointer will point will point to the next address that can be used for allocation as long as the read_ptr does not equal the stop_ptr and the IFC is at its maximum count.

5.3.5 *De-allocate Block*

This block will maintain a free physical address block count for each context. While in current context, a count shall be maintained specifying how many blocks were written into the free list at the write_ptr pointer. This count will be reset upon reset or when this context is active on the back and different than the previous context. It is actually a count of blocks in the previous context that will no longer be used. This count will be used to advance the write_ptr pointer to make available the set of physical blocks freed when the previous context was done. This allows the discard or de-allocation of any number of blocks in one clock.

5.3.6 *Operation of Incremental model*

The basic operation of the model would start with the write_ptr, stop_ptr, read_ptr pointers in the free list set to zero and the free list counter is set to zero. Also all the dirty bits and the previous context will be initialized to zero. When the first set constants happen, the reset dirty bit will not be set, so we will allocate a physical location from the free list counter because its not at the max value. The data will be written into physical address zero. Both the additional copy of the renaming table and the context zeros of the big renaming table will be updated for the logical address that was written by set start with physical address of 0. This process will be repeated for any logical address that are not dirty until the context changes. If a logical address is hit that has its dirty bits set while in the same context, both dirty bits would be set, so the new data will be over-written to the last physical address assigned for this logical address. When the first draw command of the context is detected, the previous context stored in the additional renaming table will be copied to the larger renaming table in the current (new) context location. Then the set constant logical address with be loaded with a new physical address during the copy and if the reset dirty was set, the physical address it replaced in the renaming table would be entered at the write_ptr pointer location on the free list and the write_ptr will be incremented. The de-allocation counter for the previous context (eight) will be incremented. This as set states come in for this context one of the following will happen:

1.) No dirty bits are set for the logical address being updated. A line will be allocated of the free-list counter or the free list at read_ptr pointer if read_ptr != to stop_ptr .
2.) Reset dirty set and Context dirty not set. A new physical address is allocated, the physical address in the renaming table is put on the free list at write_ptr and it is incremented along with the de-allocate counter for the last context.
3.) Context dirty is set then the data will be written into the physical address specified by the logical address.

This process will continue as long as set states arrive. This block will provide backpressure to the CP whenever he has not free list entries available (counter at max and stop_ptr == read_ptr). The command stream will keep a count of contexts of constants in use and prevent more than max constants contexts from being sent.

Whenever a draw packet arrives, the content of the re-mapping table is written to the correct re-mapping table for the context number. Also if the next context uses less constants than the current one all exceeding lines are moved to the free list to be de-allocated later. This happens in parallel with the writing of the re-mapping table to the correct memory.

Now preferable when the constant context leaves the last ALU clause it will be sent to this block and compared with the previous context that left. (Init to zero) If they differ than the older context will no longer be referenced and thus can be de-allocated in the physical memory. This is accomplished by adding the number of blocks freed this context to the stop_ptr pointer. This will make all the physical addresses used by this context available to the read_ptr allocate pointer for future allocation.

This device allows representation of multiple contexts of constants data with N copies of the logical address space. It also allows the second context to be represented as the first set plus some new additional data by just storing the delta's. It allows memory to be efficiently used and when the constants updates are small it can store multiple context. However, if the updates are large, less contexts will be stored and potentially performance will be degraded. Although it will still perform as well as a ring could in this case.

5.4 Constant Store Indexing

In order to do constant store indexing, the sequencer must be loaded first with the indexes (that come from the GPRs). There are 144 wires from the exit of the SP to the sequencer (9 bits pointers x 16 vertexes/clock). Since the data must pass thru the Shader pipe for the float to fixed conversion, there is a latency of 4 clocks (1 instruction)

between the time the sequencer is loaded and the time one can index into the constant store. The assembly will look like this

```
MOVA  R1.X,R2.X       // Loads the sequencer with the content of R2.X, also copies the content of R2.X into R1.X
NOP                   // latency of the float to fixed conversion
ADD   R3,R4,C0[R2.X]// Uses the state from the sequencer to add R4 to C0[R2.X] into R3
```

Note that we don't really care about what is in the brackets because we use the state from the MOVA instruction. R2.X is just written again for the sake of simplicity and coherency.

The storage needed in the sequencer in order to support this feature is 2*64*9 bits = 1152 bits.

5.5 Real Time Commands

The real time commands constants are written by the CP using the register mapped registers allocated for RT. It works is the same way than when dealing with regular constant loads BUT in this case the CP is not sending a logical address but rather a physical address and the reads are not passing thru the re-mapping table but are directly read from the memory. The boundary between the two zones is defined by the CONST_EO_RT control register. Similarly, for the fetch state, the boundary between the two zones is defined by the TSTATE_EO_RT control register.

5.6 Constant Waterfalling

In order to have a reasonable performance in the case of constant store indexing using the address register, we are going to have the possibility of using the physical memory port for read only. This way we can read 1 constant per clock and thus have a worst-case waterfall mode of 1 vertex per clock. There is a small synchronization issue related with this as we need for the SQ to make sure that the constants where actually written to memory (not only sent to the sequencer) before it can allow the first vector of pixels or vertices of the state to go thru the ALUs. To do so, the sequencer keeps 8 bits (one per render state) and sets the bits whenever the last render state is written to memory and clears the bit whenever a state is freed.

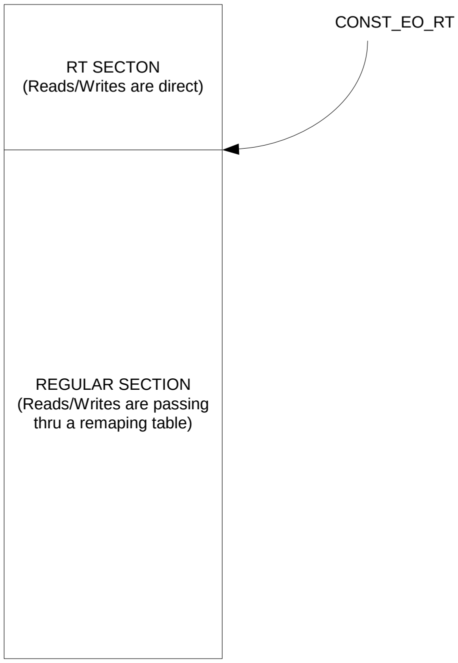

Figure 9: The Constant store

6. Looping and Branches

Loops and branches are planned to be supported and will have to be dealt with at the sequencer level. We plan on supporting constant loops and branches using a control program.

6.1 The controlling state.

The R400 controling state consists of:

Boolean[256:0]
Loop_count[7:0][31:0]
Loop_Start[7:0][31:0]
Loop_Step[7:0][31:0]

That is 256 Booleans and 32 loops.

We have a stack of 4 elements for nested calls of subroutines and 4 loop counters to allow for nested loops.

This state is available on a per shader program basis.

6.2 The Control Flow Program

We'd like to be able to code up a program of the form:

```
1:      Loop
2:      Exec    TexFetch
3:              TexFetch
4:              ALU
5:              ALU
6:              TexFetch
7:      End Loop
8:      ALU Export
```

But realize that 3: may be dependent on 2: and 4: is almost certainly dependent on 2: and 3:. Without clausing, these dependencies need to be expressed in the Control Flow instructions. Additionally, without separate 'texture clauses' and 'ALU clauses' we need to know which instructions to dispatch to the Texture Unit and which to the ALU unit. This information will be encapsulated in the flow control instructions.

Each control flow instruction will contain 2 bits of information for each (non-control flow) instruction:
a) ALU or Texture
b) Serialize Execution

(b) would force the thread to stop execution at this point (before the instruction is executed) and wait until all textures have been fetched. Given the allocation of reserved bits, this would mean that the count of an 'Exec' instruction would be limited to about 8 (non-control-flow) instructions. If more than this were needed, a second Exec (with the same conditions) would be issued.

Another function that relies upon 'clauses' is allocation and order of execution. We need to assure that pixels and vertices are exported in the correct order (even if not all execution is ordered) and that space in the output buffers are allocated in order. Additionally data can't be exported until space is allocated. A new control flow instruction:

Alloc <buffer select -- position,parameter, pixel or vertex memory. And the size required>.

would be created to mark where such allocation needs to be done. To assure allocation is done in order, the actual allocation for a given thread can not be performed unless the equivalent allocation for all previous threads is already completed. The implementation would also assure that execution of instruction(s) following the serialization due to the Alloc will occur in order -- at least until the next serialization or change from ALU to Texture. In most cases this will allow the exports to occur without any further synchronization. Only 'final' allocations or position allocations are

guaranteed to be ordered. Because strict ordering is required for pixels, parameters and positions, this implies only a single alloc for these structures. Vertex exports to memory do not require ordering during allocation and so multiple 'allocs' may be done.

6.2.1 *Control flow instructions table*

Here is the revised control flow instruction set.

Note that whenever a field is marked as RESERVED, it is assumed that all the bits of the field are cleared (0).

NOP		
47 … 44	43	42 … 0
0000	Addressing	RESERVED

This is a regular NOP.

Execute					
47 … 44	43	40 … 34	33 …16	15…12	11 … 0
0001	Addressing	RESERVED	Instructions type + serialize (9 instructions)	Count	Exec Address

Execute_End					
47 … 44	43	40 … 34	33 …16	15…12	11 … 0
0010	Addressing	RESERVED	Instructions type + serialize (9 instructions)	Count	Exec Address

Execute up to 9 instructions at the specified address in the instruction memory. The Instruction type field tells the sequencer the type of the instruction (LSB) (1 = Texture, 0 = ALU and whether to serialize or not the execution (MSB) (1 = Serialize, 0 = Non-Serialized). If Execute_End this is the last execution block of the shader program.

Conditional_Execute						
47 … 44	43	42	41 … 34	33…16	15 …12	11 … 0
0011	Addressing	Condition	Boolean address	Instructions type + serialize (9 instructions)	Count	Exec Address

Conditional_Execute_End						
47 … 44	43	42	41 … 34	33…16	15 …12	11 … 0
0100	Addressing	Condition	Boolean address	Instructions type + serialize (9 instructions)	Count	Exec Address

If the specified Boolean (8 bits can address 256 Booleans) meets the specified condition then execute the specified instructions (up to 9 instructions). If the condition is not met, we go on to the next control flow instruction. If Conditional_Execute_End and the condition is met, this is the last execution block of the shader program.

Conditional_Execute_Predicates							
47 … 44	43	42	41 … 36	35 … 34	33…16	15…12	11 … 0
0101	Addressing	Condition	RESERVED	Predicate vector	Instructions type + serialize (9 instructions)	Count	Exec Address

Conditional_Execute_Predicates_End							
47 … 44	43	42	41 … 36	35 … 34	33…16	15…12	11 … 0
0110	Addressing	Condition	RESERVED	Predicate vector	Instructions type + serialize (9 instructions)	Count	Exec Address

Check the AND/OR of all current predicate bits. If AND/OR matches the condition execute the specified number of instructions. We need to AND/OR this with the kill mask in order not to consider the pixels that aren’t valid. If the

condition is not met, we go on to the next control flow instruction. If Conditional_Execute_Predicates_End and the condition is met, this is the last execution block of the shader program.

Conditional_Execute_Predicates_No_Stall							
47 … 44	43	42	41 … 36	35 … 34	33…16	15…12	11 … 0
1101	Addressing	Condition	RESERVED	Predicate vector	Instructions type + serialize (9 instructions)	Count	Exec Address

Conditional_Execute_Predicates_No_Stall_End							
47 … 44	43	42	41 … 36	35 … 34	33…16	15…12	11 … 0
1110	Addressing	Condition	RESERVED	Predicate vector	Instructions type + serialize (9 instructions)	Count	Exec Address

Same as Conditionnal_Execute_Predicates but the SQ is not going to wait for the predicate vector to be updated. You can only set this in the compiler if you know that the predicate set is only a refinement of the current one (like a nested if) because the optimization would still work.

Loop_Start					
47 … 44	43	42 … 21	20 … 16	15…12	11 … 0
0111	Addressing	RESERVED	loop ID	RESERVED	Jump address

Loop Start. Compares the loop iterator with the end value. If loop condition not met jump to the address. Forward jump only. Also computes the index value. The loop id must match between the start to end, and also indicates which control flow constants should be used with the loop.

Loop_End						
47 … 44	43	42 … 24	23… 21	20 … 16	15…12	11 … 0
1000	Addressing	RESERVED	Predicate break	loop ID	RESERVED	start address

Loop end. Increments the counter by one, compares the loop count with the end value. If loop condition met, continue, else, jump BACK to the start of the loop. If predicate break != 0, then compares predicate vector n (specified by predicate break number). If all bits cleared then break the loop.

The way this is described does not prevent nested loops, and the inclusion of the loop id make this easy to do.

Conditionnal_Call						
47 … 44	43	42	41 … 34	33 … 13	12	11 … 0
1001	Addressing	Condition	Boolean address	RESERVED	Force Call	Jump address

If the condition is met, jumps to the specified address and pushes the control flow program counter on the stack. If force call is set the condition is ignored and the call is made always.

Return		
47 … 44	43	42 … 0
1010	Addressing	RESERVED

Pops the topmost address from the stack and jumps to that address. If nothing is on the stack, the program will just continue to the next instruction.

Conditionnal_Jump							
47 … 44	43	42	41… 34	33	32 … 13	12	11 … 0
1011	Addressing	Condition	Boolean address	FW only	RESERVED	Force Jump	Jump address

If force jump is set the condition is ignored and the jump is made always. If FW only is set then only forward jumps are allowed.

Allocate				
47 … 44	43	42…41	40 … 3~~4~~	2…~~3 …~~0
1100	Debug	Buffer Select	RESERVED	Size~~Allocation size~~

Buffer Select takes a value of the following:
01 – position export (ordered export)
10 – parameter cache or pixel export (ordered export)
11 – pass thru (out of order exports).

Size field is only used to reserve space in the export buffer for pass thru exports. Valid values are 1 (1 line) thru 9 (9 lines). It should be determined by the compiler/assembler by taking max index used +1.
~~Buffer Size takes a value of the following:~~
~~00 – 1 buffer~~
~~01 – 2 buffers~~
~~…~~
~~15 – 16 buffers~~

If debug is set this is a debug alloc (ignore if debug DB_ON register is set to off).

6.3 Implementation

The envisioned implementation has a buffer that maintains the state of each thread. A thread lives in a given location in the buffer during its entire life, but the buffer has FIFO qualities in that threads leave in the order that they enter. Actually two buffers are maintained -- one for Vertices and one for Pixels. The intended implementation would allow for:

16 entries for vertices
48 entries for pixels.

From each buffer, arbitration logic attempts to select 1 thread for the texture unit and 1 (interleaved) thread for the ALU unit. Once a thread is selected it is read out of the buffer, marked as invalid, and submitted to appropriate execution unit. It is returned to the buffer (at the same place) with its status updated once all possible sequential instructions have been executed. A switch from ALU to TEX or visa-versa or a Serialize_Execution modifier forces the thread to be returned to the buffer.

Each entry in the buffer will be stored across two physical pieces of memory - most bits will be stored in a 1 read port device. Only bits needed for thread arbitration will be stored in a highly multi-ported structure. The bits kept in the 1 read port device will be termed 'state'. The bits kept in the multi-read ported device will be termed 'status'.

'State Bits' needed include:

1. Control Flow Instruction Pointer (13 bits),
2. Execution Count Marker 4 bits),
3. Loop Iterators (4x9 bits),
4. Call return pointers (4x12 bits),
5. Predicate Bits (64 bits),
6. Export ID (1 bit),
7. Parameter Cache base Ptr (7 bits),
8. GPR Base Ptr (8 bits),
9. Context Ptr (3 bits).
10. LOD corrections (6x16 bits)
11. Valid bits (64 bits)
12. RT (1 bit) Signifies that this thread is a Real Time thread. This bit must be sent to the Constant store state machine when reading it.

Formatted: Bullets and Numbering

Absent from this list are 'Index' pointers. These are costly enough that I'm presuming that they are instead stored in the GPRs. The first seven fields above (Control Flow Ptr, Execution Count, Loop Counts, call return ptrs, Predicate bits, PC base ptr and export ID) are updated every time the thread is returned to the buffer based on how much progress has been mode on thread execution. GPR Base Ptr, Context Ptr and LOD corrections are unchanged throughout execution of the thread.

'Status Bits' needed include:

- Valid Thread
- Texture/ALU engine needed
- Texture Reads are outstanding
- Waiting on Texture Read to Complete
- Allocation Wait (2 bits)
- 00 – No allocation needed
- 01 – Position export allocation needed (ordered export)
- 10 – Parameter or pixel export needed (ordered export)
- 11 – pass thru (out of order export)
- Allocation Size (4 bits)
- Position Allocated
- First thread of a new context
- Event thread (NULL thread that needs to trickle down the pipe)
- Last (1 bit)
- Pulse SX (1 bit)

All of the above fields from all of the entries go into the arbitration circuitry. The arbitration circuitry will select a winner for both the Texture Engine and for the ALU engine. There are actually two sets of arbitration -- one for pixels and one for vertices. A final selection is then done between the two. But the rest of this implementation summary only considers the 'first' level selection which is similar for both pixels and vertices.

Texture arbitration requires no allocation or ordering so it is purely based on selecting the 'oldest' thread that requires the Texture Engine.

ALU arbitration is a little more complicated. First, only threads where either of Texture_Reads_outstanding or Waiting_on_Texture_Read_to_Complete are '0' are considered. Then if Allocation_Wait is active, these threads are further filtered based on whether space is available. If the allocation is position allocation, then the thread is only considered if all 'older' threads have already done their position allocation (position allocated bits set). If the allocation is parameter or pixel allocation, then the thread is only considered if it is the oldest thread. Also a thread is not considered if it is a parameter or pixel or position allocation, has its First_thread_of_a_new_context bit set and would cause ALU interleaving with another thread performing the same parameter or pixel or position allocation. Finally the 'oldest' of the threads that pass through the above filters is selected. If the thread needed to allocate, then at this time the allocation is done, based on Allocation_Size. If a thread has its “last” bit set, then it is also removed from the buffer, never to return.

If I now redefine 'clauses' to mean 'how many times the thread is removed from the thread buffer for the purpose of exection by either the ALU or Texture engine', then the minimum number of clauses needed is 2 -- one to perform the allocation for exports (execution automatically halts after an 'Alloc' instruction) (but doesn't performs the actual allocation) and one for the actual ALU/export instructions. As the 'Alloc' instruction could be part of a texture clause (presumably the final instruction in such a clause), a thread could still execute in this minimal number of 2 clauses, even if it involved texture fetching.

The Texture_Reads_Outstanding bit must be updated by the sequencer, based on keeping track of how many Texture Clauses have been executed by a given thread that have not yet had there data returned. Any number above 0 results in this bit being set. We could consider forcing synchronization such that two texture clauses for a given thread may not be outstanding at any time (that would be my preference for simplicity reasons and because it would require only very little change in the texture pipe interface). This would allow the sequencer to set the bit on execution of the texture clause, and allow the texture unit to return a pointer to the thread buffer on completion that clears the bit.

6.4 Data dependant predicate instructions

Data dependant conditionals will be supported in the R400. The only way we plan to support those is by supporting three vector/scalar predicate operations of the form:

PRED_SETE_# - similar to SETE except that the result is 'exported' to the sequencer.
PRED_SETNE_# - similar to SETNE except that the result is 'exported' to the sequencer.
PRED_SETGT_# - similar to SETGT except that the result is 'exported' to the sequencer
PRED_SETGTE_# - similar to SETGTE except that the result is 'exported' to the sequencer

For the scalar operations only we will also support the two following instructions:
PRED_SETE0_# – SETE0
PRED_SETE1_# – SETE1

The export is a single bit - 1 or 0 that is sent using the same data path as the MOVA instruction. The sequencer will maintain 4 sets of 64 bit predicate vectors (in fact 8 sets because we interleave two programs but only 4 will be exposed) and use it to control the write masking. This predicate is not maintained across clause boundaries. The # sign is used to specify which predicate set you want to use 0 thru 3.

Then we have two conditional execute bits. The first bit is a conditional execute “on” bit and the second bit tells us if we execute on 1 or 0. For example, the instruction:

P0_ADD_# R0,R1,R2

Is only going to write the result of the ADD into those GPRs whose predicate bit is 0. Alternatively, P1_ADD_# would only write the results to the GPRs whose predicate bit is set. The use of the P0 or P1 without precharging the sequencer with a PRED instruction is undefined.

{Issue: do we have to have a NOP between PRED and the first instruction that uses a predicate?}

6.5 HW Detection of PV,PS

Because of the control program, the compiler cannot detect statically dependant instructions. In the case of non-masked writes and subsequent reads the sequencer will insert uses of PV,PS as needed. This will be done by comparing the read address and the write address of consecutive instructions. For masked writes, the sequencer will insert NOPs wherever there is a dependant read/write.

The sequencer will also have to insert NOPs between PRED_SET and MOVA instructions and their uses.

6.6 Register file indexing

Because we can have loops in fetch clause, we need to be able to index into the register file in order to retrieve the data created in a fetch clause loop and use it into an ALU clause. The instruction will include the base address for register indexing and the instruction will contain these controls:

Bit7	Bit 6	
0	0	'absolute register'
0	1	'relative register'
1	0	'previous vector'
1	1	'previous scalar'

In the case of an absolute register we just take the address as is. In the case of a relative register read we take the base address and we add to it the loop_index and this becomes our new address that we give to the shader pipe.

The sequencer is going to keep a loop index computed as such:

Index = Loop_iterator*Loop_step + Loop_start.

We loop until loop_iterator = loop_count. Loop_step is a signed value [-128…127]. The computed index value is a 10 bit counter that is also signed. Its real range is [-256,256]. The tenth bit is only there so that we can provide an out of range value to the “indexing logic” so that it knows when the provided index is out of range and thus can make the necessary arrangements.

6.7 Debugging the Shaders

In order to be able to debug the pixel/vertex shaders efficiently, we provide 2 methods.

6.7.1 *Method 1: Debugging registers*

Current plans are to expose 2 debugging, or error notification, registers:
1. address register where the first error occurred
2. count of the number of errors

The sequencer will detect the following groups of errors:
- count overflow
- constant indexing overflow
- register indexing overflow

Compiler recognizable errors:
- jump errors
  relative jump address > size of the control flow program
- call stack
  call with stack full
  return with stack empty

A jump error will always cause the program to break. In this case, a break means that a clause will halt execution, but allowing further clauses to be executed.

With all the other errors, program can continue to run, potentially to worst-case limits. The program will only break if the DB_PROB_BREAK register is set.

If indexing outside of the constant or the register range, causing an overflow error, the hardware is specified to return the value with an index of 0. This could be exploited to generate error tokens, by reserving and initializing the 0th register (or constant) for errors.

{ISSUE : Interrupt to the driver or not?}

6.7.2 *Method 2: Exporting the values in the GPRs*

1) The sequencer will have a debug active, count register and an address register for this mode.

Under the normal mode execution follows the normal course.

Under the debug mode it is assumed that the program is always exporting n debug vectors and that all other exports to the SX block (position, color, z, ect) will been turned off (changed into NOPs) by the sequencer (even if they occur before the address stated by the ADDR debug register).

7. Pixel Kill Mask

A vector of 64 bits is kept by the sequencer per group of pixels/vertices. Its purpose is to optimize the texture fetch requests and allow the shader pipe to kill pixels using the following instructions:

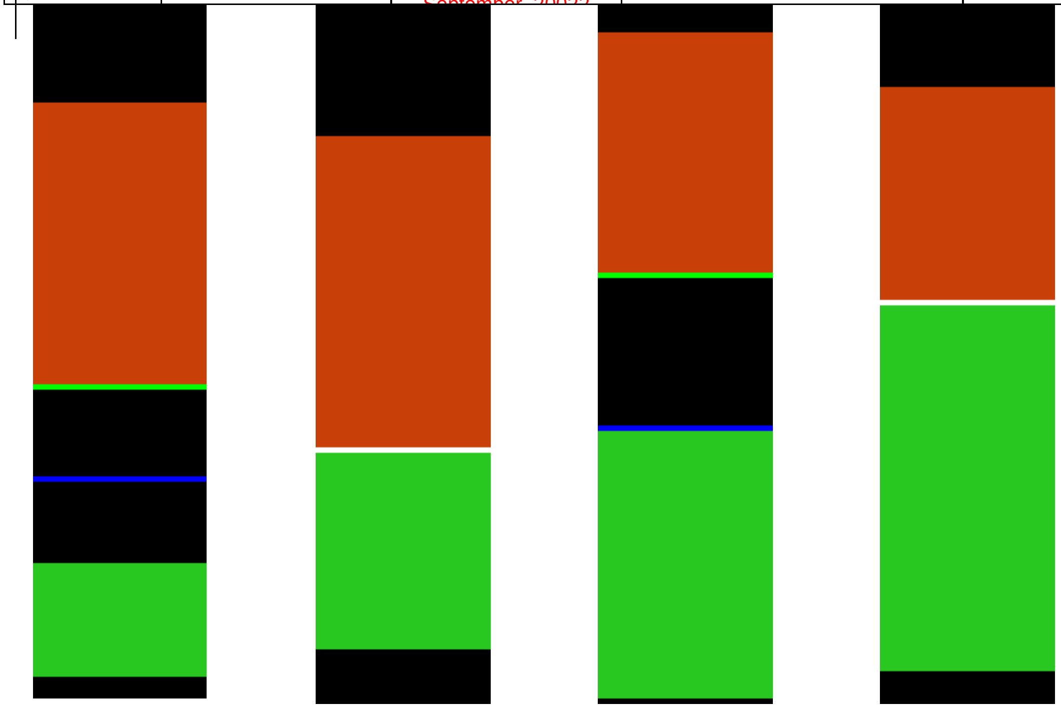
MASK_SETE
MASK_SETNE
MASK_SETGT
MASK_SETGTE

8. Multipass vertex shaders (HOS)

Multipass vertex shaders are able to export from the 6 last clauses but to memory ONLY.

9. Register file allocation

The register file allocation for vertices and pixels can either be static or dynamic. In both cases, the register file in managed using two round robins (one for pixels and one for vertices). In the dynamic case the boundary between pixels and vertices is allowed to move, in the static case it is fixed to 128-VERTEX_REG_SIZE for vertices and PIXEL_REG_SIZE for pixels.



Above is an example of how the algorithm works. Vertices come in from top to bottom; pixels come in from bottom to top. Vertices are in orange and pixels in green. The blue line is the tail of the vertices and the green line is the tail of the pixels. Thus anything between the two lines is shared. When pixels meets vertices the line turns white and the boundary is static until both vertices and pixels share the same "unallocated bubble". Then the boundary is allowed to move again. The numbering of the GPRs starts from the bottom of the picture at index 0 and goes up to the top at index 127.

10. Fetch Arbitration

The fetch arbitration logic chooses one of the n potentially pending fetch clauses to be executed. The choice is made by looking at the Vs and Ps reservation stations and picking the first one ready to execute. Once chosen, the clause state machine will send one 2x2 fetch per clock (or 4 fetches in one clock every 4 clocks) until all the fetch instructions of the clause are sent. This means that there cannot be any dependencies between two fetches of the same clause.

The arbitrator will not wait for the fetches to return prior to selecting another clause for execution. The fetch pipe will be able to handle up to X(?) in flight fetches and thus there can be a fair number of active clauses waiting for their fetch return data.

11. ALU Arbitration

ALU arbitration proceeds in almost the same way than fetch arbitration. The ALU arbitration logic chooses one of the n potentially pending ALU clauses to be executed. The choice is made by looking at the Vs and Ps reservation stations and picking the first one ready to execute. There are two ALU arbiters, one for the even clocks and one for the odd clocks. For example, here is the sequencing of two interleaved ALU clauses (E and O stands for Even and Odd sets of 4 clocks):

Einst0 Oinst0 Einst1 Oinst1 Einst2 Oinst2 Einst0 Oinst3 Einst1 Oinst4 Einst2 Oinst0…

Proceeding this way hides the latency of 8 clocks of the ALUs. Also note that the interleaving also occurs across clause boundaries.

12. Handling Stalls

When the output file is full, the sequencer prevents the ALU arbitration logic from selecting the last clause (this way nothing can exit the shader pipe until there is place in the output file. If the packet is a vertex packet and the position buffer is full (POS_FULL) then the sequencer also prevents a thread from entering an exporting clause. The sequencer will set the OUT_FILE_FULL signal n clocks before the output file is actually full and thus the ALU arbiter will be able read this signal and act accordingly by not preventing exporting clauses to proceed.

13. Content of the reservation station FIFOs

The reservation FIFOs contain the state of the vector of pixels and vertices. We have two sets of those: one for pixels, and one for vertices. They contain 3 bits of Render State 7 bits for the base address of the GPRs, some bits for LOD correction and coverage mask information in order to fetch fetch for only valid pixels, the quad address.

14. The Output File

The output file is where pixels are put before they go to the RBs. The write BW to this store is 256 bits/clock. Just before this output file are staging registers with write BW 512 bits/clock and read BW 256 bits/clock. The staging registers are 4x128 (and there are 16 of those on the whole chip).

15. IJ Format

The IJ information sent by the PA is of this format on a per quad basis:

We have a vector of IJ's (one IJ per pixel at the centroid of the fragment or at the center of the pixel depending on the mode bit). All pixel's parameters are always interpolated at full 20x24 mantissa precision.

$$P0 = A + I(0)*(B - A) + J(0)*(C - A)$$
$$P1 = A + I(1)*(B - A) + J(1)*(C - A)$$
$$P2 = A + I(2)*(B - A) + J(2)*(C - A)$$
$$P3 = A + I(3)*(B - A) + J(3)*(C - A)$$

P0	P1
P2	P3

Multiplies (Full Precision): 8
Subtracts 19x24 (Parameters): 2
Adds: 8

FORMAT OF P's IJ : Mantissa 20 Exp 4 for I + Sign
Mantissa 20 Exp 4 for J + Sign

Total number of bits : 20*8 + 4*8 + 4*2 = 200.

All numbers are kept using the un-normalized floating point convention: if exponent is different than 0 the number is normalized if not, then the number is un-normalized. The maximum range for the IJs (Full precision) is +/- 1024.

15.1 Interpolation of constant attributes

Because of the floating point imprecision, we need to take special provisions if all the interpolated terms are the same or if two of the terms are the same.

16. Staging Registers

In order for the reuse of the vertices to be 14, the sequencer will have to re-order the data sent IN ORDER by the VGT for it to be aligned with the parameter cache memory arrangement. Given the following group of vertices sent by the VGT:

0 1 2 3 4 5 6 7 8 9 10 11 12 13 14 15 || 16 17 18 19 20 21 22 23 24 25 26 27 28 29 30 31 || 32 33 34 35 36 37 38 39 40 41 42 43 44 45 46 47 || 48 49 50 51 52 53 54 55 56 57 58 59 60 61 62 63

The sequencer will re-arrange them in this fashion:

0 1 2 3 16 17 18 19 32 33 34 35 48 49 50 51 || 4 5 6 7 20 21 22 23 36 37 38 39 52 53 54 55 || 8 9 10 11 24 25 26 27 40 41 42 43 56 57 58 59 || 12 13 14 15 28 29 30 31 44 45 46 47 60 61 62 63

The || markers show the SP divisions. In the event a shader pipe is broken, the SQ is responsible to insert padding to account for the missing pipe. For example, if SP1 is broken, vertices 4 5 6 7 20 21 22 23 36 37 38 39 52 53 54 55 will not be sent by the VGT to the SQ **AND** the SQ is responsible to "jump" over these vertices in order for no valid vertices to be sent to an invalid SP.

The most straightforward, *non-compressed* interface method would be to convert, in the VGT, the data to 32-bit floating point prior to transmission to the VSISRs. In this scenario, the data would be transmitted to (and stored in) the VSISRs in full 32-bit floating point. This method requires three 24-bit fixed-to-float converters in the VGT. Unfortunately, it also requires and additional 3,072 bits of storage across the VSISRs. This interface is illustrated in Figure 11~~Figure 11Figure 11~~. The area of the fixed-to-float converters and the VSISRs for this method is roughly estimated as 0.759sqmm using the R300 process. The gate count estimate is shown in Figure 10~~Figure 10Figure 10~~.

Basis for 8-deep Latch Memory (from R300)

8x24-bit	11631 μ^2	60.57813 μ^2 per bit
Area of 96x8-deep Latch Memory	46524 μ^2	
Area of 24-bit Fix-to-float Converter	4712 μ^2 per converter	

Method 1	Block	Quantity	Area
	F2F	3	14136
	8x96 Latch	16	744384
			758520 μ^2

Figure 10:Area Estimate for VGT to Shader Interface

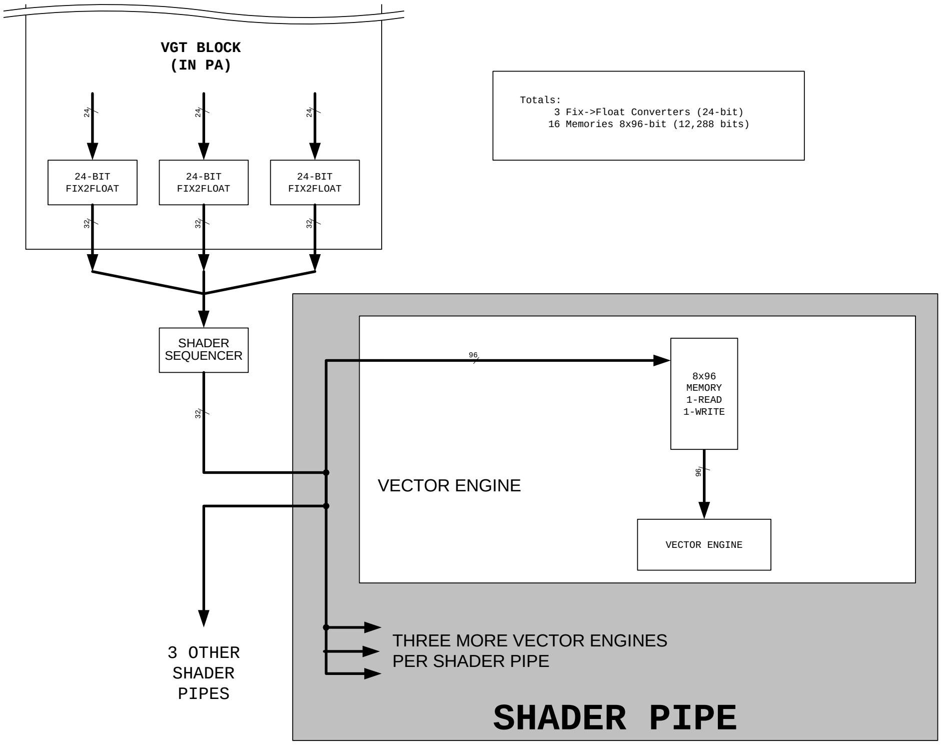


Figure 11:VGT to Shader Interface

17. The parameter cache

The parameter cache is where the vertex shaders export their data. It consists of 16 128x128 memories (1R/1W). The reuse engine will make it so that all vertexes of a given primitive will hit different memories. The allocation method for these memories is a simple round robin. The parameter cache pointers are mapped in the following way: 4MSBs are the memory number and the 7 LSBs are the address within this memory.

MEMORY NUMBER 4 bits	ADDRESS 7 bits

The PA generates the parameter cache addresses as the positions come from the SQ. All it needs to do is keep a Current_Location pointer (7 bits only) and as the positions comes increment the memory number. When the memory number field wraps around, the PA increments the Current_Location by VS_EXPORT_COUNT (a snooped register from the SQ). As an example, say the memories are all empty to begin with and the vertex shader is exporting 8 parameters per vertex (VS_EXPORT_COUNT = 8). The first position received is going to have the PC address 00000000000 the second one 00010000000, third one 00100000000 and so on up to 11110000000. Then the next position received (the 17th) is going to have the address 00000001000, the 18th 00010001000, the 19th 00100001000 and so on. The Current_location is NEVER reset BUT on chip resets. The only thing to be careful about is that if the SX doesn't send you a full group of positions (<64) then you need to fill the address space so that the next group starts correctly aligned (for example if you receive only 33 positions then you need to add 2*VS_EXPORT_COUNT to Current_Location and reset the memory count to 0 before the next vector begins).

17.1 Export restrictions

17.1.1 *Pixel exports:*

Pixels can export 1,2,3 or 4 color buffers to the SX(+z). The exports will be done in order. The PRED_OPTIMIZE function has to be turned of if the exports are done using interleaved predicated instructions. The exports will always be ordered to the SX.

17.1.2 *Vertex exports:*

Position or parameter caches can be exported in any order in the shader program. It is always better to export posistion as soon as possible. Position has to be exported in a single export block (no texture instructions can be placed between the exports). Parameter cache exports can be done in any order with texture instructions interleaved. The PRED_OPTIMIZE function has to be turned of if the exports are done using interleaved predicated instructions to the Parameter cache (see Arbitration restrictions for details). The exports will always be allocated in order to the SX.

17.1.3 *Pass thru exports:*

Pass thru exports have to be done in groups of the form:

```
Alloc 4 (8 or 12)
Execute ALU(ADDR) ALU(DATA) ALU(DATA) ALU(DATA)…
```

They cannot have texture instructions interleaved in the export block. These exports **are not guaranteed to be ordered**.

Also, when doing a pass thru export, Position MUST be exported AFTER all pass thru exports. This position export is used to synchronize the chip when doing a transition from pass thru shader to regular shader and vice versa.

17.2 Arbitration restrictions

Here are the Sequencer arbitration restrictions:

1) Cannot execute a serialized thread if the corresponding texture pending bit is set
2) Cannot allocate position if any older thread has not allocated position
3) If last thread is marked as not valid AND marked as last and we are about to execute the second to oldest thread also marked last then:
    a. Both threads must be from the same context (cannot allow a first thread)
    b. Must turn off the predicate optimization for the second thread
4) Cannot execute a texture clause if texture reads are pending
5) Cannot execute last if texture pending (even if not serial)

18. Export Types

The export type (or the location where the data should be put) is specified using the destination address field in the ALU instruction. Here is a list of all possible export modes:

18.1 Vertex Shading

0:15	- 16 parameter cache
16:31	- Empty (Reserved?)
32	- Export Address
33:~~40~~ 41	- ~~8~~ 9 vertex exports to the frame buffer and index
~~41~~42:47	- Empty
48:55	- 8 debug export (interpret as normal vertex export)
60	- export addressing mode
61	- Empty
62	- position

63 - sprite size export that goes with position export (~~point_h,point_w,edgeflag,misc)~~X= point size, Y= edge flag is bit 0, Z= VtxKill is bitwise OR of bits 30:0. Any bit other than sign means VtxKill.)

18.2 Pixel Shading

0	- Color for buffer 0 (primary)
1	- Color for buffer 1
2	- Color for buffer 2
3	- Color for buffer 3
4:~~7~~15	- Empty
~~8~~16	- Buffer 0 Color/Fog (primary)
~~9~~17	- Buffer 1 Color/Fog
1~~0~~8	- Buffer 2 Color/Fog
1~~1~~9	- Buffer 3 Color/Fog
~~12~~20:~~15~~31	- Empty
~~16:31~~	~~- Empty (Reserved?)~~
32	- Export Address
33:~~40~~41	- ~~8~~ 9 exports for multipass pixel shaders.
4~~1~~2:47	- Empty
48:55	- 8 debug exports (interpret as normal pixel export)
60 ~~60~~	- export addressing mode
~~60~~61	- Z for primary buffer (Z exported to 'alpha' component)
~~61~~62:6~~2~~3	- Empty
~~63~~	~~- Z for primary buffer (Z exported to 'alpha' component)~~

Formatted: Bullets and Numbering

19. Special Interpolation modes

19.1 Real time commands

We are unable to use the parameter memory since there is no way for a command stream to write into it. Instead we need to add three 16x128 memories (one for each of three vertices x 16 interpolants). These will be mapped onto the register bus and written by type 0 packets, and output to the the parameter busses (the sequencer and/or PA need to be able to address the realtime parameter memory as well as the regular parameter store. For higher performance we should be able able to view them as two banks of 16 and do double buffering allowing one to be loaded, while the other is rasterized with. Most overlay shaders will need 2 or 4 scalar coordinates, one option might be to restrict the memory to 16x64 or 32x64 allowing only two interpolated scalars per cycle, the only problem I see with this is, if we view support for 16 vector-4 interpolants important (true only if we map Microsoft's high priority stream to the realtime stream), then the PA/sequencer need to support a realtime-specific mode where we need to address 32 vectors of parameters instead of 16. This mode is triggered by the primitive type: REAL TIME. The actual memories are in the in the SX blocks. The parameter data memories are hooked on the RBBM bus and are loaded by the CP using register mapped memory.

19.2 Sprites/ XY screen coordinates/ FB information

XY screen coordinates may be needed in the shader program. This functionality is controlled by the param_gen_I0 register (in SQ) in conjunction with the SND_XY register (in SC) and the param_gen_pos. Also it is possible to send the faceness information (for OGL front/back special operations) to the shader using the same control register. Here is a list of all the modes and how they interact together:

The Data is going to be written in the register specified by the param_gen_pos register.

Param_Gen_I0 disable, snd_xy disable = No modification
Param_Gen_I0 disable, snd_xy enable = No modification
Param_Gen_I0 enable, snd_xy disable = Sign(faceness)garbage,(Sign Point)garbage,Sign(Line)s, t
Param_Gen_I0 enable, snd_xy enable = Sign(faceness)screenX,(Sign Point)screenY,Sign(Line)s, t

In other words,

The generated vector is (X in RED, Y in GREEN, S in BLUE and T in ALPHA):
X,Y,S,T
These values are always supposed to be positive and any shader use of them should use the ABS function (as their sign bits will now be used for flags).
SignX = BackFacing
SignY = Point Primitive
SignS = Line Primitive
SignT = currently unused as a flag.

If !Point & !Line, then it is a Poly.

I would assume that one implementation which allows for generic texture lookup (using 3D maps) for poly stipple and AA for the driver would be

```
if(Y<0) {
        R = 0.0 (Point)
} else if (S < 0) {
        R = 1.0 (Line)
} else {
        R = 2.0 (Poly)
}
```

19.3 Auto generated counters

In the cases we are dealing with multipass shaders, the sequencer is going to generate a vector count to be able to both use this count to write the 1st pass data to memory and then use the count to retrieve the data on the 2nd pass. The count is always generated in the same way but it is passed to the shader in a slightly different way depending on the shader type (pixel or vertex). This is toggled on and off using the GEN_INDEX_PIX/VTX register. The sequencer is going to keep two counters, one for pixels and one for vertices. Every time a full vector of vertices or pixels is written to the GPRs the counter is incremented. Every time a ~~state change is detected~~RST_PIX_COUNT or RST_VTX_COUNT events are received, the corresponding counter is reset. While there is only one count broadcast to the GPRs, the LSB are hardwired to specific values making the index different for all elements in the vector. Since the count must be different for all pixels/vertices and the 4 LSBs (16 positions) are hardwired to the corresponding shader unit the SQ has two choices:

1) Maintain a 19 bit counter that counts the vectors of 64. In this case the phase must be appended to the count before the count is broadcast to the SPs:

Formatted: Bullets and Numbering

Counter (19 bits)	Phase (2 bits)	Hardwired (4 bits)

2) Maintain a 21 bits counter that counts sub-vectors of 16. In this case only the counter is sent to the Sps:

Formatted: Bullets and Numbering

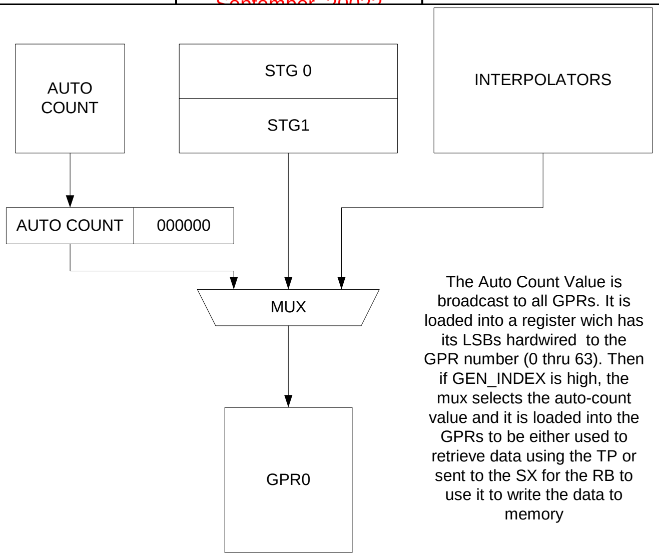
Counter (21 bits)	Harwired (4 bits)

19.3.1 *Vertex shaders*

In the case of vertex shaders, if GEN_INDEX_VTX is set, the data will be put into the x field of the third register (it means that the compiler must allocate 3 GPRs in all multipass vertex shader modes).

19.3.2 *Pixel shaders*

In the case of pixel shaders, if GEN_INDEX_PIX is set, the data will be put in the x field of the param_gen_pos+1 register.



The Auto Count Value is broadcast to all GPRs. It is loaded into a register wich has its LSBs hardwired to the GPR number (0 thru 63). Then if GEN_INDEX is high, the mux selects the auto-count value and it is loaded into the GPRs to be either used to retrieve data using the TP or sent to the SX for the RB to use it to write the data to memory

Figure 12: GPR input mux Control

20. State management

Every clock, the sequencer will report to the CP the oldest states still in the pipe. These are the states of the programs as they enter the last ALU clause.

20.1 Parameter cache synchronization

In order for the sequencer not to begin a group of pixels before the associated group of vertices has finished, the sequencer will keep a 6 bit count per state (for a total of 8 counters). These counters are initialized to 0 and every time a vertex shader exports its data TO THE PARAMETER CACHE, the corresponding pointer is incremented. When the SC sends a new vector of pixels with the SC_SQ_new_vector bit asserted, the sequencer will first check if the count is greater than 0 before accepting the transmission (it will in fact accept the transmission but then lower its ready to receive). Then the sequencer waits for the count to go to one and decrements it. The sequencer can then issue the group of pixels to the interpolators. Every time the state changes, the new state counter is initialized to 0.

21. XY Address imports

The SC will be able to send the XY addresses to the GPRs. It does so by interleaving the writes of the IJs (to the IJ buffer) with XY writes (to the XY buffer). Then when writing the data to the GPRs, the sequencer is going to interpolate the IJ data or pass the XY data thru a Fix→float converter and expander and write the converted values to the GPRs. The Xys are currently SCREEN SPACE COORDINATES. The values in the XY buffers will wrap. See section 19.2 for details on how to control the interpolation in this mode.

21.1 Vertex indexes imports

In order to import vertex indexes, we have 16 8x96 staging registers. These are loaded one line at a time by the VGT block (96 bits). They are loaded in floating point format and can be transferred in 4 or 8 clocks to the GPRs.

22. Registers

Please see the auto-generated web pages for register definitions.

23. Interfaces

23.1 External Interfaces

Whenever an x is used, it means that the bus is broadcast to all units of the same name. For example, if a bus is named SQ→SPx it means that SQ is going to broadcast the same information to all SP instances.

23.2 SC to SP Interfaces

23.2.1 *SC_SP#*

There is one of these interfaces at front of each of the SP (buffer to stage pixel interpolators). This interface transmits the I,J data for pixel interpolation. For the entire system, two quads per clock are transferred to the 4 SPs, so each of these 4 interfaces transmits one half of a quad per clock. The interface below describes a half of a quad worth of data.
The actual data which is transferred per quad is
Ref Pix I => S4.20 Floating Point I value *4
Ref Pix J => S4.20 Floating Point J value *4

This equates to a total of 200 bits which transferred over 2 clocks
and therefor needs an interface 100 bits wide

Additionally, X,Y data (12-bit unsigned fixed) is conditionally sent across this data bus over the same wires in an additional clock. The X,Y data is sent on the lower 24 bits of the data bus with faceness in the msb.
Transfers across these interfaces are synchronized with the SC_SQ IJ Control Bus transfers.

The data transfer across each of these busses is controlled by a IJ_BUF_INUSE_COUNT in the SC. Each time the SC has sent a pixel vector's worth of data to the SPs, he will increment the IJ_BUF_INUSE_COUNT count. Prior to sending the next pixel vectors data, he will check to make sure the count is less than MAX_BUFER_MINUS_2, if not the SC will stall until the SQ returns a pipelined pulse to decrement the count when he has scheduled a buffer free. Note: We could/may optimize for the case of only sending only IJ to use all the buffers to pre-load more. Currently it is planned for the SP to hold 2 double buffers of I,J data and two buffers of X,Y data, so if either X,Y or Centers and Centroids are on, then the SC can send two Buffers.

In at least the initial version, the SC shall send 16 quads per pixel vector even if the vector is not full. This will increment buffer write address pointers correctly all the time. (We may revisit this for both the SX,SP,SQ and add a EndOfVector signal on all interfaces to quit early. We opted for the simple mode first with a belief that only the end of packet and multiple new vector signals should cause a partial vector and that this would not really be significant performance hit.)

Name	Bits	Description
SC_SP#_data	100	IJ information sent over 2 clocks (or X,Y in 24 LSBs with faceness in upper bit) **Type 0 or 1**, First clock I, second clk J Field ULC URC LLC LRC Bits [63:39] [38:26] [25:13] [12:0] Format SE4M20 SE4M20 SE4M20 SE4M20 **Type 2** Field Face X Y Bits [~~63~~24] [23:12] [11:0] Format Bit Unsigned Unsigned
SC_SP#_valid	1	Valid
SC_SP#_last_quad_data	1	This bit will be set on the last transfer of data per quad.
SC_SP#_type	2	0 -> Indicates centroids 1 -> Indicates centers 2 -> Indicates X,Y Data and faceness on data bus The SC shall look at state data to determine how many types to send for the

		interpolation process.

The # is included for clarity in the spec and will be replaced with a prefix of u#_ in the verilog module statement for the SC and the SP block will have neither because the instantiation will insert the prefix.

23.2.2 *SC_SQ*

This is the control information sent to the sequencer in order to synchronize and control the interpolation and/or loading data into the GPRs needed to execute a shader program on the sent pixels. This data will be sent over two clocks per transfer with 1 to 16 transfers. Therefore the bus (approx ~~94~~ 108 bits) could be folded in half to approx ~~49~~ 54 bits.

Name	Bits	Description
SC_SQ_data	46	Control Data sent to the SQ 1 clk transfers Event – valid data consist of event_id and state_id. Instruct SQ to post an event vector to send state id and event_id through request fifo and onto the reservation stations making sure state id and/or event_id gets back to the CP. Events only follow end of packets so no pixel vectors will be in progress. Empty Quad Mask – Transfer Control data consisting of pc_dealloc or new_vector. Receipt of this is to transfer pc_dealloc or new_vector without any valid quad data. New vector will always be posted to request fifo and pc_dealloc will be attached to any pixel vector outstanding or posted in request fifo if no valid quad outstanding. 2 clk transfers Quad Data Valid – Sending quad data with or without new_vector or pc_dealloc. New vector will be posted to request fifo with or without a pixel vector and pc_dealloc will be posted with a pixel vector unless none is in progress. In this case the pc_dealloc will be posted in the request queue. Filler quads will be transferred with The Quad mask set but the pixel corresponding pixel mask set to zero.
SC_SQ_valid	1	SC sending valid data, 2nd clk could be all zeroes

SC_SQ_data – first clock and second clock transfers are shown in the table below.

Name	BitField	Bits	Description
1st Clock Transfer			
SC_SQ_event	0	1	This transfer is a 1 clock event vector Force quad_mask = new_vector=pc_dealloc=0
SC_SQ_event_id	[4:1]	4	This field identifies the event 0 => denotes an End Of State Event 1

			=> TBD
~~SC_SQ_pc_dealloc~~SC_SQ_state_id	[7:5]~~[7:5]~~	3~~3~~	~~Deallocation token for the Parameter Cache~~State/constant pointer (6*3+3)
SC_SQ_pc_dealloc	[10:8]	3	Deallocation token for the Parameter Cache
SC_SQ_new_vector	11~~8~~	1	The SQ must wait for Vertex shader done count > 0 and after dispatching the Pixel Vector the SQ will decrement the count.
SC_SQ_quad_mask	[1~~2~~5:12~~9~~]	4	Quad Write mask left to right SP0 => SP3
SC_SQ_end_of_prim	1~~3~~6	1	End Of the primitive
SC_SQ_pix_mask	[32:17]	16	Valid bits for all pixels SP0=>SP3 (UL,UR,LL,LR)
SC_SQ_provok_vtx	[3~~7~~4:3~~6~~3]	2	Provoking vertex for flat shading
~~SC_SQ_pc_ptr0~~SC_SQ_lod_correct_0	[4~~8~~3:3~~8~~5]	~~11~~9	~~Parameter Cache pointer for vertex 0~~LOD correction for quad 0 (SP0) (9 bits per quad)
SC_SQ_lod_correct_1	[52:44]	9	LOD correction for quad 1 (SP1) (9 bits per quad)
2nd Clock Transfer			
SC_SQ_lod_correct_2~~SC_SQ_pc_ptr1~~	[8:0]~~[10:0]~~	9~~11~~	LOD correction for quad 2 (SP2) (9 bits per quad)~~Parameter Cache pointer for vertex 1~~
SC_SQ_lod_correct_3	[17:9]	9	LOD correction for quad 3 (SP3) (9 bits per quad)
SC_SQ_pc_ptr0	[28:18]	11	Parameter Cache pointer for vertex 0
SC_SQ_pc_ptr~~2~~1	[~~21~~39:~~11~~29]	11	Parameter Cache pointer for vertex 1~~2~~
SC_SQ_pc_ptr2 ~~SC_SQ_lod_correct~~	[~~45~~50:~~22~~40]	~~24~~11	Parameter Cache pointer for vertex 2~~LOD correction per quad (6 bits per quad)~~
SC_SQ_prim_type	[~~48~~53:~~46~~51]	3	Stippled line and Real time command need to load tex cords from alternate buffer 000: Sprite (point) 001: Line 010: Tri_rect 100: Realtime Sprite (point) 101: Realtime Line 110: Realtime Tri_rect

Name	**Bits**	**Description**
SQ_SC_free_buff	1	Pipelined bit that instructs SC to decrement count of buffers in use.
SQ_SC_dec_cntr_cnt	1	Pipelined bit that instructs SC to decrement count of new vector and/or event sent to prevent SC from overflowing SQ interpolator/Reservation request fifo.

The scan converter will submit a partial vector whenever:

1.) He gets a primitive marked with an end of packet signal.

2.) A current pixel vector is being assembled with at least one or more valid quads and the vector has been marked for deallocate when a primitive marked new_vector arrives. The Scan Converter will submit a partial vector (up to 16quads with zero pixel mask to fill out the vector) prior to submitting the new_vector marker\primitive.

(This will prevent a hang which can be demonstrated when all primitives in a packet three vectors are culled except for a one quad primitive that gets marked pc_dealloc (vertices maximum size). In this case two new_vectors are submitted and processed, but then one valid quad with the pc_dealloc creates a vector and then the new would wait for another vertex vector to be processed, but the one being waited for could never export until the pc_dealloc signal made it through and thus the hang.)

23.2.3 SQ to SX(SP): Interpolator bus

Name	Direction	Bits	Description
SQ_SPx_interp_flat_vtx	SQ→SPx	2	Provoking vertex for flat shading
SQ_SPx_interp_flat_gouraud	SQ→SPx	1	Flat or gouraud shading
SQ_SPx_interp_cyl_wrap	SQ→SPx	4	Wich channel needs to be cylindrical wrapped
SQ_SPx_interp_param_gen	SQ→SPx	1	Generate Parameter
SQ_SPx_interp_prim_type	SQ→SPx	2	Bits [1:0] of primitive type sent by SC
SQ_SPx_interp_buff_swap	SQ→SPx	1	Swapp IJ buffers
SQ_SPx_interp_IJ_line	SQ→SPx	2	IJ line number
SQ_SPx_interp_mode	SQ→SPx	1	Center/Centroid sampling
SQ_SXx_pc_ptr0	SQ→SXx	11	Parameter Cache Pointer
SQ_SXx_pc_ptr1	SQ→SXx	11	Parameter Cache Pointer
SQ_SXx_pc_ptr2	SQ→SXx	11	Parameter Cache Pointer
SQ_SXx_rt_sel	SQ→SXx	1	Selects between RT and Normal data (Bit 2 of prim type)
SQ_SX0_pc_wr_en	SQ→SX0	8	Write enable for the PC memories
SQ_SX~~x~~1_pc_wr_en	SQ→~~SXx~~SX1	~~1~~8	Write enable for the PC memories
SQ_SXx_pc_wr_addr	SQ→SXx	7	Write address for the PCs
SQ_SXx_pc_channel_mask	SQ→SXx	4	Channel mask
SQ_SXx_pc_ptr_valid	SQ→SXx	1	Read pointers are valid.
SQ_SPx_interp_valid	SQ→SPx	1	Interpolation control valid

23.2.4 SQ to SP: Staging Register Data

This is a broadcast bus that sends the VSISR information to the staging registers of the shader pipes.

Name	Direction	Bits	Description
SQ_SPx_vsr_data	SQ→SPx	96	Pointers of indexes or HOS surface information
SQ_SPx_vsr_double	SQ→SPx	1	0: Normal 96 bits per vert 1: double 192 bits per vert
SQ_SP0_ vsr_valid	SQ→SP0	1	Data is valid
SQ_SP1_ vsr_ valid	SQ→SP1	1	Data is valid
SQ_SP2_ vsr_ valid	SQ→SP2	1	Data is valid
SQ_SP3_ vsr_ valid	SQ→SP3	1	Data is valid
SQ_SPx_vsr_read	SQ→SPx	1	Increment the read pointers

23.2.5 VGT to SQ : Vertex interface

23.2.5.1 Interface Signal Table

The area difference between the two methods is not sufficient to warrant complicating the interface or the state requirements of the VSISRs. **Therefore, the POR for this interface is that the VGT will transmit the data to the VSISRs (via the Shader Sequencer) in full, 32-bit floating-point format.** The VGT can transmit up to six 32-bit floating-point values to each VSISR where four or more values require two transmission clocks. The data bus is 96 bits wide.

Name	Bits	Description
VGT_SQ_vsisr_data	96	Pointers of indexes or HOS surface information
VGT_SQ_event	1	VGT is sending an event
VGT_SQ_vsisr_continued	1	0: Normal 96 bits per vert 1: double 192 bits per vert
VGT_SQ_end_of_vtx_vect	1	Indicates the last VSISR data set for the current process vector (for double vector data, "end_of_vector" is set on the first vector)
VGT_SQ_indx_valid	1	Vsisr data is valid
VGT_SQ_state	3	Render State (6*3+3 for constants). This signal is guaranteed to be correct when “VGT_SQ_vgt_end_of_vector” is high.
VGT_SQ_send	1	Data on the VGT_SQ is valid receive (see write-up for standard R400 SEND/RTR interface handshaking)
SQ_VGT_rtr	1	Ready to receive (see write-up for standard R400 SEND/RTR interface handshaking)

23.2.6 *SQ to SX: Control bus*

Name	Direction	Bits	Description
SQ_SXx_exp_type	SQ→SXx	2	00: Pixel without z (1 to 4 buffers) 01: Pixel with z (1 to 4 buffers) 10: Position (1 or 2 results) 11: Pass thru (4,8 or 12 results aligned)
SQ_SXx_exp_number	SQ→SXx	2	Number of locations needed in the export buffer (encoding depends on the type see bellow).
SQ_SXx_exp_alu_id	SQ→SXx	1	ALU ID
SQ_SXx_exp_valid	SQ→SXx	1	Valid bit
SQ_SXx_exp_state	SQ→SXx	3	State Context
SQ_SXx_free_done	SQ→SXx	1	Pulse that indicates that the previous export is finished **from the point of view of the SP. This does not necessarily mean that the data has been transferred to RB or PA, or that the space in export buffer for that particular vector thread has been freed up.**
SQ_SXx_free_alu_id	SQ→SXx	1	ALU ID
